Subject: RE: Potential application - Ivermectin - Statistical principles for clinical trial design [SEC=OFFICIAL]

Good morning s22

Just reflecting on our conversation the other day, and I thought the following international guideline may be helpful. This guideline has been adopted by the TGA and describes the statistical consideration for clinical trial design, and indeed the sample size for a clinical trial. I'm mindful that the clinical trials that you describe to me (in brief) may not be sufficiently powered (ie your sample size may be too small) to enable conclusions to be drawn about the efficacy of your proposed treatment. If you haven't already done so, you may wish to consider having your clinical trial design reviewed by a biostatistician, as this biostatistics report is one of several key considerations for the TGA when evaluating your application.

Statistical guideline for clinical trials: http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2009/09/WC500002928.pdf

Further, grateful if you can please confirm who will be the sponsor for this application.

Kind regards s22

Good morning s22

While the TGA can organise a meeting with your team, my understanding is that no meeting has been scheduled at this time.

There are a couple of elements that often help with the scheduling of a preliminary meeting and would be required from your team. I highlighted some of these elements in my previous email, such as having an Australian sponsor for the submission. In TGA experience, scheduling a preliminary meeting with your team as well as your Australian sponsor (https://www.tga.gov.au/role-sponsor) is very beneficial for your team to gain a full understanding of the application process and nuances as it relates to COVID-19 medicines. Similarly, providing the TGA with some preliminary information of your medicine and its clinical trial progress also help us help you, for instance:

- brief overview of the medicine
- clinical trial progress (proposed and conducted to-date)
- overseas regulatory status (authorisations, under evaluation)
- proposed manufacturing supply (if known)
- list of questions for the TGA (note that the TGA may provide written responses in lieu of a meeting) or meeting agenda

Please let me know if you need any information on sourcing a regulatory agent, or indeed whether it is your intent to be the Australian sponsor.

-
Kind regards s22

Subject: RE: Potential application - Ivermectin - The process begins - with Australia's safety in the face of Covid19 foremost on our minds - we race against the clock

REMINDER: Think before you click! This email originated from outside our organisation. Only click links or open attachments if you recognise the sender and know the content is safe.

Dear s22

Thank you for writing back to me.
While I remain in the loop, the key contact for this application will be s22 .
He has informed me that a Zoom meeting has already been organized.

I do see the email below outlines a template path forward which I trust your office will work through with s22 in a collective approach to bring essential life-saving options for Covid19 to the Australian people in the fastest and safest way possible.
I am sure the TGA and John Skerritt recognise this is no ordinary application for some pain relief medication and this medication and its indications being applied for may (will) play a key role in opening up Australia and significantly reducing the hospitalisations and death tolls of the pending wave of Covid19 infections that Australians face.

Aside from this discussion s22 , I can put you in direct touch with practicing world class Doctors in the US who are consisting reporting that 60% of the patients they are now treating for Covid19 symptoms are fully vaccinated; I say this so you will know that something more than Vaccines are needed in this fight against Covid19 and it is an urgent matter that Australia is prepared.

Every day saved in an efficient joint path through this process is critical in reducing the resultant hospitalization and death, as will be demonstrated in with the data that will be presented.
It need to be stated that the timing for this application is targeted to be within 2 weeks; delays beyond this will likely result in casualties that would have been avoided but for the length of the time of this application process.

s22 brings with him a team that should streamline this process, nevertheless, any assistance and guidance you can afford in your senior position in this process will play a critical role in the outcome for all Australians.

Again, thank you for writing and responding so quickly.

Best Regards

s22

From: s22 @health.gov.au]

To: s22 @benefel.com.au; s22 @cdd.com.au
Cc: Streamlined Submission
Subject: Potential application - Ivermecton - further information [SEC=OFFICIAL]

Dear s22 ,

Thank you for contacting the TGA regarding your potential application for ivermectin. As the Strategic Lead for COVID-19 Vaccine Regulation, I head the TGA's COVID-19 medicines regulation coordination activities.

Applications for COVID-19 medicines are being treated with the greatest priority as part of the TGA's response to the COVID-19 global pandemic. The TGA is considering applications for COVID-19 medicines under the Prescription medicine provisional approval pathway (conditional approval) and/or the standard (full) registration pathway, based on the clinical trial data for individual applications.

Sponsor
Please note that an Australian sponsor is required for submission of an application to the TGA. The sponsor has certain legal obligations for the product under the *Therapeutic Goods Act 1989* and associated legislation. You may find it helpful to consider using a regulatory affairs consultant who is familiar with TGA processes, when you are preparing your submission dossier. The TGA is unable to provide recommendations for regulatory affairs consultants or sponsors, but in the first instance you may like to reach out to an regulatory affairs consultant via the appropriate industry associations for additional advice and assistance with Australian regulatory requirements. Sponsors are encouraged to seek independent legal advice to ensure that all legislative requirements are met.

Regulatory framework
The TGA website provides detailed guidance on the regulatory framework and on submitting an application to the TGA, including data requirements and fees. Please see the following:

- Australian Regulatory Guidelines for Prescription Medicines (ARGPM) includes:
  - general guidance
  - specific guidance on technical requirements
  - format of the Common Technical Document (CTD) dossier
  - data requirements across Modules 1-5 of the CTD dossier (i.e. Australian-specific information, quality, safety, efficacy)

- International scientific guidelines adopted in Australia. The TGA closely aligns its regulatory approaches to therapeutic products with those of comparable international regulatory counterparts wherever possible. In general terms, the TGA has similar expectations for submission dossiers and their evaluation, including following international scientific guidelines, however there are often national-specific requirements that a sponsor will also need to give consideration to.

- Provisional approval pathway - The sponsor must first apply for provisional approval determination based on the relevant eligibility criteria; if the criteria are met and the product is granted provisional determination, then an application can be made for provisional registration. Phase 1/2 Clinical trial data (Module 5) are usually insufficient to obtain a positive provisional determination outcome; in general, promising early Phase 3 data on safety and efficacy is required. Quality (Module 3) and nonclinical (Module 4) data should be of sufficient maturity before submitting an application for provisional registration. Sponsors should have defined clinical and manufacturing development plans for their COVID-19 medicine, and be able to provide details to the TGA. Sponsors should identify proposed supply chains and ensure GMP clearance applications for manufacturing sites are submitted to the TGA as early as possible.

- Fees and charges for prescription medicines - The relevant fees will depend on the proposed application type and proposed pathway for your product.

Pre-submission meetings

The TGA strongly recommends that sponsors hold a pre-submission meeting with the TGA prior to submitting an application for a COVID-19 medicine. The TGA can arrange meetings to discuss, in broad terms, the TGA's **regulatory framework and administrative processes** supporting COVID-19 medicine applications. Please contact streamlinedsubmission@health.gov.au with 'COVID-19 medicine' in the subject line, and state that you are seeking a general meeting with the TGA. A **formal technical pre-submission meeting** with TGA evaluators can be requested when there is a clear clinical development plan, and preferably once Phase 2/3 studies have been fully enrolled and initiated, and that there is a clear ability to transition from provisional registration to full registration

Please review the pre-submission meeting guidance and meeting request form. The TGA would be happy to arrange a pre-submission meeting once you have submitted your meeting request, including a technical briefing package that provides details on your proposed product:

- brief overview of the medicine
- clinical trial progress (proposed and conducted to-date)
- overseas regulatory status (authorisations, under evaluation)
- proposed manufacturing supply (if known)
- list of questions for the TGA (note that the TGA may provide written responses in lieu of a meeting)

I trust the above information addresses your queries.

Kind regards s22

Dear s22 ,

Thank you for attending the videoconference on 30 August 2021 providing us with an update on the status of ivermectin triple therapy. At the meeting, we advised that we would provide you with some additional information and feedback.

Please find three documents attached which include:

- **Considerations when applying to register medicine/s for a new indication** – general points to consider across the various evaluation domains when preparing to make an application to the TGA
- **Relevant guidance for consideration** – links to regulatory guidance and information about Literature Based Submissions
- **Comments on the clinical study synopsis** – feedback on the draft study synopsis

We hope this information is useful.

Kind regards,

Grant

The Department of Health acknowledges the Traditional Custodians of Australia and their continued connection to land, sea and community. We pay our respects to all Elders past and present.

Important: This transmission is intended only for the use of the addressee and may contain confidential or legally privileged information. If you are not the intended recipient, you are notified that any use or dissemination of this communication is strictly prohibited. If you receive this transmission in error please notify the author immediately and delete all copies of this transmission.

This response is general information given to you without prejudice; it is not binding on the TGA and you should get your own independent legal advice to ensure that all of the legislative requirements are met.

Comments on the clinical study synopsis (draft 13.8.2021)

In the context that the proposed study may be used for a future regulatory application, the following preliminary comments are provided for the sponsor's consideration. Please note that these comments are not exhaustive or binding, nor should they be interpreted to pre-empt or replace the TGA's evaluation process that would be undertaken following receipt of an application. Sponsors are strongly encouraged to seek their own advice to ensure that regulatory requirements are met.

General comments

- The phase of the study should be clarified.
- For regulatory purposes, dose selection and proposed regimen would need to be justified.
- The power of the study should be carefully considered.
- The COVID-19 evidence taskforce definition of mild and moderate disease for inclusion in the study should be clarified. The taskforce recommends that patients with moderate disease (Sp02 >92% with up to 4L of O2) should be managed in hospital, when possible.
- Confirm that continuous telemonitoring is proposed (i.e. not intermittent).
- The study question should be clarified. Is it to evaluate the proportion of subjects who will achieve the endpoint following randomisation or the days required for subjects to achieve the endpoint following randomisation?

Comments on the primary endpoint

- The clinical justification/correlation of the primary endpoint (as a clinical test rather than outcome measure) should be carefully considered, in particular:
    - how the oxygen saturation level measured by telemetry/oximetry is closely corelated with clinical recovery
    - how subjects, for example with chronic lung diseases who may recover from COVID-19, but not be able to achieve oxygen saturation >98% will be managed
    - how this endpoint would translate to a potential indication for the medicines.
- The timepoint for the assessment of the primary endpoint should be made clear.
- Measurement precision should be carefully considered/controlled/validated given the choice of endpoint and the self-test proposal. How will user error be managed?
- In accordance with relevant guidance, the choice of clinically meaningful measures to assess effectiveness should be strongly considered.

Comments on the inclusion criteria

- The requirement of SpO2 < 95% could potentially exclude some mild symptomatic COVID-19 patients who may have normal SpO2 levels.
- Will the study stratify or focus on COVID-19 patients who are at high risk of developing severe COVID-19?
- Will the study include COVID-19 patients who are at an early stage of symptom onset (e.g. within 5-7 days of symptom onset) or COVID-19 patients with any duration after symptom onset?
- Will the study include people with any vaccination status (vaccinated and unvaccinated)?
- Will the study exclude patients who are concomitantly receiving another COVID-19 treatment/symptom management?

Considerations when applying to register medicine/s for a new indication

Below is a non-exhaustive list of items that should be considered by the sponsor prior to making a registration application.

General

Product sponsorship

The Australian sponsor is the legal entity responsible for the medicine/s in Australia. The sponsor is responsible for making the application for registration of the goods and also has legislated post-market responsibilities. Further details are available at: https://www.tga.gov.au/role-sponsor

Pharmacovigilance

Sponsors of registered goods also have pharmacovigilance responsibilities, these are outlined at: https://www.tga.gov.au/publication/pharmacovigilance-responsibilities-medicine-sponsors

Advisory Committee on Medicines

For an extension of indications application, subject to Delegate considerations, it is likely that advice would be sought from the independent clinical expert Advisory Committee on Medicines (ACM). The Delegate may seek advice from the ACM on a number of matters, including but not limited to clinical issues. ACM advice is considered by the Delegate when making a decision to register a product.

Dossier format

The dossier submitted must conform with the Common Technical Document format: https://www.tga.gov.au/publication/common-technical-document-ctd

From 1 November 2021, the Therapeutic Goods Administration (TGA) will begin a staged transition to Electronic Common Technical Document-only (eCTD-only) for all prescription medicines:
https://www.tga.gov.au/electronic-submissions

Quality and Manufacturing

- If domestic manufacturing sites are being used, these will need TGA licences. If a new manufacturing site is being proposed, obtaining a new licence may take some time.
- If overseas manufacturing sites are being used, the sponsor will need to demonstrate appropriate GMP. This can be achieved in multiple ways, depending on existing overseas regulatory requirements applicable to those sites (mutual recognition agreements with comparable regulators etc) but in some instances a TGA inspection may be required.
- Manufacturing quality would need to be assured within the application dossier, including batch release/QA specifications (where relevant).
- Further information about manufacturing requirements is available at: https://www.tga.gov.au/manufacturing-therapeutic-goods

Clinical

- Is the product's dose form and strength the same as a currently approved product?
- Are there data linking the proposed product with the currently registered product? This may include bioequivalence data depending on the nature of the application.
- Is it a single ingredient, composite pack or fixed dose combination?
- How does each component contribute to the product's efficacy and/or safety?
- Are there data on interaction between the components?
- What is the proposed dosage regimen and duration of treatment and is this supported by clinical trials?
- Have there been dose ranging studies to investigate different doses to select the optimal dose?
- Are there any drug interaction studies with other treatments?
- Are there well-designed and powered studies to determine efficacy, eg RCTs using the same products in the same combination and dose?
- Are there any non-supportive studies?
- Are there any ongoing studies and when are they expected to be completed?
- Who is the target population for treatment and what stage of disease is proposed for treatment?

Toxicology (non-clinical)

- Are there any appropriate animal models of COVID-19 infection to test the proposed treatment's efficacy?
- Are there toxicology data supporting the dose proposed for humans?
- Are there any *in vitro* or *in vivo* animal studies that could explain the proposed therapeutic product's mechanism of action?
- Are there any pharmacokinetic/toxicokinetic data from animal studies supporting the safety and pharmacology/efficacy studies?
- Are there any *in vitro* or *in vivo* studies that have looked at the potential pharmacological, pharmacokinetic and toxicological interactions with the ingredients in the proposed therapeutic product and with other drugs that patients may take?
- Have you completed any studies in animals that have investigated the effects on fertility, reproduction and development?
- Have you completed any toxicity studies in juvenile animals?
- Were safety-related studies conducted under GLP conditions? Do you have information on the active ingredients' batch numbers and do you know their impurity profiles?

Risk Management Plan

- It is likely that a Risk Management Plan (RMP) would be required, as is it is for other COVID-19 treatments. RMP requirements are detailed at: www.tga.gov.au/publication/risk-management-plans-medicines-and-biologicals

Guidance for Literature Based Submissions

- The TGA website includes information on literature based submissions (LBS) that covers pre-submission guidance, dossier requirements and systematic literature searches: https://www.tga.gov.au/publication/literature-based-submissions

- The requirements for each module are discussed on the TGA website. Please note that literature-based data sets are not suitable for the quality (Module 3) component of an application as published reports rarely include sufficient validation information. A conventional Module 3 dossier should be submitted for all applications with a quality component.

- Prior to lodging the Pre-submission Planning Form (PPF) for a LBS, the TGA will need to have reviewed and provided written agreement for the literature search strategy, including the databases to be searched, and the criteria for determining which search results are to be included/excluded in the application dossier.

- In situations where the methodology or regulatory approach needs further consideration/discussion, a pre-submission technical meeting is strongly encouraged. Questions about pre-submission issues can be directed to: streamlinedsubmission@health.gov.au

Relevant clinical guidance for consideration

Based on preliminary information presented by the sponsor, the following guidance is likely to be relevant to the application wholly, or in part:

- **Points to consider on application with 1. meta-analyses; 2. one pivotal study** (https://www.ema.europa.eu/en/documents/scientific-guideline/points-consider-application-1meta-analyses-2one-pivotal-study_en.pdf)

  In particular, section III.2 states:

  In cases where the confirmatory evidence is provided by one pivotal study only, this study will have to be exceptionally compelling, and in the regulatory evaluation special attention will be paid to:

  - The internal validity. There should be no indications of a potential bias.
  - The external validity. The study population should be suitable for extrapolation to the population to be treated.
  - Clinical relevance. The estimated size of treatment benefit must be large enough to be clinically valuable.
  - The degree of statistical significance. Statistical evidence considerably stronger than $p < 0.05$ is usually required, accompanied by precise estimates of treatment effects, i.e. narrow confidence intervals. The required degree of significance will depend on factors such as the therapeutic indication, the primary endpoint, the amount of supportive data and whether the alternative analyses demonstrating consistency are pre-specified. When the aim is to demonstrate non-inferiority, one study is more likely to be accepted if the lower 95% confidence bound is well away from the non-inferiority margin.
  -Data quality.

- Internal consistency. Similar effects demonstrated in different pre-specified sub-populations. All-important endpoints showing similar findings.
- Centre effects. None of the study centres should dominate the overall result, neither in terms of number of subjects nor in terms of magnitude of effect.
- The plausibility of the hypothesis tested

- **Guideline on clinical development of fixed combination medicinal products (**https://www.tga.gov.au/sites/default/files/ewp024095enfin.pdf)

  In particular, section 6 states:

  As a general rule, the choice of each substance in the fixed combination as well as the whole concept on which the rational for the fixed combination is based have to be fully justified; this can be achieved by taking into account mode(s) of action, pharmacokinetics, and treatment recommendations for a given clinical setting.

- **COVID-19: Developing Drugs and Biological Products for Treatment or Prevention Guidance for Industry (**https://www.fda.gov/media/137926/download))

  In particular, part III.A.2 states:

  FDA strongly recommends that drugs to treat COVID-19 be evaluated in randomized, placebo-controlled, double-blind clinical trials using a superiority design. In some situations, use of an active control with a superiority or noninferiority design may be appropriate.

  and part III.A.3 states:

  The drug development program should evaluate the effect of the investigational drug relative to placebo or an active comparator on clinically meaningful aspects of the disease. The relevance and appropriateness of measures may depend on the mechanism of action of the drug, the population studied, the clinical setting, the phase of drug development, and/or baseline disease severity (see Appendix A).

- It is also recommended that the sponsor review the various other adopted guidelines for prescription medicine applications which may be relevant to the application at: https://www.tga.gov.au/ws-sg-index

Subject: RE: Preliminary TGA Meeting - Topelia Australia Ltd - Ivermectin triple therapy for the treatment of COVID-19 caused by SARS-CoV-2 virus [CEPL-PROJECTS.FID116094] [SEC=OFFICIAL]
Date: Thursday, 7 April 2022 10:56:46 AM
Attachments: image003.png
image002.png
image005.png

Hi s22

Below is some guidance to address the questions posed to the TGA in your briefing document and some additional information relevant to the COVID-19 applications.

The TGA is considering applications for COVID-19 medicines under the Prescription medicine provisional approval pathway (conditional approval) and/or the standard (full) registration pathway, based on the clinical trial data for individual applications. The sponsor must first apply for provisional approval determination; if the product is granted provisional determination, then an application can be made for provisional registration. Phase 1/2 Clinical trial data (Module 5) are usually insufficient to obtain a positive provisional determination outcome; in general, promising early Phase 3 data on safety and efficacy is required. Quality (Module 3) and nonclinical (Module 4) data should be of sufficient maturity before submitting an application for provisional registration. Sponsors should have defined clinical and manufacturing development plans for their COVID-19 medicine, and be able to provide details to the TGA. Sponsors should identify proposed supply chains and ensure GMP clearance applications for manufacturing sites are submitted to the TGA at the application stage.

Quality considerations

- Regarding whether TGA would accept less than the 6 months stability data at submission. Generally, the TGA prefers to evaluate longer term stability data, but depending on the availability and strength of supporting data, shorter-term data may be considered satisfactory for evaluation purposes in the interim.

Non-clinical considerations

- Guidelines on nonclinical studies consulted by the sponsor are applicable to the proposed combination. The Pre-submission guidance for literature based submissions (LBS) is relevant to both clinical and nonclinical data.
- Pharmacology studies (e.g. *in vitro* antiviral assays and in animal models of SARS-CoV-2 infection, RNA polymerase inhibition assay as claimed for zinc) with each ingredient and/or the combination would provide support to the proposed clinical indication. Pharmacology data for non-COVID-19 indications are not relevant to the proposed clinical use.
- It is recommended that the following be assessed (which can be based on literature if available):
    - the general toxicity and reproductive and developmental toxicity of the

combination
    - drug interactions between the 3 ingredients and between the drug combination and other drugs, which may be administered with Ziverdox
    - safety of ivermectin (all types of toxicity studies including repeat dose toxicity, genotoxicity, reproductive and developmental toxicity) given the higher dose and longer dosing duration than the approved clinical use

Clinical considerations

- Before applying for provisional determination, promising (interim) phase 3 results from the clinical trial to show the effectiveness of this ivermectin triple combination will be required. The following guideline describing appropriate clinical trial size may be helpful, as early conversations had indicated that some supporting clinical trials may not be sufficiently powered (ie your sample size may be too small) to enable conclusions to be drawn about the efficacy of your proposed treatment. Further, your team may wish to consider having your clinical trial design reviewed by a biostatistician, as this biostatistics report is one of several key considerations for the TGA when evaluating your application.
- Statistical guideline for clinical trials: http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2009/09/WC500002928.pdf

Hi s22

Thank you again for your time on the telephone yesterday and updated meeting request.

I'm just waiting to hear back from Topelia that the proposed time suits, and will then accept and forward the place holder to the relevant parties.

Have a lovely day.

Kind Regards
s22

Hi s22

I'm trying to confirm placeholder mtg with TGA, unfortunately there are some challenges with TGA attendees. I've tried to catch you be phone to discuss.

Is there an alternative date (other than the 8th April) that would also be possible for you?

Kind regards s22

Subject: Preliminary TGA Meeting - Topelia Australia Ltd - Ivermectin triple therapy for the treatment of COVID-19 caused by SARS-CoV-2 virus [CEPL-PROJECTS.FID116094]

REMINDER: Think before you click! This email originated from outside our organisation. Only click links or open attachments if you recognise the sender and know the content is safe.

Dear Sir/Madam

On behalf of our client Topelia Australia Ltd, we would like to request a preliminary meeting with the TGA to discuss their development plans for the proposed ivermectin triple therapy for the treatment of COVID-19 caused by SARS-CoV-2 virus. The proposed product to be marketed under the trade name "Ziverdox", is a s47 .

The meeting is proposed for Friday 8th April 2022 at a time that suits the TGA representatives.

A background document is attached to provide the TGA with a general overview of the product; the proposed clinical, nonclinical and quality development program and data package; and a number of questions to facilitate the discussions. The outcome of the preliminary meeting will assist in finalising the proposed data set and regulatory strategy.

A formal meeting request including detailed pre-submission briefing package will be provided if a formal TGA pre-submission meeting is required in the future.

Please don't hesitate to contact me if you require any additional information to facilitate this meeting request.

Thank you in advance for your feedback.

Kind Regards

s22

1. Purpose of the meeting

Commercial Eyes Pty Ltd (CEPL) is submitting this background document on behalf of Topelia Ltd (Topelia) to facilitate discussions with the TGA in relation to their proposed medicine "Ziverdox", s47 s47 containing ivermectin, doxycycline and zinc citrate. The application is proposed to be submitted under the provisional registration pathway via a mixed (in-house studies and literature) application for the indication:

> *Ziverdox is indicated for the treatment of mild to moderate symptomatic patients diagnosed with COVID-19 caused by SARS-CoV-2 virus.*

Initial advice on the proposed medicine and regulatory strategy was sought from the TGA in August 2021. Subsequent concerns with the prescribing of ivermectin for the prevention or treatment of COVID-19 at the expense of vaccination, resulted in the TGA placing restrictions on the prescribing of oral ivermectin "New restrictions on prescribing ivermectin for COVID-19", 10 September 2021. The National COVID Clinical Evidence Taskforce (NCCET), the World Health Organisation (WHO) and the US Food and Drug Administration (FDA) also currently discourage the use of ivermectin monotherapy for COVID-19 treatment. The development program for Ziverdox has evolved taking the initial TGA advice and global concerns regarding the use of ivermectin monotherapy into consideration. This preliminary meeting is requested to seek further TGA guidance and feedback on the proposed regulatory strategy and data set, with specific questions posed as per section "5. Questions to the TGA" below.

This document is intended to provide the TGA with a general overview of the product; the clinical, nonclinical and quality development program and data package; and the proposed registration strategy. A detailed pre-submission briefing package will be provided if a formal TGA pre-submission meeting is required in the future.

2. General Overview of the Product

Topelia proposes to register Ziverdox as a s47 , comprising ivermectin s47 , doxycycline s47 and zinc s47 tablets for the treatment of COVID-19 caused by SARS-CoV-2 virus. The proposed dosage regimen is s47 .

The active ingredients in the tablet formulation are currently registered (ivermectin, doxycycline and zinc) and listed (zinc) on the ARTG and there are no novel excipients. Information relevant to the active ingredients in the proposed medicine is provided below, including specific considerations that relate to the development program.

Ivermectin

Ivermectin has been registered in Australia as an antiparasitic agent since 1999. It has been registered in an oral dose form since 27th August 1999 (Stromectol® 3 mg tablets; AUST R 181338; Merck Sharp & Dohme (Australia) Pty Ltd) for the treatment of anguillulosis and scabies. The dosage regimen is for 150 to 200 micrograms of ivermectin/kg body weight as a single dose (typically a

maximum dosing of 15 mg (Australian Product Information; Stromectol 2021)), depending on the condition.

The repurposing of ivermectin for the treatment of COVID-19 has been investigated in a large number of nonclinical and clinical studies given its apparent antiviral and anti-inflammatory properties. It is included in the formulation of Ziverdox given the body of evidence suggests it is safe and efficacious in the proposed indication.

The dose of ivermectin patients will receive is s47 . The nonclinical and clinical data sets will take into consideration the s47 , to inform the safety and efficacy of the proposed dosing regimen in the treatment of COVID-19.

Doxycycline

There are a number of products on the ARTG in tablet and capsule dose forms, containing 50 mg to 200 mg of doxycycline. The innovator product Doryx® capsules currently sponsored by Mayne Pharma International Pty Ltd was first included on the ARTG on 25th October 1991 and is registered for the treatment of infections caused by a number of micro-organisms. The maximum dose of Doryx (for primary and secondary syphilis) is 300 mg per day for 10 days.

Doxycycline is included in the formulation given the evidence suggesting efficacy against viral pathogens such as dengue fever, and regulation of pathways important in initial infection, replication and systemic response to SARS-CoV-2 (Yates et al. 2020).

s47 the safety profile of doxycycline is considered well established. The nonclinical and clinical development programs have been developed to specifically take into account the safety and efficacy of doxycycline in the proposed medicine for the treatment of COVID.

Zinc Citrate

Zinc in various salt forms is approved for use in many dosage forms in registered and listed medicines at different strengths. There doesn't appear to be any registered oral dose forms containing zinc s47

The rationale supporting the addition of zinc in the formulation of Ziverdox is its ability to inhibit the replication of RNA virus by the inhibition of RNA polymerase.

Zinc compounds are regulated as Schedule 4 for human internal use except:

a) in preparations with a recommended daily dose of 25 mg or less of zinc; or

b) in preparations with a recommended daily dose of more than 25 mg but not more than 50 mg of zinc when compliant with the requirements of the Required Advisory Statements for Medicine Labels (RASML).

s47 the

safety profile of zinc is considered well established. The nonclinical and clinical development programs have been developed to take into account the dose of zinc proposed in the regimen s47 to inform the safety and efficacy of zinc in the proposed medicine.

3. Development Program and Proposed Data Package

The proposed medicine "Ziverdox" is being developed as a s47 containing ivermectin, doxycycline and zinc citrate for the treatment of COVID-19. The rationale for using combination antiviral therapy is based on the growing understanding that intracellular infections – bacterial or viral, cannot be reliably cured using a single drug, in addition to prevent potential resistance if ivermectin is used alone (Hazan et al. 2021).

Initial advice on the proposed medicine and regulatory strategy was sought from the TGA in August 2021, and the development program has evolved taking the TGA advice into consideration.

When the TGA was initially approached regarding the medicine, Topelia proposed to register a s47

An overview of the proposed data package and development plan designed to obtain appropriate supporting data for the quality, efficacy and safety of the proposed medicine in the treatment of COVID-19 is described below.

Quality

The proposed medicine will be a s47 The active ingredients are currently registered in tablet dose form and the stability profiles established in these formulations. Compatibility of the three ingredients in the formulation will be determined during the development

There will be no new or novel excipients in the formulation.

As this is a conventional dose form, no specific challenges are anticipated in the development of the finished product with respect to chemistry, manufacturing and controls.

s47

s47

Nonclinical

The proposed nonclinical data set will be supported by literature and scientifically robust justifications as applicable. The table below provides a summary of whether a justification or literature reference is proposed to support the relevant nonclinical data set, with the rationale for the proposed action discussed under the specific headings below.

Table 1 Summary of the proposed nonclinical data set

Data requirements	Ivermectin	Doxycycline	Zinc	Combination
Pharmacology	s47			
Primary and secondary pharmacodynamics				
Safety pharmacology				
Pharmacodynamic drug interactions				
Pharmacokinetics				
Absorption, distribution, metabolism, excretion				
Pharmacokinetic drug interaction				
Toxicology				
Single and repeat dose toxicity				
Genotoxicity				
Carcinogenicity				
Reproductive and developmental toxicity studies				

J= justification
L= systematic literature review using search strategy approved by the TGA.

Pharmacology

Primary and Secondary Pharmacodynamics

s47

Safety Pharmacology

The mechanism of action (MOI) for the individual active ingredients does not include an overlap of the target organs; CNS for ivermectin, bacterial intracellular protein synthesis inhibition for doxycycline and gene expression for zinc, therefore a synergistic effect by the fixed dose combination that results in a safety concern in the target organs is considered to be unlikely. Given the unlikely interaction between the three ingredients and and the supporting clinical data proposed

for submission, s47

Pharmacodynamic Drug Interactions

Based on the available clinical data with the doublet regimen of ivermectin and doxycycline, the lack of overlap on the MOA for all three proposed ingredients, and the supporting clinical data proposed for submission, s47

Pharmacology Summary

s47

Pharmacokinetics

Absorption, Distribution, Metabolism, Excretion

The pharmacokinetic profiles of ivermectin and doxycycline are well known and described in the Product Information (PI) of currently registered products.

Zinc is absorbed throughout the whole small intestine (Maares and Haase 2020). Highest rates of absorption are unknown, believed to be in both the duodenum and jejunum. Distribution has been demonstrated to most body systems. Zinc is most readily metabolised in the small intestine lumen, then plasma, then less exchangeable zinc from other tissues, such as the liver. Zinc is excreted through a variety of pathways, including loss through faecal matter, urine, sweat, menstrual, semen, hair, nails, and skin.

Given the pharmacokinetics of each of the active ingredients are well established, and as combination studies are generally not recommended to support clinical trials or marketing in the individual agents have been tested according to current standards, s47

Pharmacokinetic Drug interactions

The approved ivermectin PI does not describe any clinical data on drug-drug interactions for ivermectin. There have been very rare post-marketing reports of increased normalisation ratio (time taken for blood to clot) when co-administered with warfarin. The PI for doxycycline also states reports of prolonged prothrombin time in patients taking warfarin and doxycycline.

Zinc deficiency is associated with bleeding and clotting abnormalities, and evidence exists that zinc serves as an effector in coagulation, anticoagulation and fibrinolysis depending on the microenvironment (Vu et al. 2013).

The pharmacokinetic drug-drug interaction between the three ingredients will be considered s47

Pharmacokinetic Summary

The pharmacokinetics section of the nonclinical data set will include scientific justifications together with literature targeted to:

- pharmacokinetic drug interactions of ivermectin, doxycycline and zinc in combination and alone
- assess the effect of concomitant use of anticoagulants

Toxicology

Single and repeat dose

The objective of single and repeat-dose studies is to inform the safety profile of a product prior to initial clinical studies. For combination products of well-established ingredients, single dose and repeated dose toxicity, as well as local tolerance investigations are not normally necessary.

s47

Genotoxicity

Ivermectin is negative for genotoxicity (Australian Product Information; Stromectol 2021).

There is no data reported for genotoxicity of doxycycline in the AU PI and the genotoxicity potential for zinc at the proposed dosage is unknown. It is proposed that a systematic literature search be undertaken to inform the genotoxic potential of doxycycline and zinc.

Carcinogenicity

According to the Stromectol PI there have been no carcinogenicity studies in humans with ivermectin. Ninety-four and 105 week carcinogenicity studies on mice and rats respectively were conducted with the closely related compound abamectin and were negative at up to 8 mg/kg/day in mice and up to 2 mg/kg/day in rats.

There are no carcinogenicity studies with doxycycline reported in the PI however, doxycycline has a long history of use at the dosages and duration of treatment proposed for Ziverdox. Zinc has been reported to not represent a carcinogenic risk to humans (Leonard et al. 1986).

s47

Reproductive and developmental toxicity studies

There are no data available on the effects of fertility for either ivermectin, doxycycline or zinc in Australian PIs.

In Australia, Ivermectin has a pregnancy Category B3, and doxycycline has a pregnancy Category D with use in pregnancy (16 weeks post conception) and use in lactation contraindicated. There is no corresponding PI for zinc therefore the pregnancy category could not be ascertained. A review of the information presented in eMIMS reveals several zinc supplements are classified as pregnancy Category D, consistent with the FDA directive for oral zinc.

Based on the information above, the use of Ziverdox in pregnancy (16 weeks post conception) will be contraindicated and contraindicated in lactation. s47 and exposure to the medicine will be managed by the pregnancy classification in the Product Information (PI).

Toxicity Summary

The nonclinical dataset will include scientifically robust justifications together with literature to support the following safety aspects of Ziverdox:

- overall safety profile of the triple therapy
- adverse event profile at proposed doses of ivermectin and zinc s47
- genotoxic potential of zinc and doxycycline

Clinical

The clinical data set is proposed to be supported by:

- Real world data written into study report format where applicable
- Literature as identified in a systematic literature review
- The clinical trial study protocol for the proposed Phase 3 clinical study (CDD20/05)
- A commitment to provide an interim analysis of the Phase 3 study results.

Scientifically robust justifications for the omission of data will also be included as applicable.
The clinical dossier to be submitted is therefore anticipated to include sufficient data to enable the TGA to weigh up the benefits and risks of the proposed medicine.

Early Treatment in COVID-19 with ITT – Real world data studies

Borody and Clancy 2021 - Ivermectin Triple Therapy

(Borody and Clancy 2021) present and analysed the data from pre-hospital treatment of Covid-19 patients in Sydney and Melbourne, Australia, using an ivermectin-doxycycline-zinc combination with observations on symptom resolution and oximetry. The data is presented on 600 patients with positive PCR symptomatic Covid-19 that were treated with a combination of ivermectin (24 mg per day), doxycycline (100 mg bd), and zinc (50 mg per day), for 10 days generally within 72 hrs of obtaining a positive PCR test for Covid-19, s47 . This was carried out
during the height of the COVID-19 pandemic infection by a group of Australian doctors [mainly general practitioners] using a protocol distributed to them but without CRO oversight. They prospectively prescribed ivermectin triple therapy (ITT) for patients with mild-moderate COVID-19 based on the Bellberry-approved lower-dose protocol so obtaining 'real world' data.

They treated over 600 consecutive patients with ITT prescribed 'off label' between June and September of 2021. A retrospective medical record review is proposed to collate the outcomes of

these patients. A new ethics approval is being sought for the study s47). The draft protocol for the study is provided in Appendix 1. This GP study was published on TrialSite News and was not peer reviewed (Borody and Clancy, 2021).

It reports treatment of a total of 600 patients with positive PCR tests using a ten-day course of ITT, which was fully completed in over 90% of those treated. Adverse events from the therapy were reported by 7% of patients, mainly minor gut symptoms of nausea, diarrhoea and heartburn. No patient stopped therapy due to adverse drug events and no patient discontinued therapy as a result of drug side effects. Two visited the hospital for less than 24 hours following a transient arrhythmia and then went home, while five were admitted to hospital (0.83%). There were no deaths. In an equivalent control group of 600, not treated with ITT, 70 were admitted to hospital (11.5%), with 6 deaths (1%). Chi-squared analysis of hospitalisation rate shows a significant decrease ($P<0.001$) in the presence of ivermectin triple therapy intervention. The control data was from contemporary infected subjects in Australia obtained from published Covid Tracking Data.

More detailed preliminary data from a subgroup in hotel and home quarantine was available for a assessment of symptoms and oxygenation status. This cohort of 126 was assessed for 10 symptoms according to a visual analogue scale (ranging from "0" for no symptoms, to "10" for most severe symptoms).

The 126 patients had a median age of 38 (range: 17-94). At least one symptom score was available for 125 of patients at baseline. Four patients did not report symptoms pre-treatment. All patients were classified as mild to moderate on the WHO ordinal scale pre-treatment. Fatigue, cough and muscle pains were the most commonly reported symptoms. Whilst fatigue and headaches were most severe. Of the patients with available pulse oximetry readings pre-treatment, the median oxygen saturation was 95% (71-99). Patients began treatment with ITT therapy within an average of 3.4 days (0-12) of diagnosis of Covid-19. Ten patients (8%) did not complete the full 10 days of treatment. Four patients did not complete the treatment due to worsening of disease, one did not complete due to improvement in symptoms, one did not complete due to adverse effects and the remaining four were stopped for unknown reasons.
In this cohort, eight (6%) of patients progressed to severe illness, critical illness; hospitalisation or intubation. Of the eight patients that progressed to severe illness during the study period, five required hospitalisation, four required oxygen support and two required intubation. No patients in this cohort died.

The majority of patients experienced improvement in symptoms (98%) post treatment with 35% reporting complete resolution of symptoms (Table 2). Symptoms that were most persistent were loss of taste and smell, cough, and fatigue. Overall, there was a significant reduction in symptom score from a median total symptom severity score of 37 (range: 0-100) at the onset of treatment to 3 (range: 0-62) at the conclusion of treatment ($P<0.0001$). Of the patients with available pulse oximetry readings post-treatment, the median oxygen saturation improved from 95% (71-99) to 98% (95-100).

A total of seven adverse events were reported during the treatment period including heartburn (n=2), diarrhoea, vomiting, face rash, exacerbation of asthma and hypertension. As mentioned previously, eight patients progressed to more severe illness during the study period, but only five required hospitalisation, four required oxygen support and two required intubation.

Table 2 Pre and post treatment symptom severity and pulse oximetry data from quarantined individuals (N=126)

Symptom	Pre-Treatment	Post-Treatment	P-Value*			
	N	Mean (SD)	Median (Range)	N	Mean (SD)	Median (Range)	
Fever	114	4.2 (4.1)	3 (0-10)	114	0.1 (0.7)	0 (0-5)	<0.0001
Headache	116	5.8 (3.3)	6 (0-10)	116	0.5 (1.1)	0 (0-5)	<0.0001
Cough	120	5.2 (3.3)	5 (0-10)	120	1.1 (1.9)	0 (0-9)	<0.0001
Loss of Taste	111	4.1 (4.5)	2 (0-10)	111	1.8 (3.2)	0 (0-10)	<0.0001
Loss of Smell	112	4.4 (4.5)	2.5 (0-10)	112	2.0 (3.5)	0 (0-10)	<0.0001
Diarrhoea	115	2.3 (3.3)	0 (0-10)	115	0.2 (0.7)	0 (0-5)	<0.0001
Vomiting	114	1.0 (2.7)	0 (0-10)	114	0.03 (0.3)	0 (0-3)	<0.0001
Fatigue	118	6.6 (3.4)	8 (0-10)	118	1.4 (2.0)	0 (0-10)	<0.0001
Muscle Pains	118	5.4 (3.7)	5 (0-10)	118	0.6 (1.4)	0 (0-7)	<0.0001
Joint Pains	114	4.7 (3.9)	5 (0-10)	114	0.4 (1.2)	0 (0-7)	<0.0001
Total Symptom Severity	124	40.9 (26.1)	37 (0-100)	124	7.5 (10.3)	3 (0-62)	<0.0001
Oximetry Reading (%)	71	93.3 (5.0)	95 (71-99)	71	98.1 (1.1)	98 (95-100)	<0.0001

Symptoms were scored on a 0-10 scale with 0 being the absence of associated symptom and 10 being the most severe presentation as reported by the patient. Total Symptom Severity Score was a combined sum of all symptoms assessed and was scored out of 100. Oximetry Readings were scored out of 100%. N = the number of respondents and SD = Standard Deviation. *Non-parametric paired t-tests were performed.

The results indicated that the combination of ivermectin, doxycycline and zinc at the proposed doses appears to be safe and efficacious, and the results of the study are also consistent with Hazan *et al* described below, noting the lower doses in the Hazan study.

Zimbabwe Prospective Trial - Ivermectin Triple Therapy

Topelia holds clinical data from a series of investigations in Zimbabwe for 36 patients treated with the proposed fixed dose combination therapy. The results of this study in 34 severe Covid-19 patients have now been published though peer review is ongoing (Stone et al. 2022).

The dosing schedule for the investigations was initially 12 mg ivermectin on the day of admission and then on days 4 and 8, plus doxycycline (100 mg B.I.D.) and zinc sulfate (60 mg/day). This regimen was used up through December 2020, when the second pandemic wave emerged in Zimbabwe. At that time, additional evidence of safety and tolerability of this regimen supported further dose escalation to a standard ivermectin dose regimen of 12 mg daily for five consecutive days, with adjunct use of doxycycline and zinc sulfate continued at the doses noted. In some cases, for which this standard

treatment regimen did not yield significant clinical gains within a few days, even higher doses of ivermectin were used, in some cases as high as 100 mg for a single dose. Pre and post treatment SpO2 values have been tracked for 34 of these patients, and the results for changes in SpO2 from pre- and post- treatment are summarised in the tables below.

Table 3 Mean standard deviation of changes in SpO_2 from pre and post treatment for COVID-19 patients treated with ivermectin triple therapy

Pre-treatment SpO_2	at +12 hours	at +24 hours	at +48 hours
60 - 84	+12.8 ± 6.7	+11.4 ± 6.1	+11.7 ± 5.8
85 - 89	+5.2 ± 2.6	+6.1 ± 2.6	+6.2 ± 2.8
90 - 93	+2.8 ± 2.7	+3.7 ± 2.3	+3.9 ± 1.8

As shown in the table, those patients with lowest, mid-range and highest pre-treatment SpO_2 values all had mean SpO_2 increases at +12 hours indicating clinical benefit for the ivermectin combination treatment.

Transient adverse effects (AEs) such as blurred vision characteristic of high dose ivermectin often occurred at those dose levels, but no serious AEs associated with ivermectin were manifested in any patient.

Literature Data

There is an increasingly number of clinical studies being undertaken to investigate the safety and efficacy of ivermectin in the treatment of COVID-19. Completed, ongoing and planned studies cover a range of strengths of ivermectin and range of treatment combinations, including the proposed combination of ivermectin, doxycycline and zinc.

To supplement the real world data, a systematic literature search will be conducted to identify all studies that meet the relevant inclusion criteria to inform the safety and efficacy of the individual components and proposed fixed dose combination for the treatment of COVID-19 and the studies written up as per the TGA LBS guidelines.

It is noted that there are a large number of clinical studies that have commenced or are to be commenced according to the FDA clinical trial data base. The status of these studies will continue to be monitored and literature studies identified will be assessed as they become available.

The initial draft of the proposed literature search strategy is provided in Appendix 2 for TGA consideration. The search terms have been developed taking into consideration the development and current body of evidence as described above.

A preliminary literature search conducted up to January 2021 has identified a number of studies pertinent to the proposed application, and the body of evidence suggests that the use of ivermectin in the treatment of COVID-19 overall has a positive risk/benefit profile when used in combination with doxycycline and zinc.

A summary of the results of some studies identified in the preliminary search are provided below.

Bryant et al 2021 – Ivermectin Alone

A systematic review and meta-analysis by (Bryant et al. 2021) assessed the efficacy of ivermectin treatment in reducing mortality, in secondary outcomes, and in chemoprophylaxis, among people with, or at high risk of, COVID-19 infection. Their systematic review up to 25th April 2021, identified 24 random controlled trials involving a total of 3,406 participants meeting their review inclusion criteria. For trials of COVID-19 treatment, 16 evaluated ivermectin among participants with mild to moderate COVID-19 only; 6 trials included patients with severe COVID-19.

The meta-analysis by the authors of 15 included trials found that ivermectin reduced risk of death by an average of 62% (95% CI 27%–81%) compared with no ivermectin (average risk ratio 0.38, 95% confidence interval 0.19–0.73; n = 2438; I^2= 49%; moderate-certainty evidence); risk of death 2.3% versus 7.8% among hospitalised patients in this analysis, respectively.

Table 4 below summarises the findings of ivermectin treatment versus no ivermectin treatment.

Low-certainty evidence found that ivermectin prophylaxis reduced COVID-19 infection by an average 86% (95% confidence interval 79%–91%). In addition, low-certainty evidence suggested that there may be no benefit with ivermectin for “need for mechanical ventilation,” whereas effect estimates for “improvement” and “deterioration” clearly favoured ivermectin use.

Meta-analysis of 11 trials, assessing 1533 participants, found that there was no significant difference between ivermectin and control in the risk of severe adverse events (aRR 1.65, 95% CI 0.44–6.09; I2 5 0%; low certainty evidence, downgraded for imprecision and study design limitations).

Table 4 Summary of findings of ivermectin versus no ivermectin for treatment of COVID-19 in any setting below shows the overall improvement

Outcomes	Illustrative comparative risks* (95% CI) Assumed risk No ivermectin	Corresponding risk Ivermectin	Relative effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)
Death from any cause	78 per 1000 (all disease severity)	48 fewer deaths per 1000 (21–63)	RR = 0.38 (0.19–0.73)	2438 (15)	Moderate†
Recovery time to negative PCR test, in days	Absolute risks were not computed due to certainty of evidence being low and, in some cases, number of events being sparse		MD = −3.20 (−5.99 to −0.40)	375 (6)	Very low†‡§
Time to clinical recovery, in days (outpatients)			MD = −1.06 (−1.63 to −0.49)	176 (2)	Very low†‡§
Time to clinical recovery, in days (mild to moderate COVID-19 inpatients)			MD = −7.32 (−9.25 to −5.39)	96 (1)	Very low†¶
Time to clinical recovery, in days (severe COVID-19 inpatients)			MD = −3.98 (−10.06 to 2.10)	33 (1)	Very low†¶
Admission to ICU			RR=1.22 (0.75–2.00)	379 (2)	Very low¶,‖
Need for mechanical ventilation			RR=0.66 (0.14–3.00)	431 (3)	Low§,‖
Length of hospital stay, in days			MD= 0.13 (−2.04 to 2.30)	68 (1)	Very low†,¶

Hazan et al 2021 – Ivermectin Triple Therapy

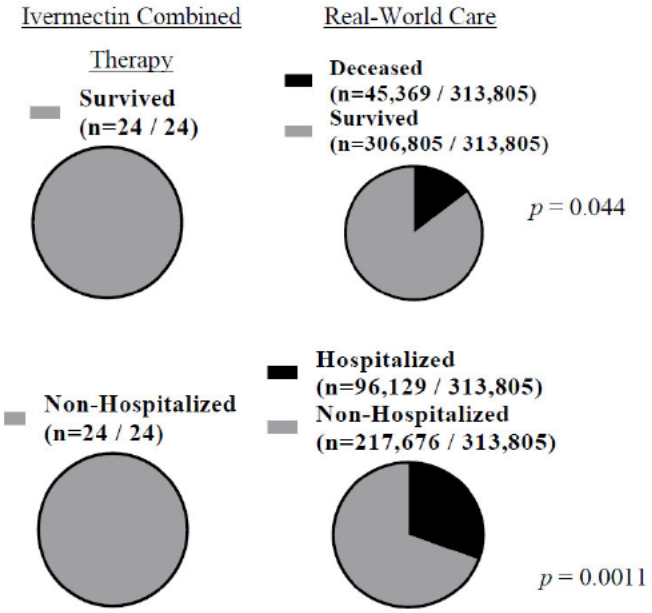
The aim of the study conducted by (Hazan et al. 2021) was to investigate the effectiveness of ivermectin combination therapy in consecutive adult patients who had failed to qualify for the blinded controlled trial, who had refused hospitalisation and whose oxygen saturation (SpO_2) was low, sometimes as low as 73%. Twenty four of 26 entered subjects received the triple therapy regimen of ivermectin (12 mg on day 1, 4 and 8), doxycycline (100 mg B.I.D.) and zinc (25 mg per day B.I.D.). Two declined the treatment due to GP's advice. The treatment arm was compared to an

externally controlled trial (synthetic) arm which was calculated from the public Center for Disease Control (CDC) data base of COVID-19 subjects.

Endpoints were time from presentation to negative SARS-CoV-2 PCR; time from presentation to symptom resolution; progression to hospitalisation; and patient survival.

Hospitalisations and deaths were significantly fewer (p<0.002 or 0.05, respectively) than in background-matched controls from the CDC database (***Figure 1***). All 24/26 treated subjects resolved symptoms in 11 days on average, and oxygen saturation improved in 24hrs (87.4% to 93.1%, p=0.001) (***Figure 2***). The two patients who declined treatment died from Covid-19.

Figure 1 Survival and Hospitalisation Rate



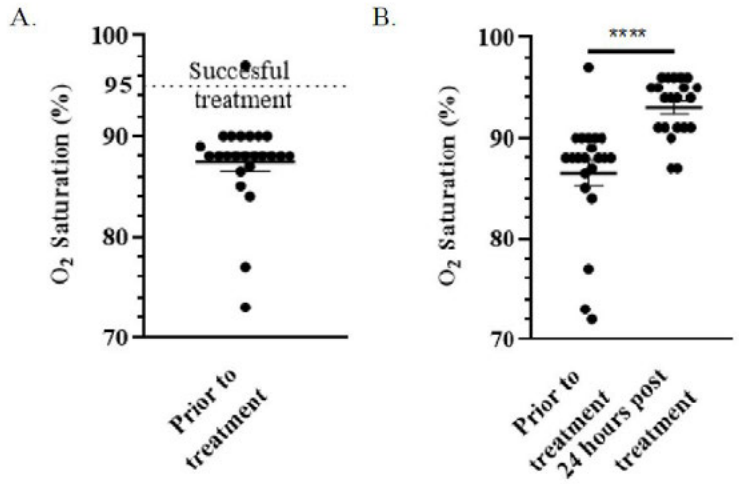


Figure 2 O_2 Saturation

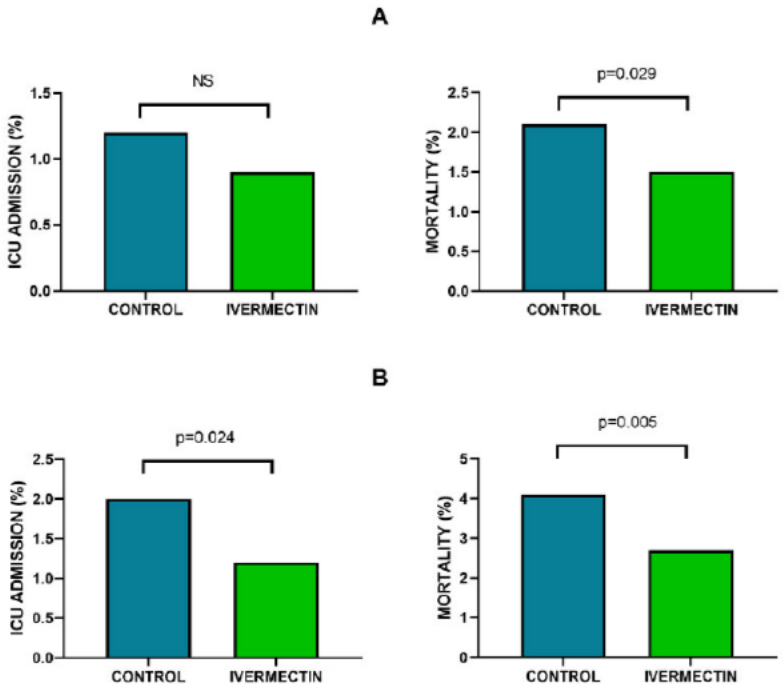
A. O_2 saturation prior to treatment was significantly ($p < 0.05$) less than 95%, the defined successful treatment reached by all subjects.
B. O_2 saturation significantly increased in subjects 24 hours after treatment (paired *t*-test, $p < 0.001$, only subjects with data before and after treatment included). O_2 saturation continued to rise, and until the defined cure of greater than 95% O_2 saturation.

Adverse effects were rare. Dizziness appears to be the only adverse event reported by the authors and this occurred in one patient. The adverse event did not prevent the patient from continuing the trial treatment.



Mayer et al 2021 – Ivermectin Used Alone

In the study by (Mayer et al. 2022) the safety and efficacy of higher dose of ivermectin in COVID-19 patients was investigated in the MEURI Program, a monitored emergency use of unregistered and experimental interventions program in Argentina. Ivermectin was used alone and not as a Triple Therapy.

Adult patients with COVID-19 were administered ivermectin at a dose of 0.6 mg/kg/day for 5 days plus standard of care. Active pharmacosurveillance was performed for 21 days, and laboratory assessments including liver function tests were performed in a subset of patients. Frequency of Intensive Care Unit (ICU) admission and COVID-19-related mortality of subjects in the ivermectin intention to treat group were compared with that observed in inhabitants of the same province during the same period not participating in the program. From 21232 subjects with COVID-19, 3266 were offered and agreed to participate in the ivermectin program and 17966 did not and were considered as controls.

ICU admission was significantly lower in the ivermectin group compared to controls among participants ≥40 year-old (1.2% vs 2.0, odds ratio 0.608; p=0.024). Similarly, mortality was lower in the ivermectin group in the full group analysis (1.5% vs 2.1%, odds ratio 0.720; p=0.029), as well as in subjects ≥40 year-old (2.7% vs 4.1%, odds ratio 0,655; p=0.005).

Figure 3 ICU admission and mortality

A: Analysis of all subjects ≥18 year-old (C n= 17966; IVM-ITT n=3266)
B: Analysis of all subjects ≥40 year-old (C n= 9022; IVM-ITT n=1851)

A total of 2613 participants were included in the safety assessment. Of the patients included in the safety assessment, 567 participants reported 819 adverse events (AEs). 82 subjects (3.13 %) discontinued ivermectin due to adverse events and all AEs resolved after treatment discontinuation. The most common AEs were diarrhea, followed by visual disorders, 240 dizziness, abdominal pain, headache and nausea. It is noted that no comparison against the control arm was reported.

Phase 3 Clinical Study

Topelia plans to conduct a multi-centre, double blind randomised controlled trial of early treatment in patients to determine the effectiveness of the proposed fixed dose combination in curing COVID-19 infection; in improving COVID-19 symptoms; in reducing the % of patients progressing to severe or critical disease; and in preventing or minimising COVID-19 related morbidity and mortality. It is anticipated that the study will be completed by December 2022 contingent on availability of acute Covid-19 infected patients.

The Phase 3 clinical study (study number: CDD20/05) title is:

- A Multi-centre Double Blind Placebo Controlled Trial of Ivermectin Combination Therapy in patients diagnosed with Novel coronavirus (COVID-19) in the community setting

The study aims to recruit 480 adult patients, who have a positive test result for SARS-CoV-2 via nasopharyngeal swab derived RT-PCR and mild to moderate symptoms. Once consent has been obtained, the study participants who meet all the eligibility criteria, will be randomised to receive either the active treatment or placebo.
The objectives of the study are as follows.

Primary objectives:

To determine the:

- Effectiveness of Ziverdox in curing COVID-19 infection assessed as % of patients having consecutive negative RT-PCR swabs (in quarantined and self-quarantined subjects at Day 7 and 8 and at Day 14 and 15 and in the elderly population in aged care facilities by day 20 where negative results can be slower to attain)
- Effectiveness of Ziverdox in improving COVID-19 infection symptoms at Day 7 and Day 14.
- % of Ziverdox treated patients who progress to severe or critical disease symptomatically
- Effectiveness of Ziverdox preventing or minimising COVID-19 related morbidity and mortality defined as % of ITT population progressing to hospitalisation and/or requiring mechanical intubation.

Secondary objectives:

- To assess the safety and tolerability of Ziverdox in patients with COVID-19 infection

An interim analysis of the results is built into the study protocol and will be provided to the TGA when available during the evaluation.
The final data from the Phase 3 study will be the confirmatory data for full registration.

Summary

The real world data with details of the proposed Phase 3 clinical study and commitment to provide the results of the interim analysis, together with supplementary literature will comprise the clinical section of the dossier.

4. Proposed Regulatory Pathway

The application for registration of Ziverdox is proposed to be submitted s47

Application Details

The application will be submitted in s47

Quality Dossier

Background

The immediacy of "real-world" data in the pre-hospital treatment of Covid-19 using re-purposed drugs has been the keystone to the development of effective therapy in a pandemic situation. The sense of a "common-message database" for the therapeutic use of ivermectin (IVM) collated by clinicians over a time frame of little more than 12 months, involving patients and research workers across geographic and social lines, is extraordinary. From over 20 countries there are 63 controlled studies accepted for meta-analysis, that have included 47,500 subjects with 625 authors.

While this compelling database on the effectiveness of IVM would not be possible without "real-life" studies, at an individual level, these trials give additional value such as information on dosage and combination therapies. They also give confidence to local doctors and regulators as they seek optimal management strategies.

Here, we report successful pre-hospital treatment of Covid-19 patients in Sydney and Melbourne, Australia, using an ivermectin-doxycycline-zinc combination with an important set of observations on symptom resolution and oximetry.

The Study

Six hundred Australian residents with positive PCR symptomatic Covid-19 were treated with a combination of ivermectin (24 mg per day), doxycycline (100 mg bd), and zinc (50mg per day), for 10 days within 48 hrs of obtaining a positive PCR test for Covid-19. The treatment period was from June to September 2021. Seven percent (7%) were given additional vitamins and nutritional supplements. Only 7% identified adverse events from the therapy, mainly minor gut symptoms of nausea, diarrhoea and heartburn. No patient stopped therapy due to adverse drug events.

A subgroup in hotel and home quarantine was available for a more detailed assessment of symptoms and oxygenation status. This cohort of 126 was assessed for 10 symptoms according to a visual analogue scale (ranging from "0" for no symptoms, to "10" for most severe symptoms). Descriptive statistics are summarised in Table 1. P-Values were calculated using Wilcoxon matched-pairs signed-rank t-tests. Chi Squared analysis was used to analyse rates of hospitalization in the 600-patient cohort.

The Outcome

A total of 600 patients with positive PCR tests were treated with the ten-day course of "Ivermectin Triple Therapy" (ITT), which was fully completed in over 90% of those treated. None discontinued therapy as a result of drug side effects. Two visited the hospital for less than 24 hours following a transient arrhythmia and then went home, while five were admitted to hospital (0.83%). There were no deaths. In an equivalent control group of 600, not treated with triple therapy, 70 were admitted to hospital (11.5%), with 6 deaths (1%). Chi-squared analysis of hospitalisation rate shows a significant decrease ($P<0.001$) in the presence of

ivermectin triple therapy intervention. The control data was from contemporary infected subjects in Australia obtained from published Covid Tracking Data.
The subgroup of 126 in quarantine had more detailed documentation. They had an average age of 42 (range: 17-94). The results of symptom analysis are in Table 1. For the 10 symptoms analysed, 98% had a total symptom score severity reduction by the end of the treatment period (P< 0.0001). Symptoms that were most persistent were loss of taste and smell, cough, and fatigue. Oximetry readings in 71 subjects were consistent with mild disease in most (Table 1), though the range extended to the low 70's indicating severe disease in some individuals. At the completion of the 10 -day treatment programme, all subjects had normal oximetry readings.

Comment

This successful study of 600 consecutive subjects treated within 2 days of testing positive on PCR for Covid-19 infection, emphasises the value of early treatment. The results are consistent with the study by Hazan et al, further supporting the value of ITT therapy (ivermectin, doxycycline and zinc).[1] The current study differs from that of Hazan et al who successfully used lower doses of IVM and a shorter treatment duration. The current study also confirms the value of oximetry in monitoring response to therapy, with all hypoxic patients having normal oximetry levels following the treatment protocol. Few become hypoxic in the first 48 hours of symptoms. The rapid increase in oximetry values following IVM, noted by Hazan[1], confirms significant hypoxia was likely avoided in this treated group. Combining oximetry with visual analogue scales to monitor symptoms, is suggested as a valuable tool for future studies.

Visual analogue scale monitoring of symptoms of Covid-19 infection showed a fall from a median total symptom severity score of 37 (range: 0-100) at the onset of treatment to 3 (range: 0-62) at the conclusion of treatment (P<0.0001). The main persistent symptoms were loss of smell/taste, cough and fatigue, recognised to persist for longer periods, however, all displayed significant severity score reductions during the treatment period (P<0.0001). The impact of early treatment with ITT on subsequent "long Covid" will be an important question to pursue. Symptom resolution with untreated Covid-19 is generally 2-4 weeks, emphasising the value of visual analogue scale assessment.

The major differences in admission to hospital and death following ITT therapy compared to contemporary controls is consistent with the large and increasing body of data measuring the impact of ivermectin-combination therapy.[1–3] The results from this study invites comparison with recently announced data by Merck from a study of their re-cycled antiviral polymerase inhibitor, Molnupiravir. The Merck study with 385 treated patients involved a similar group to that treated in the current Australian study judged by near-identical hospital admission and mortality rates in both control groups. In the Merck study, the hospital admission rate was halved (7.3% of treated patients) with no deaths, similar to data for the "first cousin" of Molnupiravir, Favipiravir, which is used extensively in Russia. The important point is that the admission rate in the Merck study is 8-fold greater than the 90% reduction in hospital admissions recorded in the current ITT study (P<0.0001). The public health impact of these findings with a cheap, safe and available therapy, in terms of reduction of load on a health system that will be further stressed as country borders are re-opened, cannot be ignored.
The current study included "real-life" data on consecutive patients thus avoiding selection bias. Therapy was given in two states of Australia, involving over 30 front-line doctors. This compelling data reinforces the value of information from a range of sources and trial methodologies in assessing treatment options, especially in a pandemic situation. The number of patients in this report was capped at 600, as the Australian regulatory body (the TGA)

intervened in the middle of Australia's third Covid wave, to prohibit further prescription of ivermectin for Covid-19 by General Practitioners.

Table 1: Pre and Post Treatment Symptom Severity and Pulse Oximetry Data from Quarantined Individuals (N=126)

	Pre-Treatment			Post-Treatment			
Fever	114	4.2 (4.1)	3 (0-10)	114	0.1 (0.7)	0 (0-5)	<0.0001
Headache	116	5.8 (3.3)	6 (0-10)	116	0.5 (1.1)	0 (0-5)	<0.0001
Cough	120	5.2 (3.3)	5 (0-10)	120	1.1 (1.9)	0 (0-9)	<0.0001
Loss of Taste	111	4.1 (4.5)	2 (0-10)	111	1.8 (3.2)	0 (0-10)	<0.0001
Loss of Smell	112	4.4 (4.5)	2.5 (0-10)	112	2.0 (3.5)	0 (0-10)	<0.0001
Diarrhoea	115	2.3 (3.3)	0 (0-10)	115	0.2 (0.7)	0 (0-5)	<0.0001
Vomiting	114	1.0 (2.7)	0 (0-10)	114	0.03 (0.3)	0 (0-3)	<0.0001
Fatigue	118	6.6 (3.4)	8 (0-10)	118	1.4 (2.0)	0 (0-10)	<0.0001
Muscle Pains	118	5.4 (3.7)	5 (0-10)	118	0.6 (1.4)	0 (0-7)	<0.0001
Joint Pains	114	4.7 (3.9)	5 (0-10)	114	0.4 (1.2)	0 (0-7)	<0.0001
Total Symptom Severity	124	40.9 (26.1)	37 (0-100)	124	7.5 (10.3)	3 (0-62)	<0.0001
Oximetry Reading (%)	71	93.3 (5.0)	95 (71-99)	71	98.1 (1.1)	98 (95-100)	<0.0001

Symptoms were scored on a 0-10 scale with 0 being the absence of associated symptom and 10 being the most severe presentation as reported by the patient. Total Symptom Severity Score was a combined sum of all symptoms assessed and was scored out of 100. Oximetry Readings were scored out of 100%. N = the number of respondents and SD = Standard Deviation. *Non-parametric paired t-tests were performed.

Conclusion

In 'Real Life' this 10-day Ivermectin Triple Therapy reported here, appears to be a very safe, effective and inexpensive early antiviral treatment for Covid-19. Further detail from the more than 30 doctors involved in treating this patient group, will be used for a formal peer-reviewed publication.

Ivermectin for Prevention and Treatment of COVID-19 Infection: A Systematic Review, Meta-analysis, and Trial Sequential Analysis to Inform Clinical Guidelines

Andrew Bryant, MSc,[1]* Theresa A. Lawrie, MBBCh, PhD,[2] Therese Dowswell, PhD,[2] Edmund J. Fordham, PhD,[2] Scott Mitchell, MBChB, MRCS,[3] Sarah R. Hill, PhD,[1] and Tony C. Tham, MD, FRCP[4]

Background: Repurposed medicines may have a role against the SARS-CoV-2 virus. The antiparasitic ivermectin, with antiviral and anti-inflammatory properties, has now been tested in numerous clinical trials.

Areas of uncertainty: We assessed the efficacy of ivermectin treatment in reducing mortality, in secondary outcomes, and in chemoprophylaxis, among people with, or at high risk of, COVID-19 infection.

Data sources: We searched bibliographic databases up to April 25, 2021. Two review authors sifted for studies, extracted data, and assessed risk of bias. Meta-analyses were conducted and certainty of the evidence was assessed using the GRADE approach and additionally in trial sequential analyses for mortality. Twenty-four randomized controlled trials involving 3406 participants met review inclusion.

Therapeutic Advances: Meta-analysis of 15 trials found that ivermectin reduced risk of death compared with no ivermectin (average risk ratio 0.38, 95% confidence interval 0.19–0.73; n = 2438; I^2 = 49%; moderate-certainty evidence). This result was confirmed in a trial sequential analysis using the same DerSimonian–Laird method that underpinned the unadjusted analysis. This was also robust against a trial sequential analysis using the Biggerstaff–Tweedie method. Low-certainty evidence found that ivermectin prophylaxis reduced COVID-19 infection by an average 86% (95% confidence interval 79%–91%). Secondary outcomes provided less certain evidence. Low-certainty evidence suggested that there may be no benefit with ivermectin for "need for mechanical ventilation,"

The preprint of this review received no funding. This updated version was funded by the crowdfunding initiative https://www.gofundme.com/f/help-us-get-lifesaving-drug-approved-for-covid19

The authors have no conflicts of interest to declare.

T. A. Lawrie and A. Bryant cowrote the review; they also sifted the search and classified studies for inclusion and entered and checked the data in RevMan and performed analyses. Data extraction was divided among T. A. Lawrie, A. Bryant, and T. Dowswell. T. Dowswell and A. Bryant graded the evidence. E. J. Fordham prepared the text on ivermectin mechanisms, use in pregnancy, and among the elderly. S. R. Hill prepared the brief economic commentary. Clinicians S. Mitchell and T. C. Tham contributed to the interpretation of the evidence in the discussion and conclusions. All authors reviewed and approved the final version of the manuscript.

This article discusses off-label use of the FDA-approved medication ivermectin against COVID-19.

whereas effect estimates for "improvement" and "deterioration" clearly favored ivermectin use. Severe adverse events were rare among treatment trials and evidence of no difference was assessed as low certainty. Evidence on other secondary outcomes was very low certainty.

Conclusions: Moderate-certainty evidence finds that large reductions in COVID-19 deaths are possible using ivermectin. Using ivermectin early in the clinical course may reduce numbers progressing to severe disease. The apparent safety and low cost suggest that ivermectin is likely to have a significant impact on the SARS-CoV-2 pandemic globally.

Keywords: ivermectin, prophylaxis, treatment, COVID-19, SARS-CoV-2

INTRODUCTION

To date, very few treatments have been demonstrated to reduce the burden of morbidity and mortality from COVID-19. Although corticosteroids have been proven to reduce mortality in severe disease,[1] there has been little convincing evidence on interventions that may prevent disease, reduce hospitalizations, and reduce the numbers of people progressing to critical disease and death.

Ivermectin is a well-known medicine that is approved as an antiparasitic by the World Health Organization and the US Food and Drug Administration. It is widely used in low- and middle-income countries (LMICs) to treat worm infections.[2,3] Also used for the treatment of scabies and lice, it is one of the World Health Organization's Essential Medicines.[4] With total doses of ivermectin distributed apparently equaling one-third of the present world population,[5] ivermectin at the usual doses (0.2–0.4 mg/kg) is considered extremely safe for use in humans.[6,7] In addition to its antiparasitic activity, it has been noted to have antiviral and anti-inflammatory properties, leading to an increasing list of therapeutic indications.[8]

Since the start of the SARS-CoV-2 pandemic, both observational and randomized studies have evaluated ivermectin as a treatment for, and as prophylaxis against, COVID-19 infection. A review by the Front Line COVID-19 Critical Care Alliance summarized findings from 27 studies on the effects of ivermectin for the prevention and treatment of COVID-19 infection, concluding that ivermectin "demonstrates a strong signal of therapeutic efficacy" against COVID-19.[9] Another recent review found that ivermectin reduced deaths by 75%.[10] Despite these findings, the National Institutes of Health in the United States recently stated that "there are insufficient data to recommend either for or against the use of ivermectin for the treatment of COVID-19,"[11] and the World Health Organization recommends against its use outside of clinical trials.[12]

Ivermectin has exhibited antiviral activity against a wide range of RNA and some DNA viruses, for example, Zika, dengue, yellow fever, and others.[13] Caly et al[14] demonstrated specific action against SARS-CoV-2 in vitro with a suggested host-directed mechanism of action being the blocking of the nuclear import of viral proteins[14,15] that suppress normal immune responses. However, the necessary cell culture EC_{50} may not be achievable in vivo.[16] Other conjectured mechanisms include inhibition of SARS-CoV-2 3CLPro activity[17,18] (a protease essential for viral replication), a variety of anti-inflammatory effects,[19] and competitive *binding* of ivermectin with the viral S protein as shown in multiple *in silico* studies.[20] The latter would inhibit viral binding to ACE-2 receptors suppressing infection. Hemagglutination via viral binding to sialic acid receptors on erythrocytes is a recently proposed pathologic mechanism[21] that would be similarly disrupted. Both host-directed and virus-directed mechanisms have thus been proposed, the clinical mechanism may be multimodal, possibly dependent on disease stage, and a comprehensive review of mechanisms of action is warranted.

Developing new medications can take years; therefore, identifying existing drugs that can be repurposed against COVID-19 that already have an established safety profile through decades of use could play a critical role in suppressing or even ending the SARS-CoV-2 pandemic. Using repurposed medications may be especially important because it could take months, possibly years, for much of the world's population to get vaccinated, particularly among LMIC populations.

Currently, ivermectin is commercially available and affordable in many countries globally.[6] A 2018 application for ivermectin use for scabies gives a direct cost of $2.90 for 100 12-mg tablets.[22] A recent estimate from Bangladesh[23] reports a cost of US$0.60—US$1.80 for a 5-day course of ivermectin. For these reasons, the exploration of ivermectin's potential effectiveness against SARS-CoV-2 may be of particular importance

FOI 26-3132 - Document 3

for settings with limited resources.[24] If demonstrated to be effective as a treatment for COVID-19, the cost-effectiveness of ivermectin should be considered against existing treatments and prophylaxes.

The aim of this review was to assess the efficacy of ivermectin treatment among people with COVID-19 infection and as a prophylaxis among people at higher risk of COVID-19 infection. In addition, we aimed to prepare a brief economic commentary (BEC) of ivermectin as treatment and as prophylaxis for COVID-19.[25]

METHODS

The conduct of this review was guided by a protocol that was initially written using Cochrane's rapid review template and subsequently expanded to a full protocol for a comprehensive review.[26]

Search strategy and selection criteria

Two reviewers independently searched the electronic databases of Medline, Embase, CENTRAL, Cochrane COVID-19 Study Register, and Chinese databases for randomized controlled trials (RCTs) up to April 25, 2021 (see **Appendix 1–3**, **Supplemental digital content 1**, http://links.lww.com/AJT/A95); current guidance[25] for the BEC was followed for a supplementary search of economic evaluations. There were no language restrictions, and translations were planned to be performed when necessary.

We searched the reference list of included studies, and of two other 2021 literature reviews on ivermectin,[9] as well as the recent WHO report, which included analyses of ivermectin.[12] We contacted experts in the field (Drs. Andrew Hill, Pierre Kory, and Paul Marik) for information on new and emerging trial data. In addition, all trials registered on clinical trial registries were checked, and trialists of 39 ongoing trials or unclassified studies were contacted to request information on trial status and data where available. Many preprint publications and unpublished articles were identified from the preprint servers MedRχiv and *Research Square*, and the International Clinical Trials Registry Platform. This is a rapidly expanding evidence base, so the number of trials are increasing quickly. Reasons for exclusion were recorded for all studies excluded after full-text review.

Data analysis

We extracted information or data on study design (including methods, location, sites, funding, study author declaration of interests, and inclusion/exclusion criteria), setting, participant characteristics (disease severity, age, gender, comorbidities, smoking, and occupational risk), and intervention and comparator characteristics (dose and frequency of ivermectin/comparator). The primary outcome for the intervention component of the review included death from any cause and presence of COVID-19 infection (as defined by investigators) for ivermectin prophylaxis. Secondary outcomes included time to polymerase chain reaction (PCR) negativity, clinical recovery, length of hospital stay, admission to hospital (for outpatient treatment), admission to ICU or requiring mechanical ventilation, duration of mechanical ventilation, and severe or serious adverse events, as well as post hoc assessments of improvement and deterioration. All of these data were extracted as measured and reported by investigators. Numerical data for outcomes of interest were extracted according to intention to treat.

If there was a conflict between data reported across multiple sources for a single study (eg, between a published article and a trial registry record), we contacted the authors for clarification. Assessments were conducted by 2 reviewers (T.L., T.D., A.B., or G.G.) using the Cochrane RCT risk-of-bias tool.[27] Discrepancies were resolved by discussion.

Continuous outcomes were measured as the mean difference and 95% confidence intervalss (CI), and dichotomous outcomes as risk ratio (RR) and 95% CI.

We did not impute missing data for any of the outcomes. Authors were contacted for missing outcome data and for clarification on study methods, where possible, and for trial status for ongoing trials.

We assessed heterogeneity between studies by visual inspection of forest plots, by estimation of the I^2 statistic ($I^2 \geq 60\%$ was considered substantial heterogeneity),[28] by a formal statistical test to indicate statistically significant heterogeneity,[29] and, where possible, by subgroup analyses (see below). If there was evidence of substantial heterogeneity, the possible reasons for this were investigated and reported. We assessed reporting biases using funnel plots if more than 10 studies contributed to a meta-analysis.

We meta-analyzed data using the random effects model (DerSimonian and Laird method)[30] using RevMan 5.4.1 software.[27,31] The results used the inverse variance method for weighting.[27] Some sensitivity analyses used other methods that are outlined below and some calculations were performed in *R*[32] through an interface[33] to the *netmeta* package.[34] Where possible, we performed subgroup analyses grouping trials by disease severity, inpatients versus outpatients, and single dose versus multiple doses. We performed sensitivity analyses by excluding studies at high risk of bias. We conducted further post hoc sensitivity analyses using alternative methods to test the robustness of results in the presence of zero events in both arms in a number of trials[35] and estimated odds ratios [and additionally RR for the Mantel–Haenszel

FOI 26-3132 - Document 3

(MH) method] using a fixed effects model. The models incorporate evidence from single-zero studies without having to resort to continuity corrections. However, double-zero studies are excluded from the analysis; so, the risk difference was also assessed using the MH method as this approach can adequately incorporate trials with double-zero events. This method can also use a random-effects component. A "treatment-arm" continuity correction was used, where the values 0.01, 0.1, and 0.25 were added where trials reported zero events in both arms. It has been shown that a nonfixed continuity correction is preferable to the usual 0.5.[35] Other methods are available but were not considered due to difficulty in interpretation, sensitivity of assumptions, or the fact they are rarely used in practice.[36–40]

Trial sequential analysis

When a meta-analysis is subjected to repeated statistical evaluation, there is an exaggerated risk that "naive" point estimates and confidence intervals will yield spurious inferences. In a meta-analysis, it is important to minimize the risk of making a false-positive or false-negative conclusion. There is a trade-off between the risk of observing a false-positive result (type I error) and the risk of observing a false-negative result (type II error). Conventional meta-analysis methods (eg, in RevMan) also do not take into account the amount of available evidence. Therefore, we examined the reliability and conclusiveness of the available evidence using trial sequential analyses (TSA).[41–43] The DerSimonian–Laird (DL) method was used because this is most often used in meta-analytic practice and was also used in the primary meta-analysis.[30]

The TSA was used to calculate the required information size (IS) to demonstrate or reject a relative reduction in the risk (RRR) of death in the ivermectin group, as found in the primary meta-analysis. We assumed the estimated event proportion in the control group from the meta-analysis because this is the best and most representative available estimate. Recommended type I and II error rates of 5% and 10% were used, respectively (power of 90%),[43] powering the result on the effect observed in the primary meta-analyses. We did not identify any large COVID-19 trials powered on all-cause mortality, so powering on some external meaningful difference was not possible. Any small RRR is meaningful in this context, given the scale of the pandemic, but the required IS would be unfeasibly high for this analysis if powered on a small difference. The only reliable data on ivermectin in its repurposed role for treatment against COVID-19 will be from the primary meta-analysis. Therefore, assuming it does not widely deviate from other published systematic reviews, a pragmatic decision was therefore made to power on the pooled meta-analysis effect estimate for all-cause mortality a priori. This is more reflective of a true meaningful difference. We used a model variance-based estimate to correct for heterogeneity. A continuity correction of 0.01 was used in trials that reported zero events in one or both arms. The required IS is the sample size required for a reliable and conclusive meta-analysis and is at least as large as that needed in a single powered RCT. The heterogeneity corrected required IS was used to construct sequential monitoring boundaries based on the O'Brien–Fleming type alpha-spending function for the cumulative z-scores (corresponding to the cumulative meta-analysis),[43] analogous to interim monitoring in an RCT, to determine when sufficient evidence had been accrued. These monitoring boundaries are relatively insensitive to the number of repeated significance tests. They can be used to further contextualize the original meta-analysis and enhance our certainty around its conclusions. We used a two-sided test, so also considered futility boundaries (to test for no statistically significant difference) and the possibility that ivermectin could harm. Sensitivity analyses were performed excluding the trial of Fonseca,[44] which was a cause of substantial heterogeneity (but retained in the core analysis because it was at low risk of bias). Its removal dramatically reduced I^2 and D^2 (diversity) estimates, thus reducing the model variance-based estimate to correct for heterogeneity. Two further sensitivity analyses were performed using 2 alternative random effect models, namely the Biggerstaff–Tweedie (BT) and Sidik–Jonkman (SJ) methods.[43]

All outcomes have been assessed independently by 2 review authors (T.D. and A.B.) using the GRADE approach,[45] which ranks the quality and certainty of the evidence. The results of the TSAs will also form part of the judgment for the primary all-cause mortality outcome. The results are presented in a summary of findings table. Any differences in judgments were resolved by discussion with the wider group. We used Cochrane Effective Practice and Organisation of Care guidance to interpret the evidence.[46]

RESULTS

Search results and risk-of-bias assessment

The combined and preliminary deduplicated total was n = 583. We also identified 11 records from other sources (reference lists, etc). See PRISMA flow diagram for inclusion and exclusion details of these references (Figure 1).

FOI 26-3132 - Document 3

The supplementary search for the BEC identified 17 studies, of which 4 were retrieved in full. No full trial- or model-based economic evaluations (cost–utility analyses, cost–effectiveness analyses, or cost–benefit analyses) were identified.

Twenty-one trials in treatment and 2 trials in prophylaxis of COVID-19 met review inclusion. One further study[47] reported separate treatment and prophylaxis components; we label this study "Elgazzar" under both questions. In effect, there were 22 trials in treatment and 3 in prophylaxis. All of these contributed data to at least one review outcome and meta-analysis. Fifteen trials contributed data for the primary outcome for ivermectin treatment (death); 3 studies reported the primary outcome for prophylaxis (COVID-19 infection). Characteristics of included studies are given in Table 1. Seventeen studies[47–63] were excluded as they were not RCTs and we identified 39 ongoing studies[64–102] and 2 studies[103,104] are awaiting classification.

A risk-of-bias summary graph is given in Figure 2. Eleven studies[23,24,44,47,105,106–111] used satisfactory random sequence generation and allocation concealment. Two trials described satisfactory sequence generation, but it was unclear whether allocation was concealed.[112,113]

Ten trials reported adequate blinding of the participants/personnel and/or the outcome assessors.[23,24,44,105,107,109,110,111,113,114] The others were either unclear or high risk for blinding. We considered blinding to be a less important criterion for evaluation of evidence related to the review's primary outcomes, namely death and laboratory-confirmed COVID-19 infection, which are objective outcomes.

We did not consider publication on preprint web sites to constitute a risk of bias because all studies were scrutinized and peer reviewed by us during the review process and, where additional information was needed, we contacted the authors for clarification.

Main findings

Twenty-four RCTs (including 3 quasi-RCTs) involving 3406 participants were included, with sample sizes ranging from 24 to 476 participants. Twenty-two trials in treatment and 3 trials in prophylaxis met review inclusion, including the trial of Elgazzar et al, which reported both components. For trials of COVID-19 treatment, 16 evaluated ivermectin among participants with mild to moderate COVID-19 only; 6 trials included patients with severe COVID-19. Most compared ivermectin with placebo or no ivermectin; 3 trials included an active comparator (Table 1). Three RCTs involving 738 participants

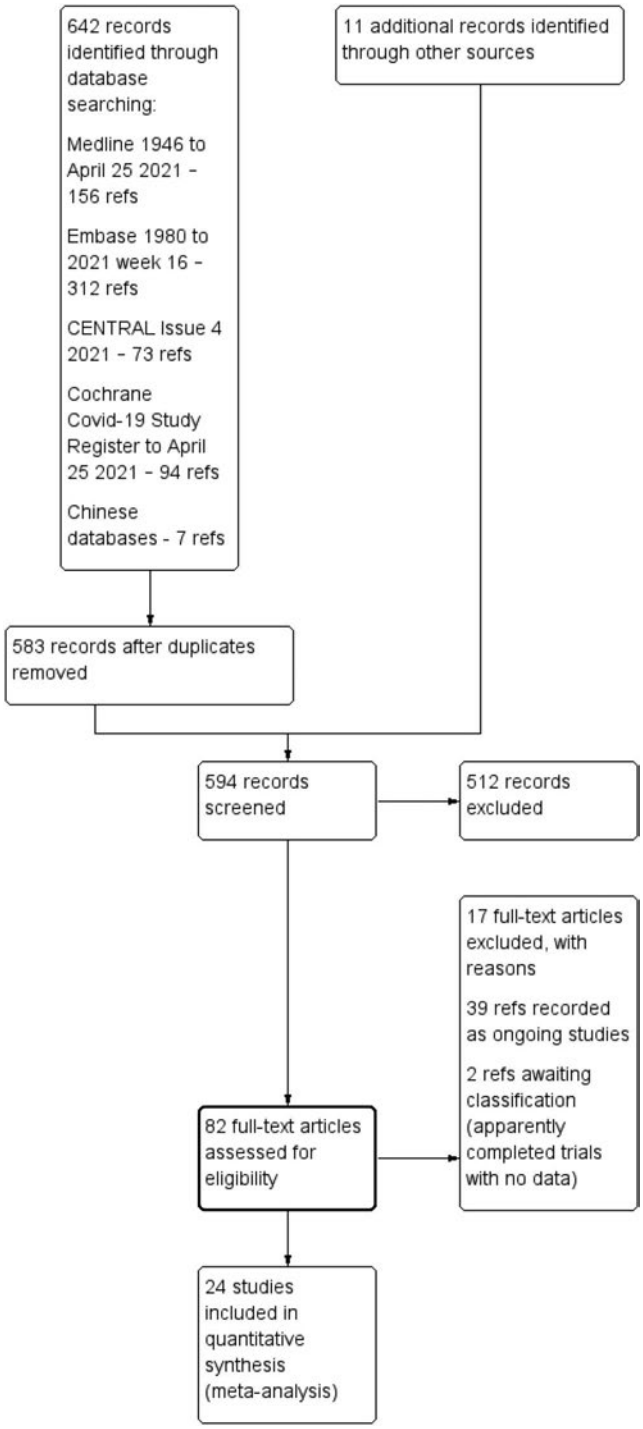

FIGURE 1. Study flow diagram from search on 25 April 2021.

were included in the prophylaxis trials. Most trials were registered, self-funded, and undertaken by clinicians working in the field. There were no obvious conflicts of interest noted, with the exception of two trials.[85,139]

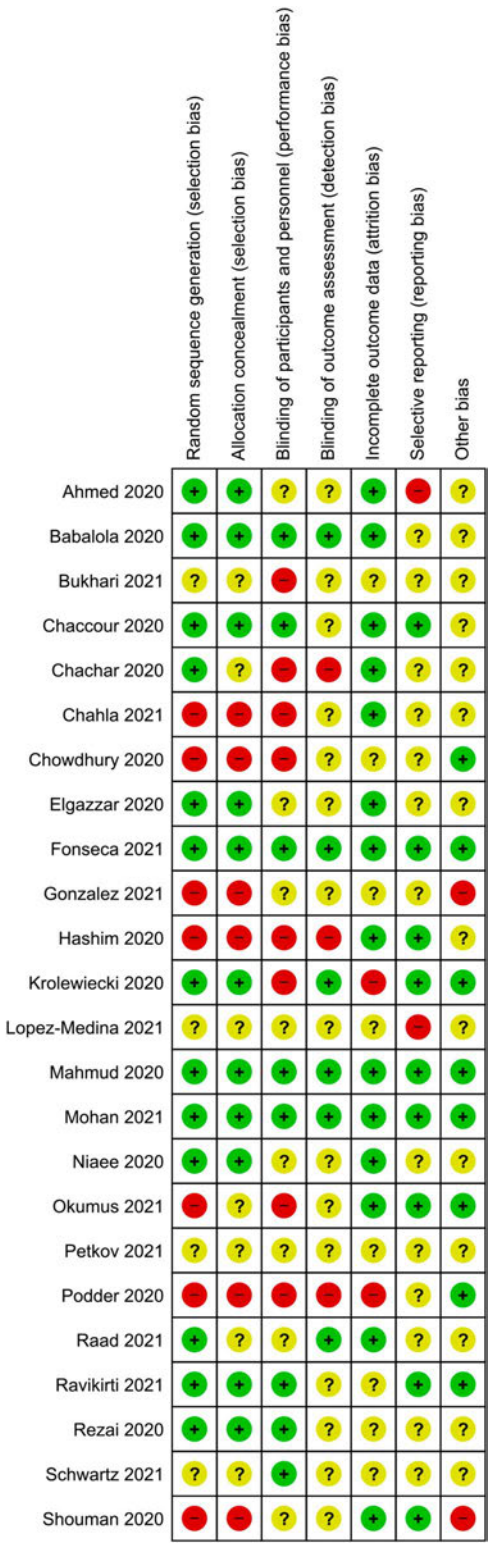

FIGURE 2. Risk-of-bias summary: review authors' judgments about each risk of bias item for each included study.

Ivermectin treatment versus no ivermectin treatment

Twenty-two trials (2668 participants) contributed data to the comparison ivermectin treatment versus no ivermectin treatment for COVID-19 treatment.

All-cause mortality

Meta-analysis of 15 trials, assessing 2438 participants, found that ivermectin reduced the risk of death by an average of 62% (95% CI 27%–81%) compared with no ivermectin treatment [average RR (aRR) 0.38, 95% CI 0.19 to 0.73; $I^2 = 49\%$]; risk of death 2.3% versus 7.8% among hospitalized patients in this analysis, respectively (SoF Table 2 and Figure 3). Much of the heterogeneity was explained by the exclusion of one trial[44] in a sensitivity analysis (average RR 0.31, 95% CI 0.17–0.58, n = 2196, $I^2 = 22\%$), but because this trial was at low risk of bias, it was retained in the main analysis. The source of heterogeneity may be due to the use of active comparators in the trial design. The results were also robust to sensitivity analyses excluding 2 other studies with an active treatment comparator (average RR 0.41, 95% CI 0.23–0.74, n = 1809, $I^2 = 8\%$). The results were also not sensitive to the exclusion of studies that were potentially at higher risk of bias (average RR 0.29, 95% CI 0.10–0.80, 12 studies, n = 2095, $I^2 = 61\%$), but in subgroup analysis, it was unclear as to whether a single dose would be sufficient. The effect on reducing deaths was consistent across mild to moderate and severe disease subgroups. Subgrouping data according to inpatient and outpatient trials was not informative because few outpatient studies reported this serious outcome. The conclusions of the primary outcome were also robust to a series of alternative post hoc analyses that explored the impact of numerous trials that reported no deaths in either arm. Extreme sensitivity analyses using a treatment arm continuity correction of between 0.01 and 0.5 did not change the certainty of the evidence judgments (Table 3).

Trial sequential analysis

TSA, using the DL random-effects method, showed that there may have been sufficient evidence accrued before the end of 2020 to show significant benefit of ivermectin over control for all-cause mortality. The cumulative z-curve in Figure 8 crossed the trial sequential monitoring boundaries after reaching the required IS, implying that there is firm evidence for a beneficial effect of ivermectin use over no ivermectin use in mainly hospitalized participants with mild to moderate COVID-19 infection.

Table 2. Summary of findings table of ivermectin versus no ivermectin for COVID-19 treatment in any setting.

Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)
	Assumed risk No ivermectin	Corresponding risk Ivermectin			
Death from any cause	78 per 1000 (all disease severity)	48 fewer deaths per 1000 (21–63)	RR = 0.38 (0.19–0.73)	2438 (15)	Moderate†
Recovery time to negative PCR test, in days	Absolute risks were not computed due to certainty of evidence being low and, in some cases, number of events being sparse		MD = −3.20 (−5.99 to −0.40)	375 (6)	Very low†,‡,§
Time to clinical recovery, in days (outpatients)			MD = −1.06 (−1.63 to −0.49)	176 (2)	Very low†,‡,§
Time to clinical recovery, in days (mild to moderate COVID-19 inpatients)			MD = −7.32 (−9.25 to −5.39)	96 (1)	Very low†,¶
Time to clinical recovery, in days (severe COVID-19 inpatients)			MD = −3.98 (−10.06 to 2.10)	33 (1)	Very low†,¶
Admission to ICU			RR=1.22 (0.75–2.00)	379 (2)	Very low¶,‖
Need for mechanical ventilation			RR=0.66 (0.14–3.00)	431 (3)	Low§,‖
Length of hospital stay, in days			MD= 0.13 (−2.04 to 2.30)	68 (1)	Very low†,¶
Admission to hospital			RR 0.16 (0.02–1.32)	194 (2)	Very low†,¶
Duration of mechanical ventilation	Not reported				
Improvement (mild to moderate COVID-19)*	635 improved per 1000	159 more per 1000 (from 51 more to 286 more)	RR 1.25 (1.08–1.45)	681 (5)	Low†,‡
Deterioration (any disease severity)	143 per 1000	93 fewer per 1000 (from 50 fewer to 116 fewer)	RR 0.35 (0.19–0.65)	1587 (7)	Low†,‡

The TSA was used to calculate the IS required to demonstrate or reject a 62% RRR of death in the ivermectin group, as observed in the primary meta-analysis. This estimate is similar to effect estimates reported in other reviews.[10] We assumed a 7.8% event proportion in the control group, which was the average control group

event rate from the primary meta-analysis. We used a model variance-based estimate of 49.1% (diversity estimate) to correct for heterogeneity. The required IS was 1810 participants (Figure 8), which was exceeded by the total number of observed participants in the meta-analysis (n = 2438). In the TSA plots, the red dashed lines in Figure 8 represent the trial sequential monitoring boundaries using the O'Brien–Fleming alpha-spending function. The solid blue line is the cumulative z-curve and represents the observed trials in the cumulative meta-analysis. The adjusted significance boundaries for the cumulative z-curve were constructed under the assumption that significance testing may have been performed each time a new trial was added to the meta-analysis. In Figure 8, the z-curve crosses the boundary after reaching the required IS, thereby supporting the previous conclusion in RevMan 5.4.1[31] using the DL method that ivermectin is superior to control in reducing the risk of death.

Sensitivity analyses

Sensitivity analysis excluding the trial of Fonseca[44] significantly reduced heterogeneity in the meta-analysis and thus the diversity estimate in the TSA using the DL model. This strengthened the suggestion in the primary core analysis that the required IS had been reached (Figure 9). Because the DL estimator could potentially underestimate the between-trials variance,[43] we performed further sensitivity analyses using 2 alternative random-effects model approaches. The results of the primary TSA analysis were robust to sensitivity analysis using the BT method with the same parameters, excluding the Fonseca[44] trial, which was a cause of substantial heterogeneity (Figure 10). The TSA

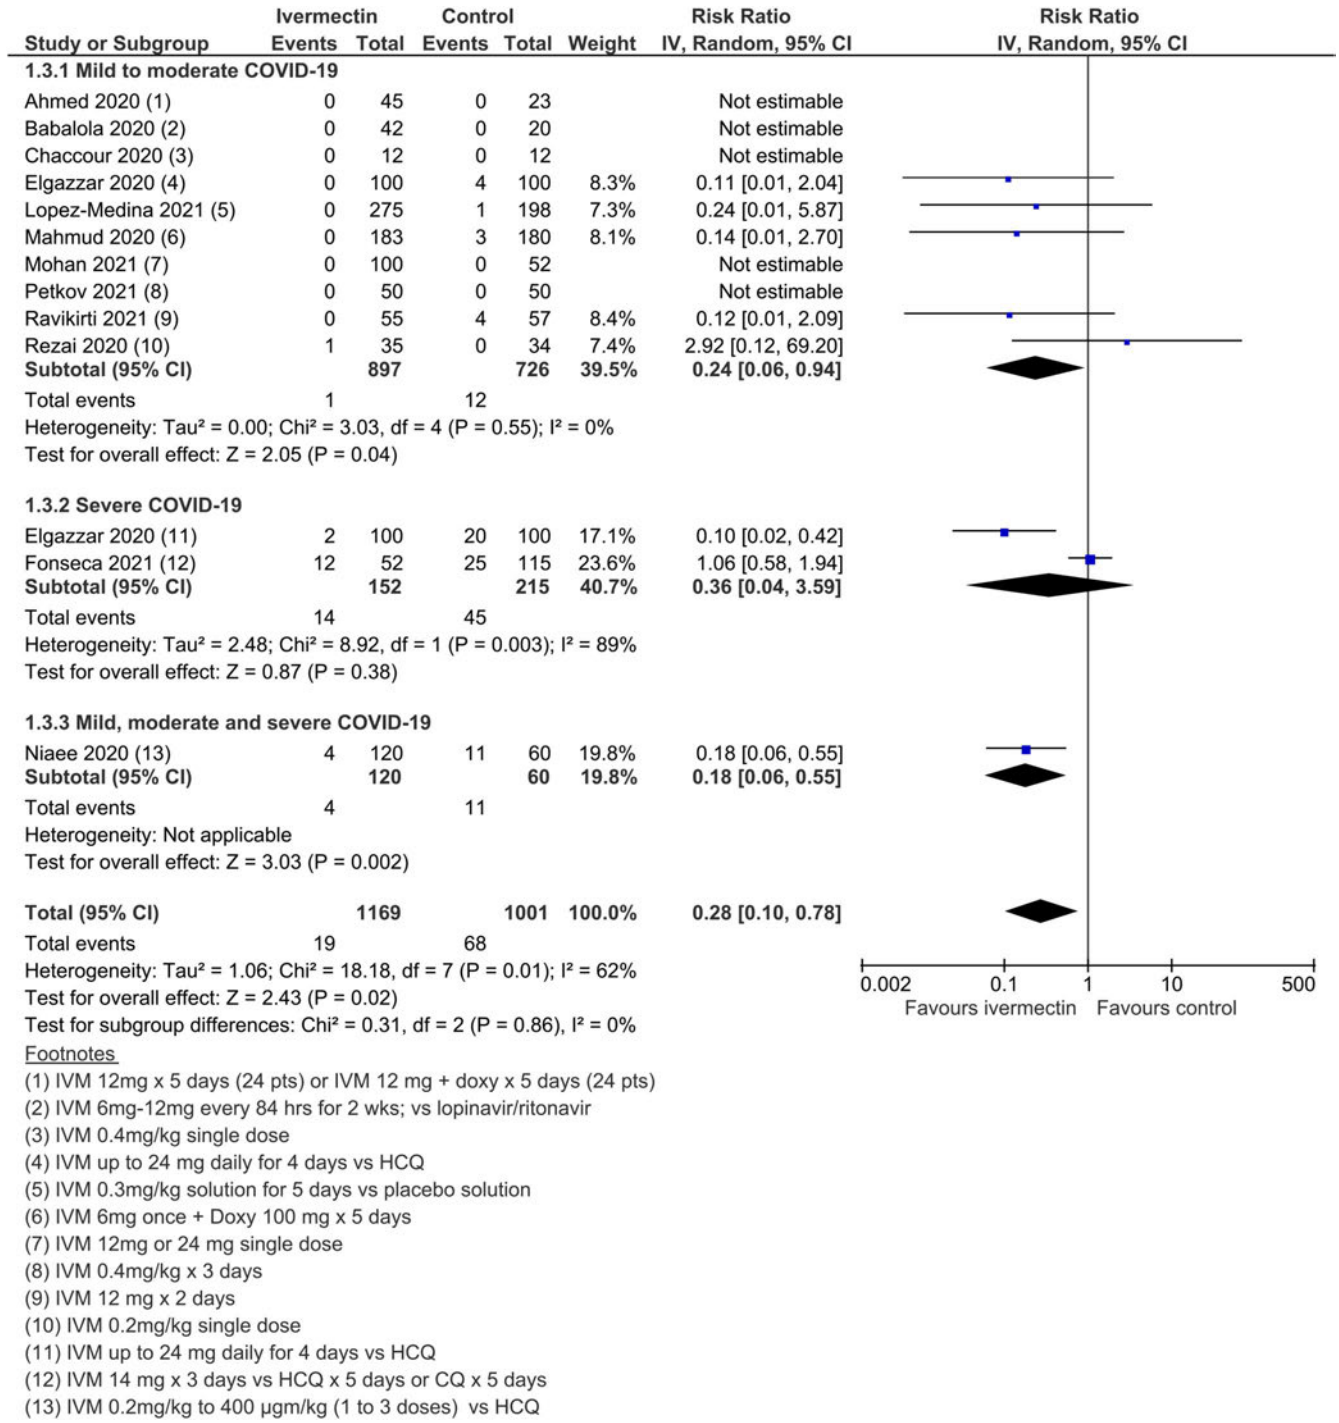

FIGURE 5. Death due to any cause, excluding high risk-of-bias studies.

comprehensively confirms the result of the conventional meta-analysis. The required IS was 1064.

The required IS was not reached in the TSA using the SJ method, largely because diversity from the model was high (Figure 11). The SJ estimator may overestimate the between-trials variance in meta-analyses with mild heterogeneity, thus producing artificially wide confidence intervals.[43] When the diversity estimate was reduced to the same as in the DL model, the required IS was reached in the SJ model (data not shown). There was no evidence of futility using the SJ method in any scenario.

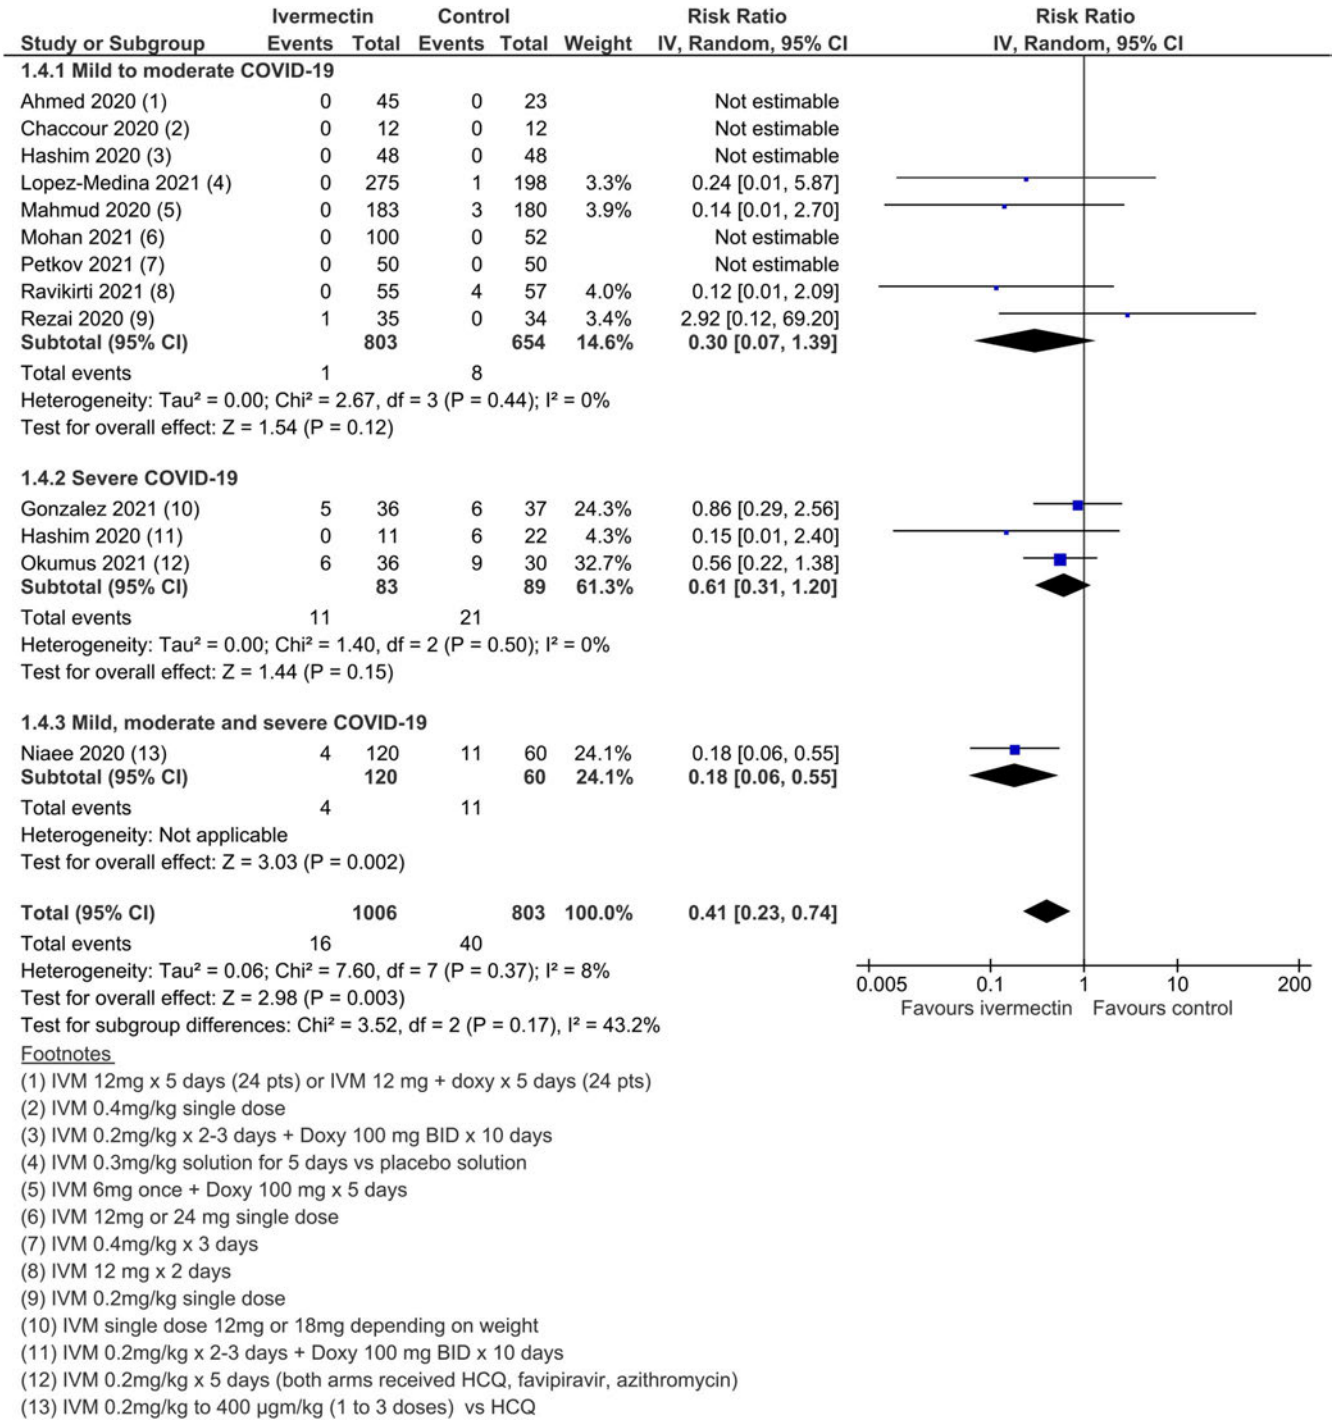

FIGURE 6. Death due to any cause, excluding studies with active controls.

Certainty of the evidence for all-cause mortality

Overall, death from any cause, taking into account all composite analyses, was judged to provide moderate-certainty evidence (SoF Table 2 and Figures 4–11). A funnel plot corresponding to the primary outcome of death from any cause did not seem to suggest any evidence of publication bias (Figure 7). Furthermore, the ease with which trial reports can be uploaded as preprints should reduce this risk.

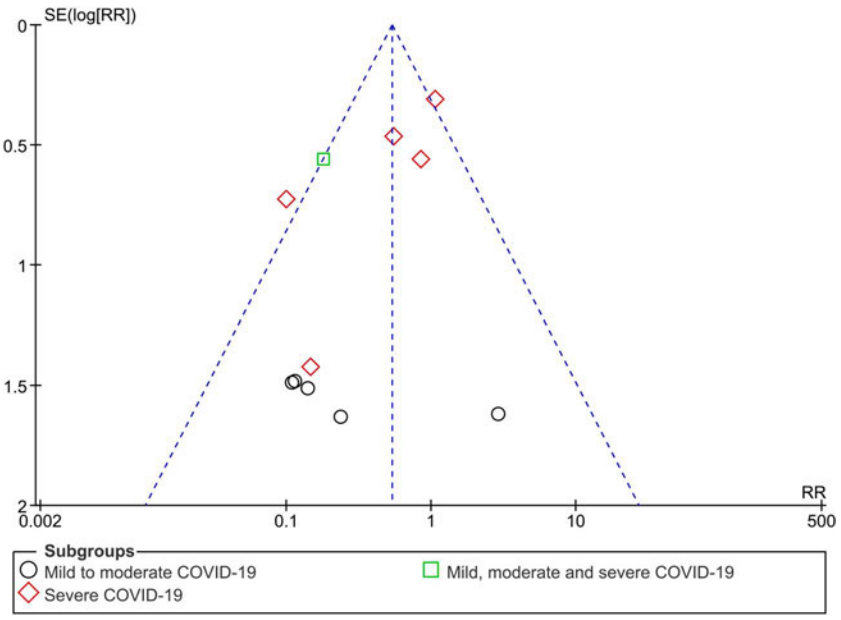

FIGURE 7. Funnel plot of ivermectin versus control for COVID-19 treatment for all-cause death (subgrouped by severity).

Secondary outcomes

Secondary outcomes provided low to very low certainty evidence (SoF Table 2). Low-certainty findings suggested that there may be no benefit with ivermectin for "need for mechanical ventilation," whereas effect estimates for "improvement" and "deterioration" favored ivermectin but were graded as low certainty due to study design limitations and inconsistency (Figures 12–14). All other secondary outcome findings were assessed as very low certainty.

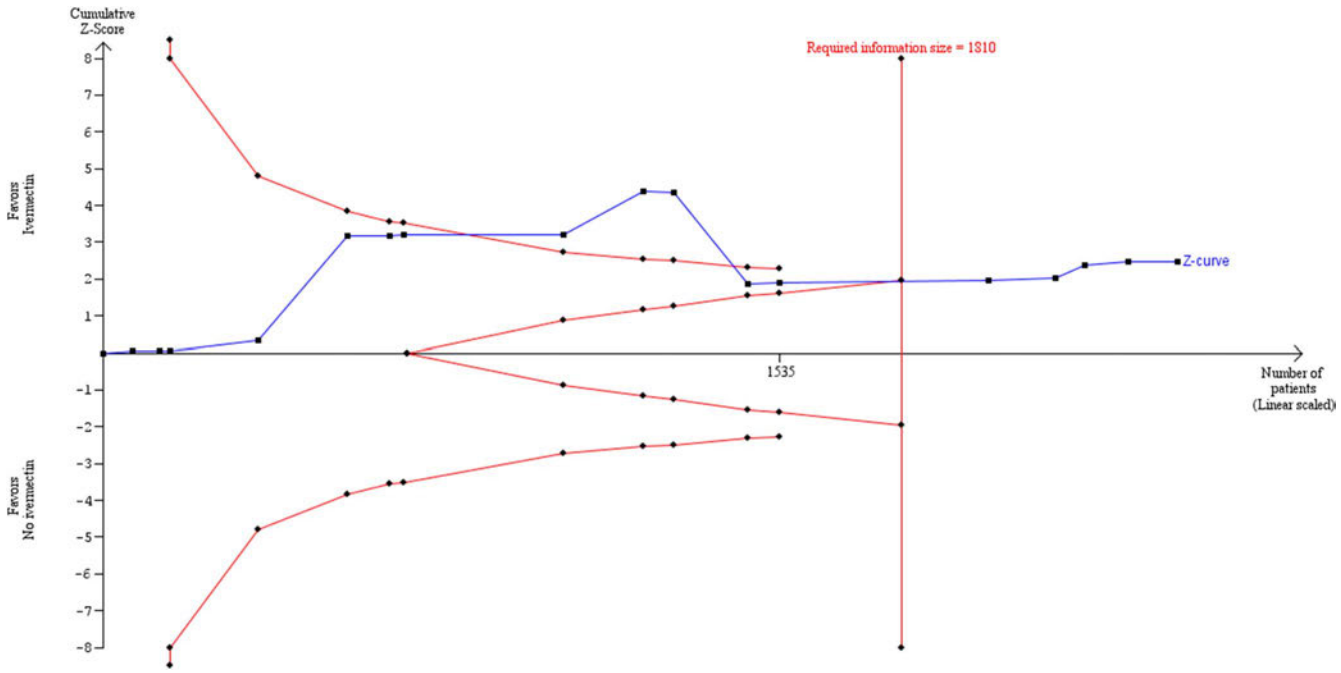

FIGURE 8. Trial sequential analysis using DL random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, RRR = 62%, and diversity = 49.5%.

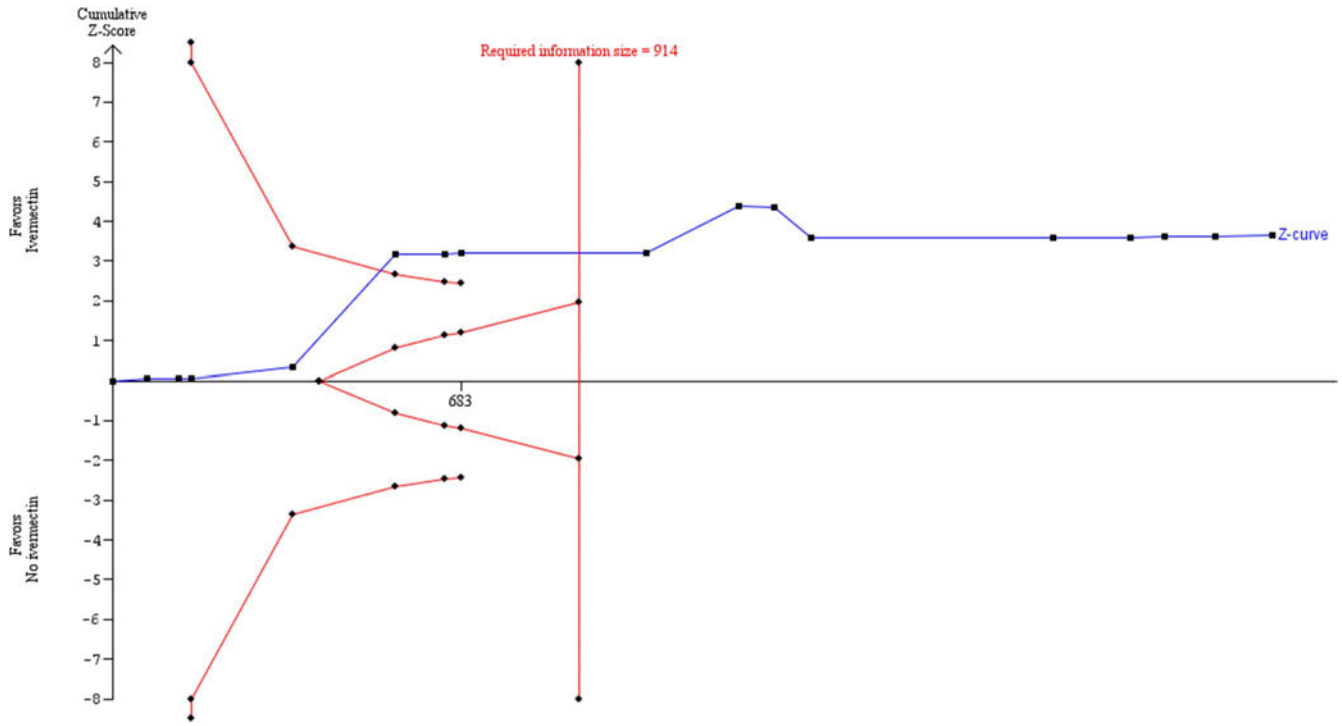

FIGURE 9. Sensitivity analysis excluding an outlier study responsible for the heterogeneity, showing trial sequential analysis using DL random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, = 62%, and diversity = 0%.

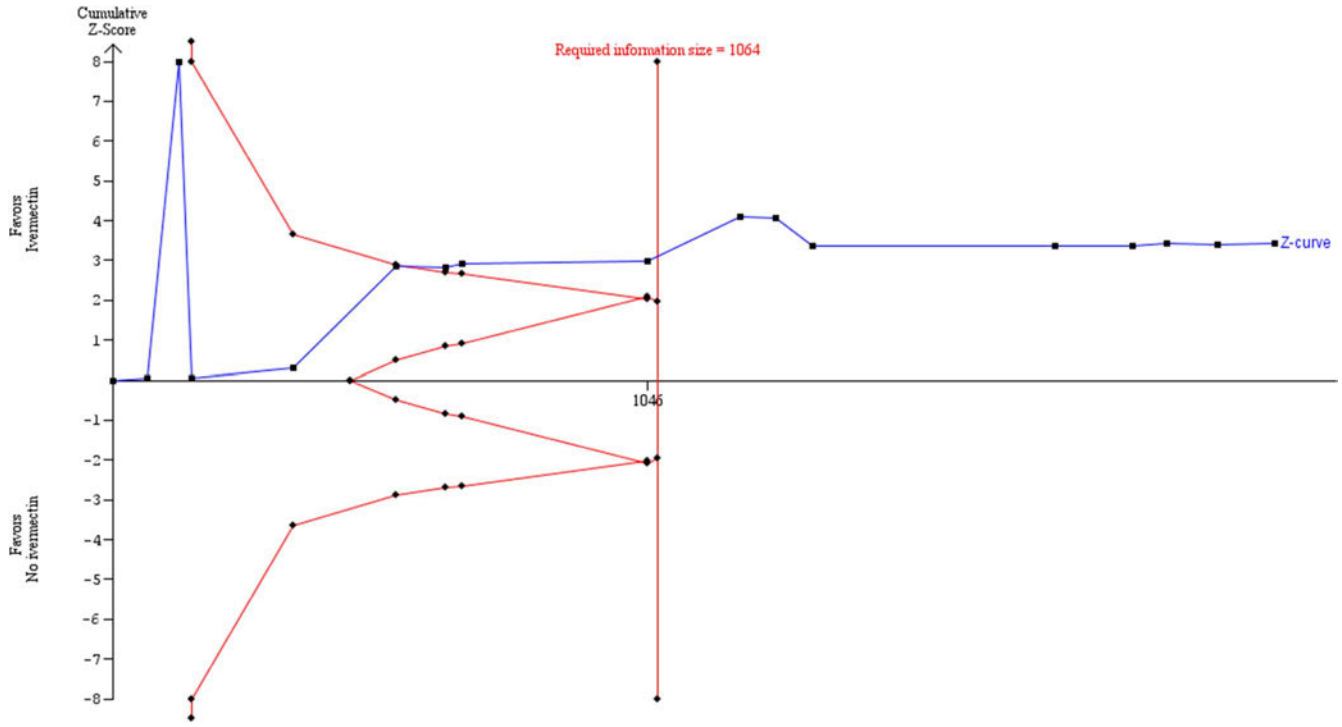

FIGURE 10. Sensitivity analysis excluding an outlier study responsible for the heterogeneity, showing trial sequential analysis using Biggerstaff–Tweedie random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, RRR = 62%, and diversity = 14.2%.

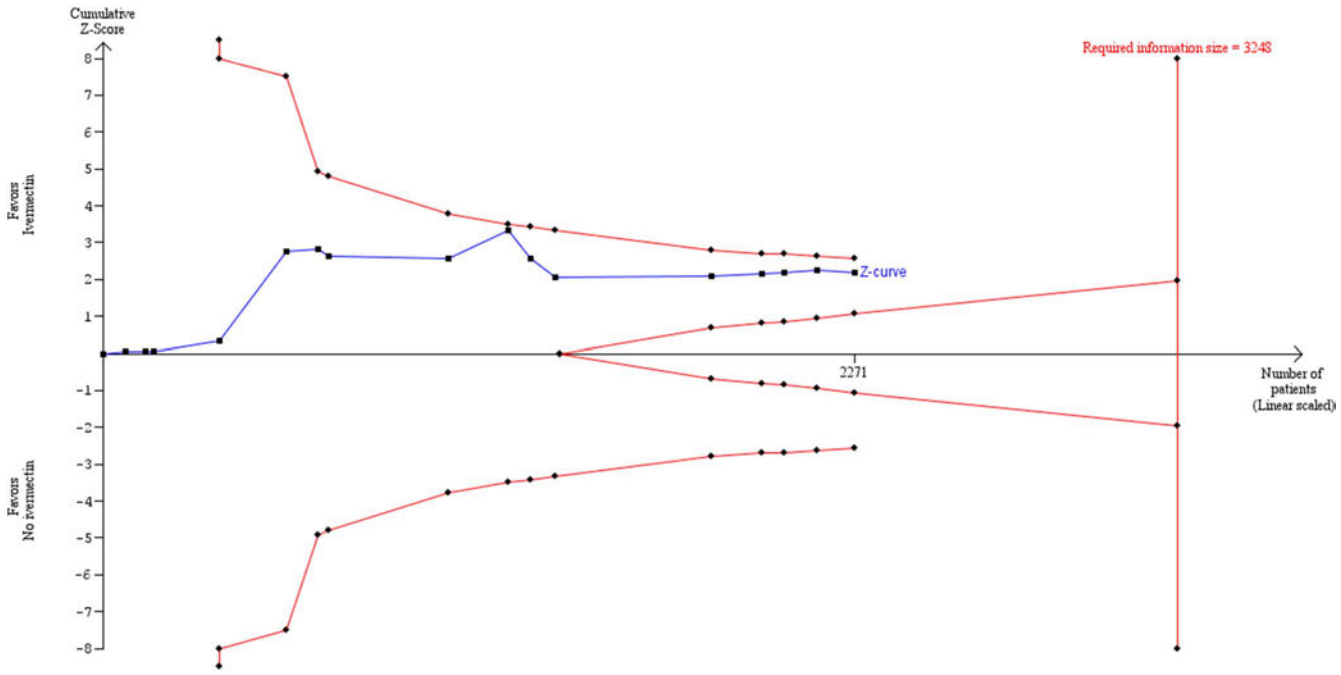

FIGURE 11. Sensitivity analysis excluding an outlier study responsible for the heterogeneity, showing trial sequential analysis using Sidik–Jonkman random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, RRR = 62%, and diversity = 71.9%.

Meta-analysis of 11 trials, assessing 1533 participants, found that there was no significant difference between ivermectin and control in the risk of severe adverse events (aRR 1.65, 95% CI 0.44–6.09; $I^2 = 0\%$; *low certainty evidence*, downgraded for imprecision and study design limitations). Seven severe adverse events were reported in the ivermectin group and 2 in controls. The SAEs were as follows: 2 patients in the Mahmud trial[107] had esophagitis (this is a known side effect of doxycycline, which was coadministered with ivermectin in this trial); one patient in the study by Krolewiecki et al[106] had hyponatremia (this trial used high-dose ivermectin for 5 days); and 2 patients in a study from Turkey[115] had serious "delirium-like behavior, agitation, aggressive attitude, and altered state of consciousness," which the authors attributed to metabolic insufficiencies in MDR-1/ABCB1 or CYP3A4 genes, screening for which was a study feature. In the Lopez-Medina et al[85] trial, there were 2 SAEs in each arm (SoF Table 2).

Ivermectin prophylaxis versus no ivermectin prophylaxis

Three studies involving 738 participants evaluated ivermectin for COVID-19 prophylaxis among health care workers and COVID-19 contacts. Meta-analysis of these 3 trials, assessing 738 participants, found that ivermectin prophylaxis among health care workers and COVID-19 contacts probably reduces the risk of

COVID-19 infection by an average of 86% (79%–91%) (3 trials, 738 participants; aRR 0.14, 95% CI 0.09–0.21; 5.0% vs. 29.6% contracted COVID-19, respectively; *low-certainty evidence*; downgraded due to study design limitations and few included trials) (Figure 15). In 2 trials involving 538 participants, no severe adverse events were recorded (SoF Table 4).

DISCUSSION

The findings indicate with moderate certainty that ivermectin treatment in COVID-19 provides a significant survival benefit. Our certainty of evidence judgment was consolidated by the results of trial sequential analyses, which show that the required IS has probably already been met. Low-certainty evidence on improvement and deterioration also support a likely clinical benefit of ivermectin. Low-certainty evidence suggests a significant effect in prophylaxis. Overall, the evidence also suggests that early use of ivermectin may reduce morbidity and mortality from COVID-19. This is based on (1) reductions in COVID-19 infections when ivermectin was used as prophylaxis, (2) the more favorable effect estimates for mild to moderate disease compared with severe disease for death due to any cause, and (3) on the evidence demonstrating reductions in deterioration.

The evidence on severe adverse events in this review was graded as low certainty, partly because there were too few events to reach statistical significance. Evidence from a recent systematic review of ivermectin use among people with parasitic infections suggests that ivermectin administered at the usual doses (0.2 or 0.4 mg/kg) is safe and could be safe at higher doses.[7,116] A recent World Health Organization document on ivermectin use for scabies found that adverse events with ivermectin were primarily minor and transient.[22]

We restricted the included studies to the highest level of evidence, that is, RCTs, as a policy. This was despite there being numerous observational but nonrandomized trials of ivermectin, which one could argue could also be considered in an emergency. We included preprint and unpublished data from completed but not yet published trials due to the urgency related to evidence synthesis in the context of a global pandemic.[117] Although there is the potential for selective reporting of outcomes and publication bias, we have factored in these considerations in interpreting results and forming conclusions. We adhered to PRISMA guidelines and the WHO statement on developing global norms for sharing data and results during public health emergencies.[117]

There are a number of limitations with this review. Several of the studies contributing data did not

FOI 26-3132 - Document 3

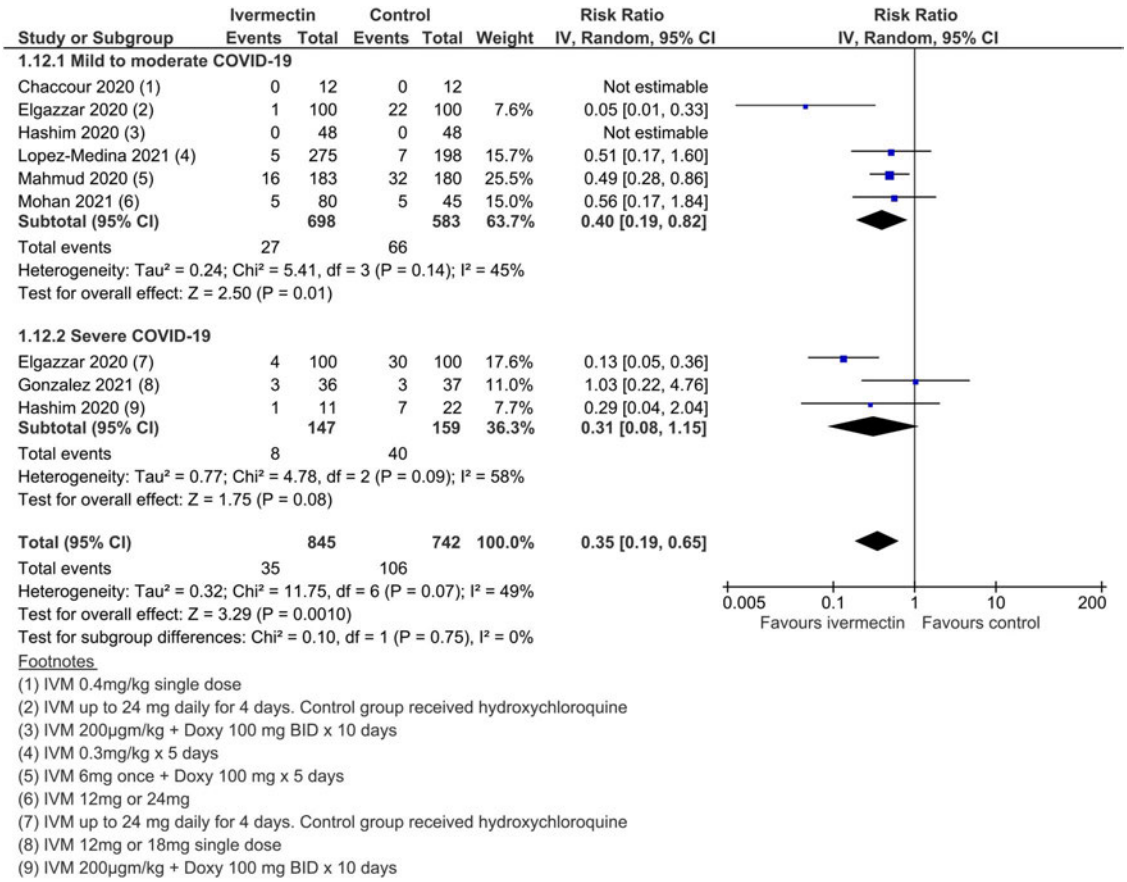

FIGURE 14. Deterioration.

provide full descriptions of methods, so assessing risk of bias was challenging. Where descriptions of study methods were sparse or unclear, we attempted to contact authors to clarify methods, but lack of information led us to downgrade findings in several instances. Overall interpretation of findings was hampered due to variability in the participants recruited, treatment regimen, and the care offered to those in control groups. We have tried to take this variation into account through subgroup and sensitivity analyses. Nevertheless, dosing and treatment regimens and the use of ivermectin with other components of "standard care" require further research. We did not include laboratory outcome measures, such as viral clearance. The latter and other biochemical outcomes have been reported in several studies and reviews and tend to favor ivermectin.[10,47,105,108] Several trials reported continuous data, such as length of hospital stay, as medians and interquartile ranges; therefore, we were unable to include these data in meta-analysis. Because we did not undertake in our protocol to perform narrative evidence synthesis, and because these data tended to favor ivermectin, the certainty of the effects of ivermectin on these continuous outcomes may be underestimated.

At least 5 other reviews of ivermectin use for COVID-19 have been published, including one coauthored with Nobel Laureate Professor Satoshi Ōmura, discoverer of ivermectin,[9,10,118,119,120] but only 3 have been peer-reviewed[9,118,120] and only 2 attempt full systematic review.[10,119] We applied AMSTAR 2,[121] a critical appraisal tool for systematic reviews of health care interventions, to the 2 nonpeered systematic reviews[10,119] and both were judged to be of low quality (Table 5). However, there was also a suggestion that ivermectin reduced the risk of death in treatment of COVID-19 in these reviews.

The recently updated WHO therapeutics guidelines[12] included 7 trials and 1419 people in the analysis of mortality. Reporting a risk reduction of 81% (odds ratio 0.19, 95% CI 0.09–0.36), the effect estimate favoring ivermectin was downgraded by 2 levels for imprecision, although the justification for this is unclear as the reported CI is precise (64%–91%).

In addition to the evidence from systematic reviews, the findings of several controlled observational studies

FOI 26-3132 - Document 3

Table 4. Summary of findings table of ivermectin versus no ivermectin for COVID-19 prophylaxis in healthy population (people without COVID-19 infection).

	Illustrative comparative risks* (95% CI)				
	Assumed risk	Corresponding risk			
Outcomes	No ivermectin	Ivermectin	Relative effect (95% CI)	No of participants (studies)	Quality of the evidence (GRADE)
COVID-19 infection	296 per 1000	245 fewer infections per 1000 (234–269)	RR = 0.14 (0.09–0.21)	738 (3)	Low†
Admission to hospital	Not reported				
Death from any cause	Not reported				
Serious adverse events	No events occurred in 538 participants (2 studies), therefore the effect could not be estimated.				

GRADE working group grades of evidence; High quality: Further research is very unlikely to change our confidence in the estimate of effect; Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate; Low quality: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate; Very low quality: We are very uncertain about the estimate.
*The basis for the assumed risk (eg, the median control group risk across studies) is provided in footnotes. The corresponding risk (and its 95% CI) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).
†Downgraded −2 for study design limitations.
NNT, number needed to treat.

are consistent with existing evidence and suggest improved outcomes with ivermectin treatment.[55,57,59] Similarly, with respect to ivermectin prophylaxis of frontline workers and those at risk, controlled observational studies from Bangladesh and Argentina (the latter which involved 1195 health care workers) have shown apparent reductions in COVID-19 transmission with ivermectin prophylaxis, including in some reports total protection (zero infections) where infection rates in the control group exceeded 50%.[122,123] A very large trial of ivermectin prophylaxis in health care workers in India[124] covered 3532 participants and reported risk ratios not significantly different from this meta-analysis (prophylaxis outcome).

Clarifying ivermectin safety in pregnancy is a key question in patient acceptability for pregnant women contracting COVID-19. A recent meta-analysis[5] found little evidence of increased risk of abnormal pregnancies but similarly weak evidence of absence of risk. For (pre-exposure) prophylaxis in pregnancy, where vaccines may be contraindicated, the alternative of hydroxychloroquine has been advocated.[125,126] In addition to safety and relative efficacy, different risk–benefit judgments may be presented for prophylaxis

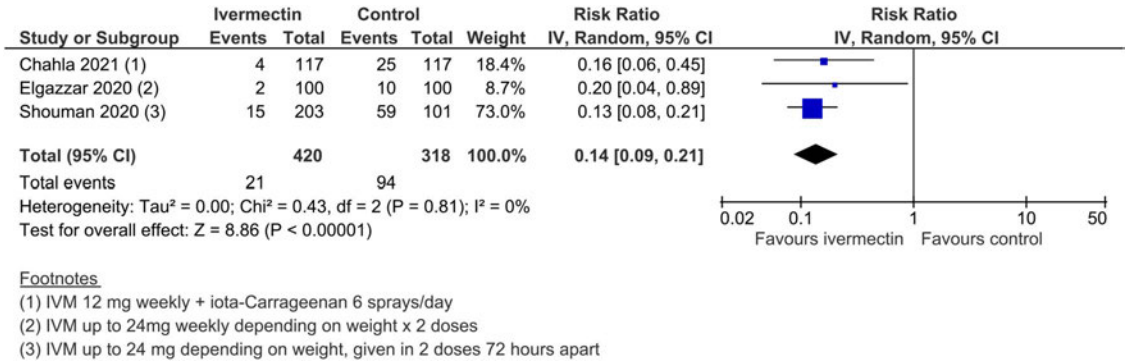

FIGURE 15. COVID-19 infection (prophylaxis studies).

Table 5. Methodological quality of other systematic reviews (AMSTAR 2).

Castañeda-Sabogal et al 2021[119]	−**	−	−††	−‡‡	−*	+	NA	+

Assessed using AMSTAR 2[121]; +, adequately assessed; −, inadequately assessed; ?, unclear assessment; NA, not applicable (less than 10 included studies in meta-analysis).

*Not documented or inadequately reported.

†Participant population, description of comparator interventions, and time frame for follow-up were not described or inadequately reported.

‡No summary of risk-of-bias assessment was given in the main text in the review, other than stating trials were of poor, fair, or high quality. There were some further details about bias in the discussion, but these were largely generic and did not follow the recommended Cochrane tool used to assess risk of bias in RCTs.

§A meta-analysis for all-cause death was presented but authors did not specify why meta-analyses were not conducted for other outcomes, which included at least 2 trials reporting the same comparison and outcome, other than in some parts of the discussion. For example, if viral clearance was reported in most trials, there would have been scope to have performed subgroup analyses and/or split the time point for each comparison to account for the varying duration of follow-up across trials. Instead, they gave a vote count-type narrative of the results, which did not follow synthesis without meta-analysis (SWiM) in systematic review reporting guidelines.[144]

¶There was some further details about bias in the discussion, but this was largely generic and did not follow the recommended Cochrane tool used to assess risk of bias in RCTs. Similarly, in terms of certainty/quality of the evidence, the authors used terms in a summary table that included "good," "fair," and "limited," without offering any explanation or justification.

‖Outcomes were reported but lacked definitions.

#A significant number of pertinent RCTs have not been included in the review. Given the adequate due diligence of review process, the comprehensive nature of the search strategy is questionable.

**No description of risk-of-bias assessment in any domain apart from missing outcome data but attrition rates not documented to justify judgment.

††Authors did not report data from RCTs that we obtained from various sources and some conclusions were not reflective of the observed data. It was reported that in an analysis of 4 preprint retrospective studies at high risk of bias, ivermectin was not associated with reduced mortality (logRR 0.89, 95% CI 0.09–1.70, $P = 0.04$). Although the caveat of studies being at high risk of bias and statistical heterogeneity should be added to any interpretation, it is incorrect to interpret these results as not demonstrating a potential association based on the observed result. Furthermore, the high risk of bias judgment is not adequately justified.

‡‡A sensitivity analysis was performed excluding those studies without adjustment for confounding but no details are provided. Given that there was some evidence of a potential association with ivermectin treatment and survival in 4 retrospective studies (although downplayed as no association due to concerns about attrition), it is highly implausible that any sensitivity analysis would not remove any suggestion of association.

FOI 26-3132 - Document 3

(pre- and post-exposure), and for treatment, with pregnancy a high-risk status for COVID-19.

RCTs in this review did not specifically examine use of ivermectin in the elderly, although this is a known high-risk group for severe COVID-19. In the setting of care homes, it is also notorious for rapid contagion. A standard indication for ivermectin in the elderly is scabies. We identified 2 recent reports suggesting that ivermectin may be efficacious as prevention and treatment of COVID-19 in this age group.[50,127] A letter on positive experience in 7 elder care facilities in Virginia covering 309 patients was sent to NIH[127] and has recently been submitted for publication.

There is also evidence emerging from countries where ivermectin has been implemented. For example, Peru had a very high death toll from COVID-19 early on in the pandemic.[128] Based on observational evidence, the Peruvian government approved ivermectin for use against COVID-19 in May 2020.[128] After implementation, death rates in 8 states were reduced between 64% and 91% over a two-month period.[128] Another analysis of Peruvian data from 24 states with early ivermectin deployment has reported a drop in excess deaths of 59% at 30+ days and of 75% at 45+ days.[129] However, factors such as change in behavior, social distancing, and face-mask use could have played a role in this reduction.

Other considerations related to the use of ivermectin treatment in the COVID-19 pandemic include people's values and preferences, equity implications, acceptability, and feasibility.[130] None of the identified reviews specifically discussed these criteria in relation to ivermectin. However, in health care decision making, evidence on effectiveness is seldom taken in isolation without considering these factors. Ultimately, if ivermectin is to be more widespread in its implementation, then some considerations are needed related to these decision-making criteria specified in the GRADE-DECIDE framework.[130]

There are numerous emerging ongoing clinical trials assessing ivermectin for COVID-19. The trade-off with policy and potential implementation based on evidence synthesis reviews and/or RCTs will vary considerably from country to country. Certain South American countries, Indian states, and, more recently, Slovakia and other countries in Europe have implemented its use for COVID-19.[129,131,132,133,134] A recent survey of global trends[118] documents usage worldwide. Despite ivermectin being a low-cost medication in many countries globally, the apparent shortage of economic evaluations indicates that economic evidence on ivermectin for treatment and prophylaxis of SARS-CoV-2 is currently lacking. This may impact more on LMICs that are potentially waiting for guidance from organizations like the WHO.

Given the evidence of efficacy, safety, low cost, and current death rates, ivermectin is likely to have an impact on health and economic outcomes of the pandemic across many countries. Ivermectin is not a new and experimental drug with an unknown safety profile. It is a WHO "Essential Medicine" already used in several different indications, in colossal cumulative volumes. Corticosteroids have become an accepted standard of care in COVID-19, based on a single RCT of dexamethasone.[1] If a single RCT is sufficient for the adoption of dexamethasone, then a fortiori the evidence of 2 dozen RCTs supports the adoption of ivermectin.

Ivermectin is likely to be an equitable, acceptable, and feasible global intervention against COVID-19. Health professionals should strongly consider its use, in both treatment and prophylaxis.

ACKNOWLEDGMENTS

This work was inspired by the prior literature review of Dr Pierre Kory.

The authors thank Information Specialist, Jo Platt, of the Cochrane Gynaecological, Neuro-oncology, and Orphan Cancer (CGNOC) group for designing the search strategy and running the search, as well as Anna Noel Storr for reviewing the strategy. The authors also thank Isabella Rushforth for her voluntary assistance with the preparation of the reference lists.

The authors thank Gill Gyte for detailed comments, feedback, and involvement in this review, and Michael Grayling and David Tovey for useful peer review comments before submission. The authors also thank the external peer reviewers for their helpful comments and Peter Manu for the opportunity to publish our findings.

Abstract

Ivermectin is a safe, inexpensive and effective early COVID-19 treatment validated in 20+ RCTs. Having developed combination therapies for *Helicobacter pylori*, we tested various COVID-19 combinations and describe the most effective. In 24 consecutive COVID-19 subjects with high risk features, hypoxia and untreated moderate-severe symptoms averaging 9 days, we trialed this novel combination comprising ivermectin, doxycycline, zinc, and Vitamins D and C. It was highly effective. All subjects resolved symptoms in 11 days on average, and oxygen saturation improved in 24hrs (87.4% to 93.1%, p=0.001). Hospitalizations and deaths were significantly fewer (p<0.002 or 0.05, respectively) than in background-matched controls from the CDC database. Triple combination therapy is safe and effective even in moderate-severe patients with hypoxia treated in the outpatient setting.

Trial Registration: N/A, see methods.

Keywords: SARS-CoV-2, COVID, Coronavirus, Ivermectin, Doxycycline, Zinc

Introduction

There is currently a lack of effective treatments for early or ambulatory patients with COVID-19. Patients testing positive are sent home to isolate and generally, no specific line of treatment is prescribed in this phase of the illness. However, there is growing evidence that certain repurposed drugs with good safety profiles, taken early, can significantly improve outcomes and even avoid or delay the need for immune-modulators, antiplatelet / antithrombotic therapy, and the administration of oxygen [1].

Among the most extensively studied of such COVID-19 therapeutics is ivermectin (IVM), a drug that has been used safely in 3.7 billion doses worldwide since 1987 [2-4]. Recently, Dr. Satoshi Omura, the 2015 Nobel prize co-laureate for the discovery of IVM, and colleagues comprehensively reviewed studies to date on IVM activity against COVID-19, concluding that the preponderance of the evidence demonstrated such efficacy [2]. IVM has been tested in more than 20 randomized controlled trials (RCTs) for COVID-19 treatment, with statistically highly significant clinical benefits in almost all of these and a pooled mortality reduction of 78% for the treatment vs. control groups [5]. Five such studies for IVM treatment of COVID-19 recently published in top-tier medical journals have all shown multiple clinical benefits for IVM vs. controls, most of these with high statistical significance on the order of $p < 0.002$ [6-10]. IVM is well tolerated at much greater than the standard single dose of 200 μg/kg [11,12] and has been used in RCTs for COVID-19 treatment at cumulative doses of 1,500 μg/kg [13], 1,600 μg/kg [14], and 3,000 μg/kg [15] over 4 or 5 days either without or with mild and transient adverse effects. Not surprisingly, IVM has become extensively used in the prevention and early disease management of COVID-19, particularly in non-Western countries.

medRxiv preprint doi: https://doi.org/10.1101/2021.07.06.21259924; this version posted July 7, 2021. Despite this strong evidence of clinical benefit in COVID-19 for IVM therapy, variation in therapeutic regimens especially with respect to addition of a broad spectrum antibiotic and zinc, has led to confusion as to how best to manage acute infections. Indeed, the most impressive of the early ambulatory multi-drug therapy, claiming 87% and 75% reductions in hospitalization and deaths, respectively, both with a P value of 0.001, in 869 high risk subjects, left optimal management strategy unclear due to a mixed use of IVM and hydroxychloroquine (HCQ) [16]. There is an immediate need for an effective, safe, and practically available combination therapy formulated on the basis of the best available data.

At a cellular level, IVM modulates communication between the cytoplasm and nucleus, creating a hostile environment for assemblage of virus, while at the same time reducing cytokine-mediated inflammation. In addition, IVM inhibits pathology following infection with the COVID-19 virus, by specifically blocking binding of the virus “Spike” protein to the ACE2 receptor. Finally, IVM has been associated with favorable changes in cellular innate immunity [17].

Our group has been developing antiviral drug combinations for COVID-19 and found IVM to be particularly effective as a co-therapy for use early in COVID-19 to shorten the time to symptom resolution and to prevent hospitalization. IVM used alone can at times be only partially effective but not curative [6,1,19] yet a higher dose of IVM plus azithromycin and zinc has achieved a 92% mortality reduction vs. controls [14]. Thus, we chose a combination of safe and widely available medications, approved for other indications and without drug-drug interactions or QT prolongation that inhibits intracellular virus replication and possess some anti-inflammatory properties.

FOI 26-3132 - Document 3

The use of combination therapy for intracellular bacterial infections is not new and has been used successfully to treat Tuberculosis, *Helicobacter pylori* infections, leprosy and intracellular viral infections such as *Hepatitis B & C* - where a single component of the combination therapies is rarely curative. In some viral infections e.g. HIV, even combined multiple antiviral drugs cannot completely cure but suppress the viral load perpetually. IVM is best known for its broad-spectrum efficacy for parasite infections, its high cure rate and limited drug resistance when used in combination [20]. Although useful, IVM used alone is not the 'magic bullet'. Combinations can help lower individual doses and reduce side effects. To cover all age group requirements, we combined IVM with doxycycline and zinc as active components and with Vitamins D and C as replacement 'excipients' given to supplement common clinical deficiencies in the aged.

This study reports the use of the above combination therapy in consecutive, ambulatory, complex, at times profoundly hypoxic patients whose oxygen saturation (SpO_2) was as low as 73%. Participants were treated by an experienced clinical trials team within Ventura Clinical Trials Inc..

Methods:

Subjects:

Subjects were identified from patients referred by physicians, or word-of-mouth in Los Angeles, Ventura County, CA, and other states in the USA. These patients were referred to participate in clinical trials under clinicaltrials.gov ID NCT04482686 (which is a double-blind Randomized Control Trial). However some did not qualify for this trial as their oxygen saturation was less than 90%, and were deemed too sick to enter a placebo-controlled trial. Given they were excluded and refused to go to the hospital, they were treated off-label via telemedicine, during Aug. 2020 and Feb. 2021. Subjects were given the opportunity to participate in this open label

medRxiv preprint doi: https://doi.org/10.1101/2021.07.06.21259924; this version posted July 7, 2021. trial with IRB oversight once the diagnosis was made via swab RT-qPCR testing once the diagnosis was made via swab RT-qPCR testing. Inclusion criteria were as follows 1) positive PCR for COVID-19; 2) informed consent; 3) age $\geq$ 18 years, and 4) agreement to practice two highly effective methods of birth control if of childbearing potential. Exclusion criteria included 1) allergies or drug interactions with the combination therapy components; 2) listed comorbidities, including seizure risk; and 3) pregnancy.

Treatment:

Treatment began as soon as practical, within 72 hrs. of patients presenting to Ventura Clinical Trials. All screened subjects met the inclusion criteria and were enrolled consecutively. Treatment was defined as 'IVM Combination Therapy' (ICT) and consisted of ten days of oral: Doxycycline (100mg twice a day), IVM (12mg on day 1, day 4, and day 8), Zinc (25mg twice a day), Vitamin D_3 (1500 IU twice a day) and Vitamin C (1500mg twice a day). ICT was given daily for ten days only.

Two patients (#10 and #23) received an initial treatment on day one of 36 mg IVM (rather than 12mg) due to particularly low SpO_2 or expected clinical need.

Monitoring:

Subjects self-recorded symptoms in their daily logs (supplementary 1) for the first 10 days. Electrocardiograms (EKGs), blood pressure, temperature (reported in ^0F) and SpO_2, were collected via provided medical equipment at home. On days 1, 5, 10 and 30, SARS-CoV-2 testing swabs were self-collected by subjects and sent to pathology for testing. Pregnancy tests were performed as appropriate.

FOI 26-3132 - Document 3

Endpoints:

Endpoints were 1) time from presentation to negative SARS-CoV-2 PCR; 2) time from presentation to symptom resolution; 3) progression to hospitalization; 4) patient survival.

Externally Controlled Trial (ECT) Arm:

Given the challenges for COVID-19 of enrolling high risk severely hypoxic patients in an open-label trial with an untreated control arm, our treated group arm survival was compared to the control group survival rate in the general population. This ECT, also known as a synthetic control arm, was calculated from the public CDC database of COVID-19 subjects [21]. Available information includes age range, presence of any chronic condition (COVID-19-vulnerability or otherwise, conditions not specified), date of infection, and whether the COVID-19 diagnosis was laboratory-confirmed. We used information from all subjects who met the following criteria: 1) age 50+ years; 2) laboratory-confirmed COVID-19 diagnosis; 3) death/survival, race, and sex status available and known; 4) infection prior to March 2021; and 5) subject had any co-morbidities. This synthetic control arm development was carried out after our clinical data were obtained, and so selection criteria chose the control subjects closely matched to the subjects in our study, all of whom had some underlying condition and a large majority were over 50 years of age. The CDC database was analysed using CSViewer vs. 1.3 (EasyMorph Inc, Toronto, ON, CA, http://easymorph.com).

Covidex calculations and statistics:

medRxiv preprint doi: https://doi.org/10.1101/2021.07.06.21259924; this version posted July 7, 2021. FOI 26-3132 - Document 3

Covidex and Covidex-F are ambulatory SARS-CoV-2 infection disease severity measures that we developed and validated in this study. They are weighted particularly to emphasize SpO_2, and Covidex-F includes a variable for body temperature.

Covidex score = 1 pt. (if history of sleep apnea) + 1 pt. (if history of COPD) + 1 pt. (if history of cardiovascular disease) + 1pt. (if history of asthma) + 1pt (if history of prior clots, ischemia or stroke) + 1pt (if obese, i.e. 30 kg/m^2 < BMI < 40 kg/m^2) + 2pts (if severely obese, i.e. BMI $\geq$ 40) + 1pt (if age $\geq$ 60 years) + [95-(SpO_2 as a percentage)]pts. For instance, a hypothetical patient with a history of asthma and morbid obesity with a SpO_2prior to treatment of 85% would have a Covidex score of 1 (for asthma) + 2 (for obesity) + 10 (for $SpO_2$of 85%) = 12 pts.

Covidex-F score = Covidex score + 1 pt. (if temperature on presentation between 99.5^0F and 100.4^0F) + 2 pts. (if temp on presentation between 100.4^0F and 103.5^0F) + 3 pts. (if temp on presentation $\geq$ 103.5^0F).

Best-fit lines were made to assess the correlation between Covidex scores and time from treatment to symptom resolution. Regression was carried out in Prism version 8 (GraphPad Prism software for Windows, San Diego, California USA, www.graphpad.com) using least square regression without weighting or special handling of outliers. All graphs were prepared by and statistical analysis done using GraphPad Prism version 8, and the error bar are indicative of the standard error of the mean (SEM).

Results:

Table 1 lists all subjects in the study, two of which did not consent to ICT treatment (subjects #10 and #26), and their associated race, gender, symptoms, fever, and other clinical notes. All subjects had COVID-19-related symptoms on presentation, and the symptom range was broad with several showing shortness of breath (SOB). The vast majority of subjects, 21 of 24

medRxiv preprint doi: https://doi.org/10.1101/2021.07.06.21259924; this version posted July 7, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. (87.50%), had fever on presentation with a mean temperature for all 24 subjects of 101.2 $\pm$ 0.32 ^{0}F. Specifically, 1/24 (4.17%) had low grade fever (99.5-100.4), 18/24 (75.00 %) had medium grade fever (100.5-103.4), and 2/24 (8.33%) had high grade fever ($\geq$ 103.4) ^{0}F.

Table 2 summarizes the demographics and past medical history (PMH) of subjects who consented to treatment (total n=24, 2 additional subjects who declined treatment are excluded). Notably, patients were older (a known COVID-19 vulnerability) with a mean age of 66 $\pm$ 2.75 years, and a range of 43 to 94 years (Table 2A). The population of the 24 subjects consenting to treatment (not subjects #10 and #26, Table 1) was 63% males. Death of untreated subjects #10 and #26 excluded downstream analysis in the other figures.

Table 2B lists the number of patients who had comorbidities associated with COVID-19 vulnerability, based on CDC guidelines[22]. These comorbidities are chronic kidney disease, chronic obstructive pulmonary disease (COPD), Down syndrome, cardiovascular disease, immunocompromised state including HIV, obesity (body mass index [BMI] of 30 kg/m^2 or higher but $<$ 40 kg/m^2), severe obesity (BMI $\geq$ 40 kg/m^2), pregnancy, sickle cell disease, smoking, type 2 diabetes. Of note, no subjects had cancer, Down syndrome, or sickle cell disease and none were pregnant nor were smokers.

Many subjects had multiple comorbidities associated with COVID-19 vulnerability, as outlined in Table 2B. In total, 11/24 (45.83%) subjects had COVID-19-vulnerable comorbidities of which 3 (12.50%) had 2 separate comorbidities, and 2 (8.33%) had 3 co-morbidities.

A minority of subjects (n = 7) had other COVID-19 treatment(s) prior to and/or during ICT administration, namely Remdesivir (n = 1 subject), involvement in a placebo-controlled trials of HAZDpaC (n = 4 subjects, trial clinicaltrials.gov NCT04334512; may have been given treatment or placebo) and hydroxychloroquine (HCQ, n = 3 subjects).

FOI 26-3132 - Document 3

Fig. 1 demonstrates all subjects recovered from COVID-19, typically within one to two weeks. Fig. 1A shows various durations for each subject and average values (one outlier excluded). Time from onset of symptoms to treatment initiation is shown in column 1 and averages 9.2 $\pm$ 2.1 days. Time from start of treatment to symptom resolution was11.6 $\pm$ 1.4 days. Time from first positive to first negative PCR was 16.9 $\pm$ 1.6 days and is less than three weeks. Time from start of treatment to first negative PCR was 11.5 $\pm$ 1.6 days and is also less than three weeks.

Fig. 1B shows that 100% of subjects survived COVID-19, without need for hospitalization or ventilator use. As noted in Table 2, many of these subjects were older and with comorbidities. When compared to the synthetic control arm, derived from the CDC database (see methods, and as follows), this was a significant increase in survival rate (p = 0.044) and decrease in hospitalization rate (p = 0.0011), evaluated via χ^2 test. Of note, the patients in this CDC database likely did receive treatment, of an unknown nature. Thus, the survival rate of this synthetic control reflects the "typical" survival rate in the USA, which is significantly less than the 100% survival rate observed on ICT.

The 100% survival rate on ICT was compared with survival rates from the CDC database of COVID-19 subjects. 356,424 control subjects were obtained, based on qualification criteria described in the methods section. These criteria focused on older subjects (50+ years), similar to our study population, that also had underlying conditions. One should note that the underlying condition criteria information available in this database refers to chronic conditions of any type, whether or not the condition induces COVID-19-vulnerability. With this definition, 100% of control subjects and ICT-treated subjects had underlying conditions of any type.

Our critical finding in Fig. 2 (see also Table 2), showed that 23/24 patients were hypoxic with SpO_2 < 90%. Some subjects consenting to treatment had SpO_2 as low as 73%, 77%, 84% and

medRxiv preprint doi: https://doi.org/10.1101/2021.07.06.21259924; this version posted July 7, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

85% on presentation. As a whole, shown in Fig. 2A, the SpO_2 of subjects was significantly less than 95%, the defined point of cure (95% CI of mean SpO_2= 85.5 to 89.4, Mean = 87.4 $\pm$ 0.93%). Subjects' SpO_2 increased within 24 hrs. of treatment. Their mean SpO_2 before treatment (for subjects with data before and after 24 hrs.) was 86.5% $\pm$ 1.3, and after 24 hrs. of treatment, 93.1% $\pm$ 0.63, a highly significant and rapid increase ($p < 0.001$). SpO_2 then continued to rise. Treatment continued for 10 days reaching the point of successful treatment or cure, which was $SpO_2 > 95\%$. Successful treatment was reached for all subjects. That is, there was a 100% restoration rate in terms of SpO_2. No patient who accepted treatment required hospitalization.

Two subjects (#10 and #26) declined treatment. These subjects did not recover SpO_2 and died from COVID-19 infection. An adverse drug event of dizziness was reported by one subject, who nevertheless continued with treatment successfully otherwise.

Fig. 3 shows the validation of the Covidex and Covidex-F scores we developed, defined in our methods. These scores provide an index of COVID-19 predicted severity, based on past medical history, O_2 just before treatment and fever grade on presentation. The mean Covidex score was 10.34 $\pm$ 1.08 and the mean Covidex-F score was 11.63 $\pm$ 1.13, with 87% and 85% of the score points, respectively, coming from the contribution of the SpO_2 term. In other words, approximately 80 to 90 % of this score is weighted towards SpO_2. It should also be noted, the PMH aspects that contribute to this score emphasize respiratory, cardiovascular, and obesity histories and differ from CDC defined COVID-19-vulnerabilities.

Covidex and Covidex-F are both plotted vs. time from treatment to symptom resolution. Both shows statistically significant correlations (Covidex: $p = 0.0096$, $r^2 = 0.2078$; Covidex-F: $p = 0.0288$, $r^2 = 0.2790$), indicating that either Covidex or Covidex-F is associated with and may predict time to symptom resolution.

Discussion:

We report for the first time a highly effective ICT which led to 100% survival and cure in unselected ambulatory 'moderate to severely' ill COVID-19 patients with hypoxia managed as outpatients. Given our experience developing combination therapies for *H. pylori*, we trialed a number of different IVM-based combinations on ambulatory COVID-19 patients, searching for a cure, and found the above combination to be the best as a 'foundation therapy' for COVID 19. Understanding that a personalized approach may require added HCQ or other components in some patients much like *H.pylori* resistant to triple therapy sometimes requires quadruple therapy. Hypoxia is a demonstrated predictor of COVID-19 mortality [23]. For example, several of these patients had profound hypoxia, measured by oximetry, at 73%, 77%, 84% and 85% on presentation. Despite a symptom to treatment delay of 9.2 days, our treatment brought rapid improvement – beginning in some within 12 hrs. with a mean SpO_2 rising from 86.5 to 93.1 in the first 24 hrs. There was a parallel improvement in the symptoms including loss of cough, fever and tiredness. Also, the time from the start of treatment to the first negative PCR averaged 11.5 $\pm$ 1.6 days. Generally, such ill patients would have been admitted to the hospital, yet all those treated with the ICT avoided hospitalization and none died.

Turning to the ECT 'synthetic control arm' it is clear that the ICT was statistically superior to the control arm even though a small patient group was reported. The very low adverse effects from reported studies and this treatment group supports the use of ICT if clinical symptoms and risk factors for COVID-19 progression are present, even in cases with PCR pending results. ECT

arms are now increasingly used, especially where the control arm or 'standard-of-care' arm may have a fatal outcome[24].

The rationale for using combination antiviral therapy is based on our growing understanding that intracellular infections – bacterial or viral, cannot be reliably cured using a single drug. It is also based on our knowledge that IVM resistance is common. Hence, there is no single 'silver bullet' for COVID-19, and the indiscriminate use of IVM *alone* could induce COVID-19 resistance by generating drug-resistant strains. Resistance to IVM was the case when used alone in scabies, nematodes, strongyloidiasis, microfilaridermias, onchocerca and volvulus [19,25-31]. We are now seeing resistance develop even in combined therapies using two antibiotics for *H. pylori*. This teaches us to use IVM in COVID-19 only in combination therapies, especially so, with growing reports of mutant strains resulting in vaccine breakthrough infections [32]. Hence, the proposed combination therapy was developed to induce *cure* more rapidly, *prevent* resistance, and *overcome mutant strain* emergence - no replication no mutation.

Regarding strategies in the development of combination therapies, intracellular coronavirus replication requires several active drugs to inhibit viral replication. IVM, doxycycline and zinc all individually inhibit coronavirus replication and, although there are other candidates, we have proposed the above combination based on efficacy, component safety profiles, inexpensive nature, and lack of drug-drug interaction. The combination of IVM and doxycycline has also been demonstrated to act in synergy against COVID-19 [33]. This combination also appears to overcome the need for high doses of IVM identified by Caly and colleagues when used alone[34]. Further, given that zinc plays a key role in antiviral activity [34536] it would combine well with the ionophores (IVM and doxycycline) to increase its intracellular concentration and expedite viral clearance [37]. We have also assessed drug-drug interactions and found that the

medRxiv preprint doi: https://doi.org/10.1101/2021.07.06.21259924; this version posted July 7, 2021. combination of zinc with IVM and doxycycline has no reported interactions. Additionally, each of these drugs has a low adverse side effects profile and no QT prolongation as reported with azithromycin.

Overall, based on the current literature, a 10-day combination therapy of IVM, doxycycline and zinc will not only improve symptoms [6,7] but also accelerate recovery from COVID-19. We have chosen a safe IVM dosage approved for parasites of 36mg over 10 days, and this dose has been shown to be both effective and safe in COVID-19 treatments [38]. The staggered IVM dosage over 10 days is proposed based on the half-life clearance of the drug in plasma (up to 66 hrs.)[39]. The proposed duration would allow constant availability of adequate plasma level IVM to facilitate zinc entry into the cells. Hence, the above rationale explains why some publications have already shown that IVM alone is not adequate to cure COVID-19 [6,18,19] while a multidrug regimen is likely to be more efficacious [40].

While underpowered, this study enrolled *consecutive subjects* into study and did not bias subject selection from different time points. Many of the enrolled subjects were profoundly ill with subjective assessments that may have resulted in hospital admission and/or intubation. Yet, ICT anti-viral activity appears to have rapidly restored SpO_2 and reversed other symptoms which could not be explained simply by the developing immunity.

A weakness of this study is the lack of a concomitantly enrolled control arm. However, given the potential fatal outcomes Tess Lawrie et al. indicated [41] *'it is no longer ethical to approve the use of a control arm as so many profoundly ill patients in the control arm would die'*, as did our two subjects who declined treatment [42]. Hence our study has made use of the ECT or 'synthetic' control arm which has enabled us to make matched age and comorbidity comparisons. Institutional Review Boards should now include the provision to include available

synthetic arms and reject trials that include in a COVID-19 trial a control arm as published by Lawrie[41].

This study builds on an extensive literature, to provide a practical inexpensive, safe, readily available and highly effective triple therapy aiming to prevent resistance and one that can confidently be used as a routine treatment for outpatient COVID-19.

Figure and table legends:

Table 1: Listing of subjects and COVID-associated symptoms on presentation and other characteristics. O_2% Sat = SpO_2 just before time of treatment initiation. O_2% Sat post 24 hrs. = SpO_2 24 hrs. after treatment initiation. Rx Start date = Day 1 of ICT administration. SOB = Shortness of Breath

Table 2. A. Age and demographics of subjects. B. Prevalence of COVID susceptible co-morbidities. C. Number of concurrent comorbidities in subjects.

Figure 1: Complete recovery was seen in all patients within 1 to 3 weeks.
A. Time in days to various stages of symptom onset and resolution.
Nearly all subjects resolved symptoms and became PCR negative in 3 weeks
Col 1: Symptom onset to start of treatment (n = 23, mean = 9.17 $\pm$ 2.05)
Col 2: Start of treatment to resolution of symptoms. (n = 23, mean = 11.61 $\pm$ 1.38)
Col 3: First PCR positive to first PCR negative (n = 10, mean = 16.90 $\pm$ 1.58)
Col 4: Start of treatment to first PCR negative (n =10, mean = 11.50 $\pm$ 1.60)
B. Top, 100% survival rate was seen in patients, which is significantly higher ($p = 0.044$ via χ^2 test) than synthetic control from CDC database of equivalent or less COVID-vulnerable subjects. Bottom, No (0%) patients required hospitalization, which is significantly less ($p = 0.0011$ via χ^2 test) than synthetic control from database.

Figure 2. A. O_2 saturation prior to treatment was significantly ($p < 0.05$) less than 95%, the defined successful treatment reached by all subjects. B. O_2 saturation significantly increased in subjects 24 hours after treatment (paired *t*-test, $p < 0.001$, only subjects with data before and after treatment included). O_2 saturation continued to rise, and until the defined cure of greater than 95% O_2 saturation.

Figure 3: Ambulatory COVID scores, Covidex and Covidex-F (see methods for definition; Covidex-F includes fever measure) vs. time from start of treatment to symptom resolution. There

Safety and efficacy of a MEURI Program for the use of high dose ivermectin in COVID-19 patients

Short Title: A MEURI Program with ivermectin for COVID-19

Abstract

Background

In the absence of antiviral alternatives, interventions under research for COVID-19 might be offered following guidelines from WHO for monitored emergency use of unregistered and experimental interventions (MEURI). Ivermectin is among several drugs explored for its role against SARS-CoV-2, with a well-known safety profile but conflicting data regarding clinical utility for COVID-19. The aim of this report is to inform on the results of a MEURI Program of high-dose ivermectin in COVID-19 carried out by the Ministry of Health of the Province of La Pampa, Argentina.

Methods

COVID-19 subjects, within 5 days of symptoms onset were invited to participate in the program, which consisted in the administration of ivermectin 0.6 mg/kg/day for 5 days plus standard of care. Active pharmacosurveillance was performed for 21 days, and hepatic laboratory assessments were performed in a subset of patients. Frequency of Intensive Care Unit (ICU) admission and COVID-19-related mortality of subjects in the ivermectin intention to treat group were compared with that observed in inhabitants of the same province during the same period not participating in the program.

Results

From 21232 subjects with COVID-19, 3266 were offered and agreed to participate in the ivermectin program and 17966 did not and were considered as controls. A total of 567 participants reported 819 adverse events (AEs); 3.13% discontinued ivermectin due to adverse. ICU admission was significantly lower in the ivermectin group

compared to controls among participants ≥40 year-old (1.2% vs 2.0, odds ratio 0.608; p=0.024). Similarly, mortality was lower in the ivermectin group in the full group analysis (1.5% vs 2.1%, odds ratio 0.720; p=0.029), as well as in subjects ≥ 40 year-old (2.7% vs 4.1%, odds ratio 0,655; p=0.005).

Conclusion

This report highlights the safety and possible efficacy of high dose ivermectin as a potentially useful intervention deserving public health-based consideration for COVID-19 patients.

Introduction

COVID-19 constitutes a public health emergency at a global scale since its appearance in Wuhan, China, in December 2019 (1). By August 2021, over 200 million cases and 4 million deaths have been reported worldwide (2). Vaccine rollout campaigns, which currently offer the best hopes for pandemic control, are a key targeted pharmacologic intervention for containment of disease spread and impact on the incidence of severe cases (3,4).

Despite having an asymptomatic or mild course in most cases, COVID-19 constitutes a significant burden on health systems unprepared to cope with outbreaks requiring, among other things, massive testing capacity for rapid case detection and isolation, expansion of intensive care unit (ICU) capacity and case management guidelines for a previously unknown pathogen. This public health crisis has been, and still is, more profound in countries with weaker health systems (5).

The unprecedented progress in vaccine development has not been matched by the development of antiviral molecules, either new or repurposed, that could contribute to the treatment or prevention of COVID-19. With convalescent plasma, monoclonal antibodies, hydroxychloroquine and antiretrovirals among many molecules tested in-vitro and in observational and clinical trials, different treatment guidelines only agree in the use of corticosteroids, thromboprofilaxis and respiratory support, none of them an antiviral, in their recommendations (6,7).

Ivermectin (IVM) is an endectocide drug widely used for the treatment and control of onchocerciasis and lymphatic filariasis through mass drug administration programs, which has a wide therapeutic index and a benign safety profile (8,9). Besides its known

uses, it has been evaluated as an antiviral, demonstrating in vitro activity against zika, rabies and dengue among other viruses (10). In the case of dengue, a recently published randomized clinical trial from Thailand showed positive although inconclusive results (11). For SARS-CoV-2, early on the pandemic, the report of the antiviral activity of IVM in Vero cells cultures sparked widespread interest in the potential utility of this oral, safe and affordable drug against COVID-19 (12). However, after over a year of several publications addressing this question, there is a lack of clear evidence for or against the use of IVM in COVID-19 patients (6,13). With at least two completed double-blind randomized clinical trials (RCTs) showing no effect in clinical endpoints, other smaller randomized trials using higher doses identified significant antiviral effects (14–18). That undefined landscape is summarized by the current NIH COVID-19 treatment Guidelines stating that there is insufficient data to recommend either for or against the use of IVM in COVID-19 patients (6).

In 2016, the World Health Organization (WHO) issued the Guidance for Managing Ethical Issues in Infectious Diseases Outbreaks, with the aim of complementing existing guidance on ethics in public health in situations of great uncertainty and including recommendations for the use of unproven interventions outside clinical trials, which based on a WHO response developed in the context of the outbreak of Ebola Virus Disease in Western Africa in 2014 are called “monitored emergency use of unregistered and experimental interventions” (MEURI) (19). These interventions apply when no proven effective treatments exist, it is not possible to initiate clinical trials immediately, existing preliminary data supports the intervention, relevant regulatory, ethical and scientific authorities approve such use, resources are available to minimize risks and patient´s informed consent is obtained. Proper monitoring and timely sharing

of the results with the wider medical and scientific community are also requirements to MEURI activities.

The aim of this report is to inform about the satisfactory safety and efficacy results of a MEURI Program for the use of high dose IVM in COVID-19 patients, carried out by the Ministry of Health of the Province of La Pampa, in the Patagonian region of Argentina.

Methods

MEURI Program for the use of high dose IVM in COVID-19 patients.

By the end of January 2021, the Ministry of Health of the Province of La Pampa (Argentina) authorized the implementation of a MEURI program based on the use of high dose IVM in COVID-19 adult patients (older than 18 year-old). In order to be able to participate, subjects had to be able to provide written informed consent, have a confirmed diagnosis of COVID-19 infection (by means of RT-PCR or antigen test) and symptoms onset within 5 days before entering the program. Exclusion criteria included pregnancy, breast feeding, hypersensitivity to IVM or acute allergic states, and active use of warfarin. Women with child-bearing potential were eligible if they were taking effective contraceptive measures before entering the program and agreed to continue with these measures for at least 30 days after receiving the last dose of IVM. Meanwhile ambulatory and inpatient subjects were allowed to participate (as long as they accomplished all inclusion criteria and had no exclusion criteria), admission to

ICU was considered an exclusion criteria. Every member of the health staff of the Province of La Pampa was instructed to invite to participate in the program to every COVID-19 patient identified within the first five days of symptoms onset. However, participation in the program was voluntary, and physicians could decide not to include subjects in the program based on their medical criteria.

Ethical approval was obtained from the Provincial Ethics Committee of La Pampa, and participating individuals provided written informed consent.

Intervention

Participants were evaluated at program entry with complete medical history and a brief physical exam. At the beginning of the program, safety laboratory assessments before and at the end of treatment were mandatory. However, after a preliminary safety analysis that triggered an amendment approved by the Ethics Committee, these assessments were no longer mandatory and could be performed or not, based on medical judgment.

Patients received oral treatment with IVM for 5 consecutive days within 30 minutes of food ingestion, preferentially of high fat content, at approximately 24 h intervals. IVM 6 mg, 9 mg and 18 mg tablets were used, combined to in all cases at a dose of 0.6 mg/kg/day based on baseline weight rounding to the lower full (6 mg) dose. There were no specific guidelines regarding medical management of COVID-19 infection for the participants in the IVM program, which was the same as for the rest of the population.

Safety Assessment

Active pharmacosurveillance was performed during the first 21 days after treatment start by means of the completion of a follow up chart, and safety assessment was based in all subjects that participated in the program in which follow up safety data was reported.

Hepatic safety assessment

Hepatic safety assessment was based on the analysis of hepatic lab exams performed before and after IVM treatment in a subset of patients, and consisted of laboratory determinations of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP) and total bilirubin levels. Drug induced liver injury was defined according to the Latin American Association for Study of the liver definition, that includes (i) ALT elevation ≥5 ULN, (ii) ALP elevation ≥2 ULN (in the absence of known bone pathology driving the increase in ALP level) or (iii) ALT ≥3 ULN and simultaneous elevation of total bilirubin concentration above 2 ULN (20).

Efficacy analysis

In order to estimate the efficacy of the implementation of the program, the clinical evolution of the subjects in the IVM intention to treat (ITT) group was compared with that observed in inhabitants of the same province during the same analyzed period (from January 20, 2021 to May 20 2021) who did not participate in the program (control group, C). To identify them, the analysis of the National Health Surveillance System (SNVS 2.0) was used, which records, among other events, the notification of COVID-19 cases, their clinical and demographic characteristics and the respective laboratory studies, in a mandatory, nominal and immediate way, according to a national regulation.

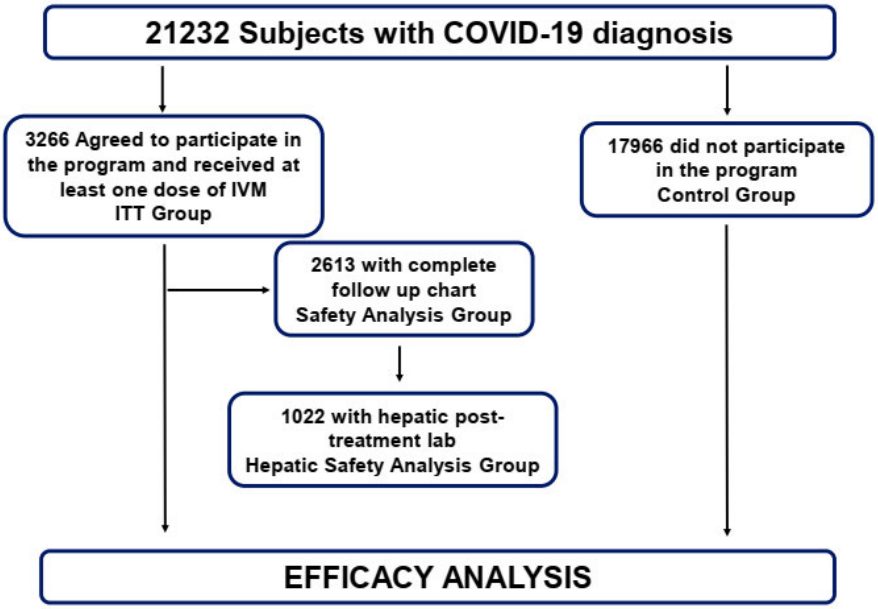
Given that the registration methodology differs between the one used in the IVM-monitored intervention program and the one used for registering subjects and events in SNVS 2.0 database, it was decided to consider variables not dependent on the registration method in the system for the efficacy analysis. Specifically, the primary objectives of the evaluation were the analysis of the impact of the program on the frequency of ICU admission and COVID-19-related death. It should be noted that both ICU admission and death registration is carried out centrally, so their identification is independent of the type of follow-up carried out.

In order to compare the clinical course of both groups, subjects under 18 years of age and pregnant women were excluded from the analysis.

In the univariate efficacy analysis, subgroup analysis was performed according to age group (subjects ≥ 18 year old -whole sample- or subjects ≥ 40 year old), immunization status (excluding subjects with at least one vaccine dose) and mean IVM prescribed dose.

Statistical analysis-

Baseline characteristics of the two groups (C and IVM) were compared by means of Student`s T- test and Chi square. The clinical evolution was evaluated by Chi square Test and logistic regression analysis. Whenever possible, number needed to treat (NNT) values for IVM were estimated for the end points of ICU admission and death. The NNT values were estimated as the inverse of the difference in estimated absolute risk between control and IVM groups. In all cases, p-values <0.05 were considered statistically significant. All analysis were performed with GraphPad Prism version 9.1.0 for Windows (La Jolla, California).).



Results

Recruitment

A total of 21232 non-pregnant adults were identified as COVID-19 positive between Jan 20 2021 and May 20 2021. Of these, 3266 agreed to participate in the program and received at least one dose of IVM, and were included in the ITT analysis group. A group of 17966 subjects that did not participate in the program were included in the C group. Descriptive characteristics of the population are presented in Table 1.

Safety follow up data was obtained from 2613 subjects that participated in the program and were included in the Safety Analysis Group. Of these, 1022 were followed with post-treatment hepatic lab exams, and were included in the Hepatic Safety Analysis group (Fig 1).

Safety Analysis

A total of 2613 participants were included in the safety assessment. Five hundred sixty seven (567) participants reported 819 adverse events (AEs). Eighty-two subjects (3.13

239 %) discontinued IVM due to adverse events and all AEs resolved after treatment
240 discontinuation. The most common AEs were diarrhea, followed by visual disorders,
241 dizziness, abdominal pain, headache and nausea (Table 2). Although many of the
242 symptoms presented during treatment resemble COVID, they were all assumed to be
243 related to IVM treatment.

244

245 **Table 2.** Safety analysis among subjects receiving ivermectin (n 2613). The table
246 shows adverse events reported in more than 0.5% of subjects

.ADVERSE EVENT	N (%)
Diarrhea	**155 (5.93%)**

Pruritus	**14 (0.53%)**
Insomnia	**14 (0.53%)**
Drowsiness	**14 (0.53%)**

Hepatic safety analysis

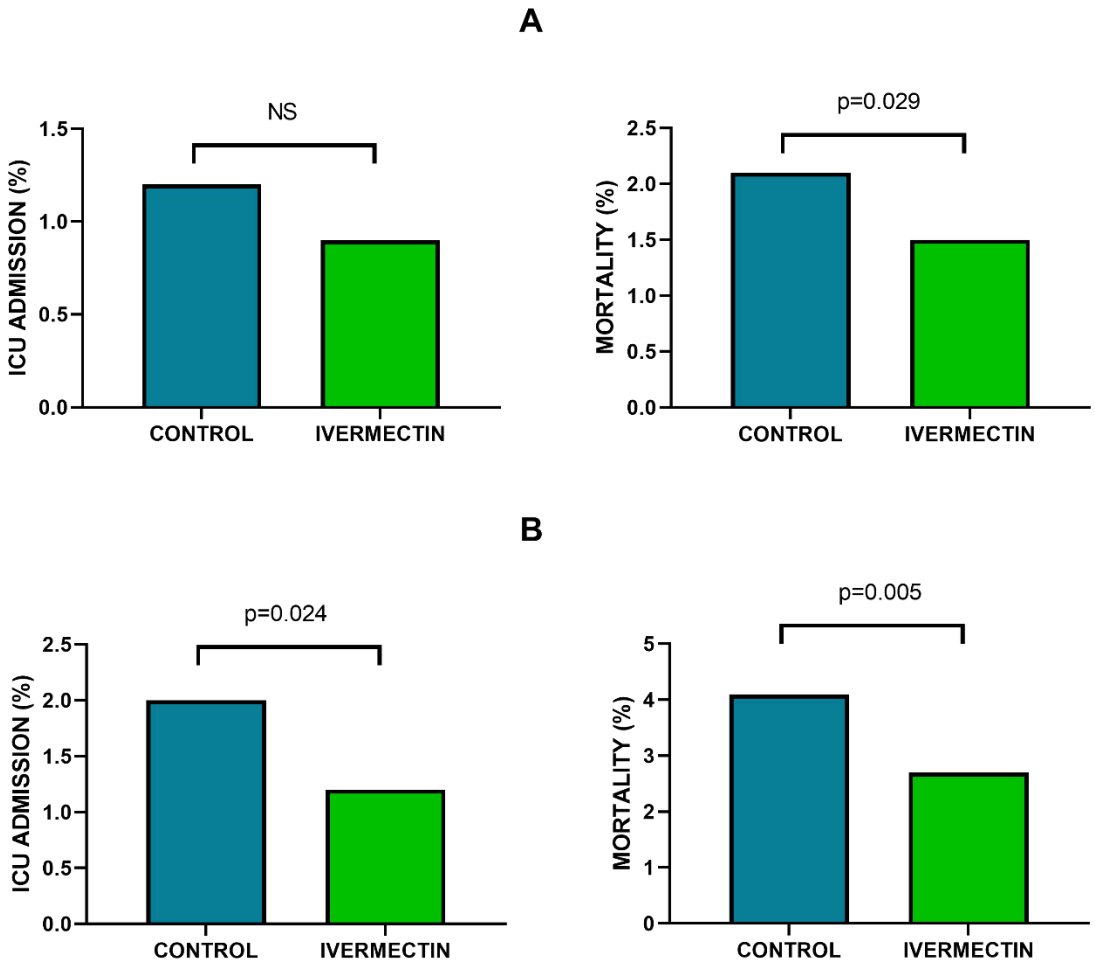
Although there was a small but statistically significant increase in ALT, AST and total bilirubin values after IVM treatment (Table 3), among 1022 subjects that were followed up with laboratory determinations after IVM treatment, only one presented liver enzyme values compatible with low grade drug induced liver injury, that lead to drug discontinuation on day 4 of treatment. According to medical records, this subject had

abnormal baseline ALT and AST values (AST 240 U/l, ALT 375 U/l, Total Bilirrubin 0,63 mg/dl and the values peaked to AST 366 U/l ALT 630 U/l total bilirrubin 0.8 mg/dl and returned to AST 111 U/l, ALT 214 U/l and total bilirrubin 0.62 mg/dl. Considering the total hepatic safety sample (n=1022), this represents an incidence of 0.98/1000 treated subjects.

Table 3. Hepatic safety analysis.

VARIABLE	PRE-TREATMENT	POST-TREATMENT
AST (n=1000)	34.07±29.59 U/l	36.15±31.35 U/l **
ALT (n=988)	25.67±14.93 U/l	27.61±25.07 U/l **
Total bilirrubin (N=966)	0.44±0.24 mg/dl	0.47±0.24 mg/dl **
Alkaline phosphatase (n=1000)	146.32±77.27 U/l	120.60±93.33 U/l **

** $p < 0.001$ vs pre-treatment values.



Program´s efficacy

In order to evaluate the program´s efficacy, the clinical evolution of subjects in the IVM-ITT analysis group (n= 3266) was compared with 17966 subjects that did not participate in the program (C group).

In the whole sample analysis, there was a non-significant tendency towards lower ICU admission in the IVM-ITT group compared with C (0.9% vs 1.2%, odds ratio 0.738) (95% CI 0.497-1.097, NNT 333, NS). Mortality rate was significantly lower in the IVM-ITT group (1.5% vs 2.1%) with an odds ratio of 0.720 (95% CI 0.535-0.969, NNT 172, (p=0.029) (Fig 2 A).

Regarding clinical evolution of subjects ≥ 40 year old (C n= 9022; IVM-ITT n=1851), ICU admission was significantly lower (1.2% vs 2.0, with an odds ratio of 0.608 (95% CI 0.393-0.940), NNT 128, (p=0.024). Mortality rate was significantly lower (2.7% vs 4.1%, with an odds ratio of 0.655 (95% CI 0.485-0.884), NNT 74, (p=0.005) (Fig 2 B).

Fig 2. ICU admission and mortality in IVM-ITT and C groups. Fig 2A: Analysis of all subjects ≥18 year-old (C n= 17966; IVM-ITT n=3266); Fig 2B: Analysis of all subjects ≥40 year-old (C n= 9022; IVM-ITT n=1851).

In the analysis of all non-immunized subjects (C: n= 16226; IVM: n=2936), there was a non-significant tendency towards lower ICU admission in the IVM-ITT group compared with C (0.7% VS 1.1%, odds ratio 0.639 (95% CI 0.406-1.005, NNT 250; p=0.051). Mortality rate was significantly lower in the IVM-ITT group (1.1% vs 1.7%, with an odds ratio of 0.628 (95% CI 0.434-0.907, NNT 158; p=0.012).

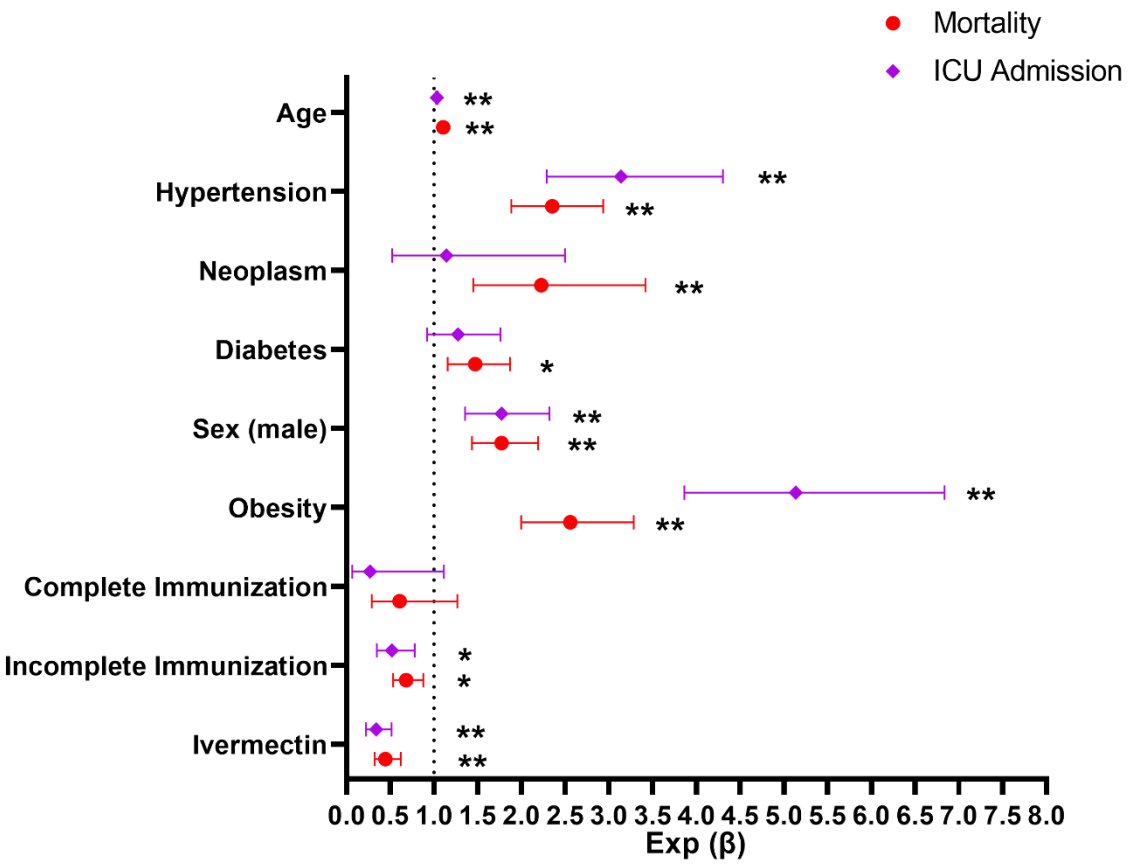
Regarding clinical evolution of non-immunized subjects ≥ 40 year old (C n=7463 and IVM-ITT n=1556), ICU admission was significantly lower (1.0% vs 2.1%, with an odds

ratio of 0.487 (95% CI 0.290-0.816, NNT 95;p=0.005). Mortality rate was significantly lower (2.1% vs 3.6%), with an odds ratio of 0.566 (95% CI 0.391-0.820, NNT 66;p=0.002).

A total of 2895 subjects in the IVM group had complete data regarding weight-based ivermectin dose information (of 3266 subjects assigned to IVM, 146 had missing data regarding the prescribed dose, and 335 had missing body weight data).

Mean IVM prescribed dose was 44.15±11.83 mg/day, mean IVM prescribed dose per kg of body weight was 0.54±0,09 mg/kg/day . Based on these values, two IVM groups were created: Low-dose IVM (with prescribed dose lower than 0.54 mg/kg/day, n=1157) and High-dose IVM (with a prescribed dose equal or higher than 0.54 mg/kg/day, n=1738). No significant differences were observed between groups regarding descriptive characteristics (age, gender, immunization status and comorbidities; data not shown).

In the whole sample analysis of High-dose IVM vs Low-dose IVM, there was a non-significant tendency towards lower ICU admission in the IVM-ITT group compared with C (0.6% vs 1.2%), with an odds ratio of 0.472 (95% CI 0.209-1.067; p=0.065). There were no significant differences in mortality rate (1.2 vs 1.6%) -odds ratio of 0.733 (95% CI 0.392-1.369;NS).



Regarding clinical evolution of subjects with an age of ≥ 40 year old (Low-dose IVM n=645 and High-dose IVM n=1016, there was a non significant tendency towards lower ICU admission in the High-dose IVM group (0.8% VS 1.7%)-with an odds ratio of 0.457 (95% CI 0.183-1.143;p=0.086). There were no significant differences in mortality rate (2.1% VS 2.9%) -odds ratio of 0.695 (95% CI 0.371-1.304;NS).

In the analysis of all subjects receiving High-dose IVM (n= 1738) vs C (n=17966), ICU admission was significantly lower in the High-dose IVM group compared with C (0.6% vs 1.2%), with an odds ratio of 0.494 (95% CI 0.261-0.934), NNT 172, (p=0.027). Similarly, mortality rate was lower in the High-dose IVM group compared with C (1.2 vs 2.1%) -odds ratio of 0.566 (95% CI 0.364-0.881, NNT 111;p=0.01).

Regarding clinical evolution of subjects with an age of ≥ 40 year old (C n=9212; IVM-ITT n=1016), ICU admission was significantly lower in the High-dose IVM group compared with C (0.8% vs 2.0%), with an odds ratio of 0.383 (95% CI 0.188-0.780, NNT 81;p=0.006). Similarly, mortality rate was lower in the High-dose IVM group compared with C (2.1 vs 4.1%) -odds ratio of 0.498 (95% CI 0.319-0.776, NNT 50; p=0.002).

The logistic regression analysis was performed after adjusting for sex, age, immunization status and comorbidities, and IVM treatment remained negatively associated with ICU admission rate and mortality rate (Fig 3).

Fig 3. ICU admission and mortality in patients receiving ivermectin within MEURI program vs Control after controlling for other variables by multiple logistic regression analysis. Age was considered as a continuous variable. Subjects were considered immunized after 14 days of their last vaccine dose. ** p<0.001; * p<0.01.

Discussion

This report of a monitored intervention program with ivermectin in COVID-19 patients provides observational data on a significant number of adult patients that through the incorporation of clinical and demographic data from a large number of patients from the same province and period but not participating in the program (control group) allowed a comparison and analysis of hard clinical endpoints as are admission to ICU

348 and death. This comparison provides results that suggest a significant positive clinical
349 impact of this intervention that, in the context of a lack of proven antiviral alternative
350 treatments for ambulatory patients against COVID-19, the safety, availability and
351 affordability of IVM and the growing concerns on vaccine efficacy against emerging
352 variants of SARS-CoV-2, deserves consideration as a potential tool for case
353 management.

354 The approach taken in the Province of La Pampa for the use of IVM through a MEURI
355 Program supported and leaded by the provincial Ministry of Health was based on
356 preliminary but inconclusive data on efficacy and a more solid reference base on the
357 safety of the drug, even at higher doses than those approved for other indications in
358 Argentina, as strongyloidiasis and scabies (21). With the incorporation of over three
359 thousand cases that completed treatment and follow up, including 1022 with clinical
360 laboratory monitoring, this intervention program contributes the largest analysis on the
361 safety of high dose ivermectin at a regimen of 600 µg/kg/day for 5 consecutive days.
362 This regimen was selected based on a proof-of-concept trial that identified a significant
363 antiviral activity against SARS-CoV-2 in a subgroup of participant who achieved high
364 IVM median plasma concentrations without any significant safety issues (16). In view
365 of that seemingly dose response antiviral effect, participants of our program were
366 advised to ingest the daily doses of IVM after a meal with adequate fat content in view
367 of the lipophilic nature of IVM (12,22) . The favorable safety profile of this regimen of
368 high dose IVM in a setting with conditions for high oral bioavailability confirms prior
369 communications with smaller sample sizes, on the safety of these regimens and allows
370 to focus in exploring the clinical efficacy of these regimens for a variety of clinical
371 indications for which IVM is in pre-clinical and clinical development as a repurposed
372 drug including COVID-19, dengue, trichuriasis and malaria. The finding of a single

case of clinically significant increase in liver enzymes, in an individual with baseline abnormal values highlights these clinical and laboratory findings and provides evidence for the design of simplified MEURI Programs, should they be considered appropriate.

The controversial findings around the efficacy of IVM in COVID-19 is currently preventing from making firm recommendations to clinicians. The situation is worsened by confusing messages through social and traditional media plus articles from peer-reviewed journals that are published and afterwards retracted as well as the uncontrolled use of medical and veterinary products by the population (23). Meta-analyses that included studies with a variety of regimens have reached different interpretations and conclusions, preventing the achievement of consistent findings (13,24–26). In this context, a MEURI Program appears as the mean to attempt monitored and controlled use of a treatment not approved for the indication but with preliminary results of adequate safety and potential efficacy. While the impossibility to perform clinical trials was not an absolute situation at the time of the design of our Program, the means and capacities of a provincial Ministry of Health were beyond the scope and resources available.

The role of IVM against SARS-CoV-2 is supported by the biologic plausibility based on in vitro and in vivo studies of mechanistic analyses and antiviral effects. Its proposed antiviral mechanism is thought to be mediated by its ability to inhibit the nuclear import of viral proteins mediated by IMPa/b1 heterodimer, and the promotion of defense mechanisms such as pyroptosis in infected epithelial cells, suggesting its possible role as a broad spectrum antiviral agent (27). These proposed effects might explain the antiviral activity against SARS-CoV-2 reported by our group and Biber et

al, in two small randomized controled trials (16,18). However, randomized clinical trials published on this topic have shown a lack of efficacy regarding clinical outcomes. Lopez Medina et al. reported on the failure to show a significant effect of 300 µg/kg of IVM for 5 consecutive days versus placebo in symptom´s resolution among 400 patients with mild disease recruited during the first week of COVID-19 in a single center in Colombia (14). This trial, that was originally designed to demonstrate improvement of 2 points in WHO Ordinary Scale but suffered from fewer than estimated events, included a population with a median age of 37 year-old and administered IVM on an empty stomach, as indicated by the manufacturer, which probably prevented from maximizing oral biovailability of this highly lipophilic drug. In the study from Vallejos et al. in Argentina (15), 501 patients with mild early COVID-19 infection were randomized to receive placebo or IVM for two consecutive days at up to 200 µg/kg (the currently approved dose for other indications). Neither hospitalization (primary outcome) nor other secondary outcomes including polymerase chain reaction test negativity and safety outcomes showed statistically significant differences between groups in this population with fewer events than estimated a priori and a mean age of 42 year-old (SD ± 15.5).

The seemingly contrasting efficacy results between our analysis of an intervention program versus the double-blind, placebo-controlled RCTs might not be discordant at closer look with reasons laying in several factors pertaining to IVM regimens, population size and outcomes; but potential bias in our results is another possibility to be considered and explored. The IVM regimen used in our program provided a higher total exposure to the drug through a higher dose per day, longer treatment (compared to the trial by Vallejos) and administration with food, which while equally safe might have allowed reaching drug levels at the relevant tissues above the threshold required

for an antiviral activity resulting in better clinical outcomes. This postulated dose effect has been observed in other studies and the high levels achieved in lungs and nasopharingeal mucosa were seen in an animal model (28). In terms of the populations included in the analyses, it is relevant to consider that both RCTs reached fewer primary endpoints than estimated for the sample size calculation; notwithstanding those potential limitations, which might have been affected by the age of the population recruited to those trials, neither adjustments nor secondary outcomes identified any significant clinical findings. Despite sound trial methodology, failure to demonstrate the effect of an intervention might reside in contextual elements as is the recruitment of subjects at very low risk of achieving the primary outcome regardless of the use of an intervention (29,30), as might have been the case in both RCTs as well as our observational analysis, which due to the significantly larger population size, was able to identify a statistically significant treatment effect in admission to ICU and death in restricting the analysis to those >40 year-old.

Statistically significant differences in observational studies should be viewed with caution since the clinical and public health relevance of those results might not be judged as relevant despite the statistics. Based on that, NNT ratios provide an indicator that could inform clinicians and policy makers on the value and convenience of this intervention. Effect size is another element to be considered in the evaluation of an intervention, since the ability of trials to rule-out the effect of an intervention grows in the required sample size in direct relationship to the decrease in the effect size, with direct implications in the feasibility of a clinical trial and the convenience of an intervention (31). In the present analysis, as expected, NNT related to ICU admission and mortality prevention differed significantly between subgroups, with a lower NNT in higher risk groups, as subjects older than 40 year-old.

As an observational intervention, our analyses are susceptible to bias, which constitute the most significant limitation of this report and a major concern in COVID-19 in view of the multitude of publications of studies and observations designed, run and published at unprecedented speed (32). The risk of confounding factors introducing bias in the comparison between groups cannot be completely ruled out, although several measures were taken to minimize its occurrence, like the verification of balanced age distribution, vaccination status and prevalence of comorbidities, with a special attention paid to current oncologic processes that could identify patients with terminal disease. In reference to it, in a sub-analysis that excluded individuals with current oncologic processes the differences between IVM and C groups remained significant (data not shown). Survivor bias was assessed and controlled in a sub-analysis (data not shown) through the exclusion from the analysis of all individuals in the control groups whose death occurred within the first 4 days since diagnosis, since those individuals were in all likelihood not offered the intervention, maintaining a significant association in favor of IVM in terms of mortality frequency in the higher risk groups (non-immunized subjects older than 40 year-old). In order to limit the mortality assessment to death related to COVID-19 in the C group, deaths were only considered for the analysis when occurring during the original hospital admission or within a month after discharge. Regarding the possible influence of differences in the prevalence of comorbidities between groups, it is important to highlight that, meanwhile most comorbidities were balanced between groups, a higher percentage of participants in the IVM group reported hypertension and obesity compared to C. Although these differences could be attributed to methodological differences in the identification of comorbidities, should they be real, describe a higher risk of disease progression and, consequently, would not explain the better outcomes observed in this group.

A per-protocol analysis including only individuals that completed the whole treatment, which could provide information of the full potential of the regimen was not performed since individuals on therapy that had their treatments interrupted at hospital admission were identified and given that situation, performing a per-protocol analysis would have given biased results that would wrongfully inflate the efficacy of the intervention.

One limitation of the present work is the absence of a detailed record of the refusal of patients to participate in the IVM program. Specifically, since the start of the program in January 2021, every physician in the province was authorized to offer this treatment to patients who met the inclusion criteria. However, the inclusion of patients was left to the discretion of the treating physician and to the acceptance by the patient. For this reason, the non-inclusion of patients in the IVM program could be due both to the refusal of patients to receive treatment after it was offered, to non-compliance with the inclusion criteria, or to the decision by the treating physician not to offer this treatment option. Unfortunately, no information is available to confirm the reason for not including each individual patient.

When looking at our findings in the context of the results and conclusions of rigorous RCTs, other observational clinical studies, virologic .and molecular biology studies for the evaluation of IVM in COVID-19, we conclude on the plausibility and potential clinical utility of IVM at higher doses than currently approved, optimizing its bioavailability but with a relatively moderate effect size in high-risk population groups. Without safety concerns at the doses used in our program, this report highlights IVM as an intervention that deserves a dispassionate, careful, public health-based consideration for the treatment of patients during present COVID-19 pandemic until

superior therapeutic alternatives become available and affordable, and highlights the importance of performing adequately powered RCTs in order to confirm our findings.

Abstract: The emergence of COVID-19 in March 2020 challenged Zimbabwe to mount a response with limited medical facilities and therapeutic options. Based upon early clinical indications of efficacy for the macrocyclic lactone Ivermectin (IVM) against COVID-19, IVM-based combination treatments were deployed to treat this infection. Data were retrospectively analyzed for 34 severe, hypoxic COVID-19 patients, median age 56.5, who were provided this treatment at clinics or at home between August 2020 and May 2021, for whom SpO2 values were recorded all on room air. All but three of these 34 patients had significantly increased SpO2 values within 24 hours after the first IVM dose. The mean increase in SpO2 as a percentage of full normalization to SpO2=97 was 55.1% at +12 hours and 62.3% at +24 hours after start of treatment. These results parallel similar sharp, rapid increases in SpO2, all on room air, for 24 mostly severe COVID-19 patients in the USA (California) who were given an IVM-based combination treatment. All patients in these Zimbabwe and California critical series recovered. These rapid increases in SpO2 values after IVM treatment stand in sharp contrast to declines in SpO2 and associated pulmonary function following onset of moderate or severe COVID-19 symptoms under standard care.

1. Introduction

Evaluating the efficacy of COVID-19 therapeutics is challenging since most patients typically recover; the worldwide cumulative case fatality rate was 2% as of September 2021 [1]. Thus, randomized clinical trial (RCT) results are important, yet interpretations, for example, of the more than 20 mostly positive RCT results for COVID-19 treatment with the drug ivermectin (IVM) [2-5] are controversial. Even for a drug such as remdesivir that was tested with several RCTs having large patient cohorts, opposite conclusions were drawn by the US FDA [6] and the World Health Organization [7] as to efficacy against COVID-19.

As a complement to positive RCT results for a COVID-19 therapeutic, a quantifiable determination of rapid, major improvement in pulmonary function, especially for severe COVID-19 patients, would further indicate efficacy and provide insights into that drug's underlying biological mechanism. The simplest indicator of lung function is blood oxygen saturation level, SpO2, measured with a pulse oximeter. However, the administration of supplemental oxygen to any COVID-19 patient would preclude meaningful pre-and post-treatment comparisons of SpO2 values. For this retrospective study conducted in

FOI 26-3132 - Document 3

Zimbabwe, ironically, challenges that constrained treatment capabilities also provided the opportunity to track changes in SpO2, all on room air, for 34 hypoxic, severe COVID-19 patients within 12 to 48 hours after beginning IVM-based combination treatment (see Figure 1).

Zimbabwe, a landlocked country in Southern Africa that shares a border with South Africa, had its first reported case of COVID-19 in March 2020 [8]. Eight cases and one death from COVID-19 followed in the same month [9]. COVID-19 wards were created at a general practice clinic by converting two staff rooms into a 4-bed ward and a storeroom into a 2-bed ward. Available equipment included several oxygen cylinders, an oxygen concentrator, six beds, and three monitors for SpO2 and blood flow parameters. The staff consisted of the lead author, another primary care physician, and either one or two nurses at different times, each on 12-hours shifts. During the initial months of the pandemic, in the absence of proven therapies and protocols, the standard of care evolved through early August 2020 to include corticosteroids, anticoagulants and antibiotics, as used elsewhere in the world during this period.

However, the efficacy of these treatments was found to be limited, and by the end of July 2020, several COVID-19 deaths were recorded in the country. Based upon reports of initial success using IVM for COVID-19 treatment from colleagues in Johannesburg, South Africa, the College of Primary Care Physicians of Zimbabwe (CPCPZ) adopted and included IVM in their COVID-19 treatment protocol from August 8, 2020, starting initially with a 10-12 mg stat dose. Treatment of COVID-19 with IVM continued after the first patients showed improved outcomes, with more rapid recoveries achieved at doses higher than the standard of 200 ug/kg as initially used. In August 2020, after it became apparent that IVM added to standard of care was significantly reducing the death rate, together with the hospital system being overwhelmed, CPCPZ physicians decided to treat COVID-19 patients where an IVM-based protocol could be administered, including at local general practice clinics which had nursing care and oxygen, and at some patients' homes with nursing support and oxygen supplementation as available.

1.1 IVM for COVID-19 treatment

The decision to include IVM in COVID-19 treatment protocols in Zimbabwe was made as the pandemic swept through that nation, overwhelming limited clinical care facilities, with no drug developed to treat COVID-19 being generally accepted as effective. A published case-controlled study of IVM treatment for COVID-19 conducted at four US hospitals [10] that had been initially released in a preprint in June 2020 found a 40% reduction in mortality among 173 patients treated with low dose IVM vs 107 case-matched controls (15% vs 25.2% deaths). Interest in IVM was supported by its Nobel prize-honored pedigree and its extensive use to treat a variety of human diseases in over 3.7 billion doses worldwide since 1987 [2,11,12]. Another favorable characteristic of this drug is its extraordinary record of safety, well tolerated at high doses [13,14], including in studies for COVID-19 treatment [15,16]. It is generally non-toxic even at doses far exceeding the therapeutic range [17,18]. Since August 2020, inpatient and outpatient treatments of COVID-19 with IVM have been applied across 25 countries [2], with more than 20 RCTs conducted for IVM treatment regimens [2-5].

A comprehensive review of clinical studies for IVM treatment of COVID-19 by the Nobel co-laureate for IVM, Dr Satoshi Omura, and colleagues, concluded that IVM yielded major reductions in mortality [2]. Two animal studies of IVM treatment at low human-equivalent doses, one for the SARS-CoV-2 virus in golden hamsters [19] and another for a related betacoronavirus (MHV-A59) in mice [20], found statistically significant treatment benefits. The indicated biological mechanism of IVM, competitive binding with SARS-CoV-2 spike protein [21], is likely non-epitope specific, possibly yielding full efficacy against emerging viral mutant strains.

The demonstrated safety of IVM at much higher than standard doses [13-16] allowed the latitude for dose escalation for IVM treatment of COVID-19 over time, and

FOI 26-3132 - Document 3

combination therapy centered around IVM plus doxycycline and zinc became the standard COVID-19 treatment protocol used by the CPCPZ. This application of multiple drugs against COVID-19 was based on Zimbabwe's experience with prior infectious diseases, for which early, aggressive use of multiple drugs has been a core treatment principle. The potential efficacy of these adjuncts was later supported by successful clinical trials results with treatments using IVM in combination with doxycycline [22] or with doxycycline and zinc [23]. This combination therapy for COVID-19 has been researched and advanced by Thomas Borody [5], who in 1990 published the first clinical trial of using a triple therapy of three inexpensive repurposed drugs for *H. pylor*i [24], the underlying bacterial cause of peptic ulcers. This triple therapy of repurposed drugs became the worldwide standard of care for peptic ulcers a decade later, after the patents for the palliative drugs Tagamet and Zantac expired, and the discovery of *H. pylor*i as the cause of peptic ulcers was honored with the Nobel Prize for Medicine in 2005 [5].

2. Materials and Methods

This study is a retrospective review of clinical data collected for 34 severe COVID-19 patients for whom SpO2 values were monitored all on room air during the course of their treatment, with therapeutic agents selected by their physicians to offer the greatest chances for clinical benefits and recovery. Clinical data were collected for additional patients in Zimbabwe for whom SpO2 values on room air were not recorded, thus not fitting the inclusion criteria of this analysis, with mortality and deterioration outcomes for that larger patient series having been previously reported [25].

2.1 Outcomes

Outcomes tracked were changes in SpO2 values from within one hour before treatment to 12, 24 and 48 hours after start of treatment (first dose of IVM), for 34 COVID-19 patients for whom a pre-treatment SpO2 value and at least one SpO2 value up to +48 hours after start of treatment were available, all obtained on room air.

2.2 Participants

The 34 COVID-19 patients of this study were from Harare, treated by CPCPZ physicians either at local clinics or at patients' homes.

2.3 Inclusion and Exclusion criteria

Patients selected for analysis were of age 18 or older and had treatment start dates between August 8, 2020, and May 31, 2021. Patients were required to have been found COVID-19 positive either by a PCR test or a clinical diagnosis made by criteria including exposure to a COVID-19 patient, hypoxia, lymphopenia, monocytosis, elevated LDH, elevated dimer, and/or radiology consistent with pulmonary abnormalities caused by the virus. Patients selected had an SpO2 value on intake of 51-93%, with all SpO2 values recorded and documented to have been obtained on room air (in almost every case because oxygen was not available), and at least one SpO2 value obtained within 48 hours after IVM administration. These patients thus fit the US National Institutes of Health's definition of severe COVID-19, a sufficient condition of which is an SpO2 value of 93% or below [26].

2.4 Treatment

All patients were administered an IVM-based combination therapy also including doxycycline and zinc plus selected other agents from the standard of care used prior to August 2020. These agents used in combination with IVM included corticosteroids, clopidogrel, aspirin, enoxaparin, a nebulized nano-silver preparation (applied for all patients), rivaroxaban, zinc sulfate, azithromycin, doxycycline, and in some cases, an IV antibiotic. Patients treated in a clinic were assessed by a nurse upon admittance, with blood drawn and PCR tests conducted as feasible given the patient's condition and with severe symptoms necessitating immediate treatment. For those patients who contacted a

FOI 26-3132 - Document 3

CPCPZ physician from home requesting treatment, an online questionnaire was first completed by the patient, after which, if COVID-19 was still a suspected diagnosis, a nurse visit to the home was conducted, with associated follow up per the procedures described for in-clinic patients.

Table 1. Patient age group, sex, and range of pre-treatment SpO2 values.

Age Group	Sex	Initial SpO2 (%) 66-84	85-89	90-93	Total
25-49

* Mean age=55; median age=56.5.

As evidence of IVM safety and tolerability accrued following its use beginning in August 2020, its stat dose of 10 mg as used for the earliest patients was increased on September 11, 2020, to 10-12 mg every four days for three doses. Subsequently, the dosage was further increased to 12 mg IVM on the day of admission and then on days 4 and 8 plus doxycycline (100mg b.i.d.) and zinc sulfate (60mg/day). The latter regimen was used up through December 2020, when the second pandemic wave emerged in Zimbabwe. At that time, additional evidence of safety and tolerability of this regimen supported further dose escalation to a standard IVM dose regimen of 12 mg daily for five consecutive days, with adjunct use of doxycycline and zinc sulfate continued at the doses noted. In some cases, for which this standard treatment regimen did not yield significant clinical gains within a few days, even higher doses of IVM were used, in some cases as high as 100 mg for a single dose. Transient adverse effects (AEs) such as blurred vision characteristic of high dose IVM often occurred at those dose levels, but no serious AEs associated with IVM were manifested in any patient.

2.5 Data collection

SpO2 values were tracked using monitors that continually displayed these plus readings for pulse rate and blood pressure and waveform images of blood pulses. For those patients treated at home, the intake nurse provided a pulse oximeter to the patient, unless the patient had one which the nurse deemed of reliable quality. The patient or a family member took SpO2 readings regularly, using the same oximeter as used for the pre-treatment reading. In most cases, these readings were taken daily, with much lower frequency after SpO2 values had risen significantly and the patient's clinical condition had correspondingly improved. Patients were instructed to message the nurse immediately if SpO2 ever decreased from a higher value to 93% or below or if any new clinical symptoms of concern developed.

FOI 26-3132 - Document 3

2.6 Analytical methods

For the 34-patient severe COVID-19 patients of this study, a measure of percent normalization toward a fully optimal SpO2 value of 97 was applied, which for pre-and post-treatment SpO2 values S_0 and S_1, is: $100*(S_1-S_0)/(97-S_0)$, capped at 100%. Pre- and post-treatment SpO2 values were plotted for all 34 patients using this percent normalization measure in Figure 1 and were also presented directly in Figure 2, Figure 3, and Table S1.

3. Results

Figures 1 and 2 and Table S1 show the progression of pre-treatment and post-treatment SpO2 values within 48 hours after the start of treatment (including first dose of IVM) for the 34 COVID-19 patients of this study, all of whom were treated with IVM, doxycycline and zinc. All of these patients recovered. SpO2 values are shown at pre-treatment, all recorded within one hour before the start of treatment and within 12, 24 and 48 hours after first dose of IVM. The SpO2 value shown for a given patient at time x is that for the latest post-treatment time ≤ x. (Thus, for example, for a patient having an SpO2 measurement at hour 17 as the only one in the first 48 hours after initial treatment, that would be used as their +24 and +48 hour values.)

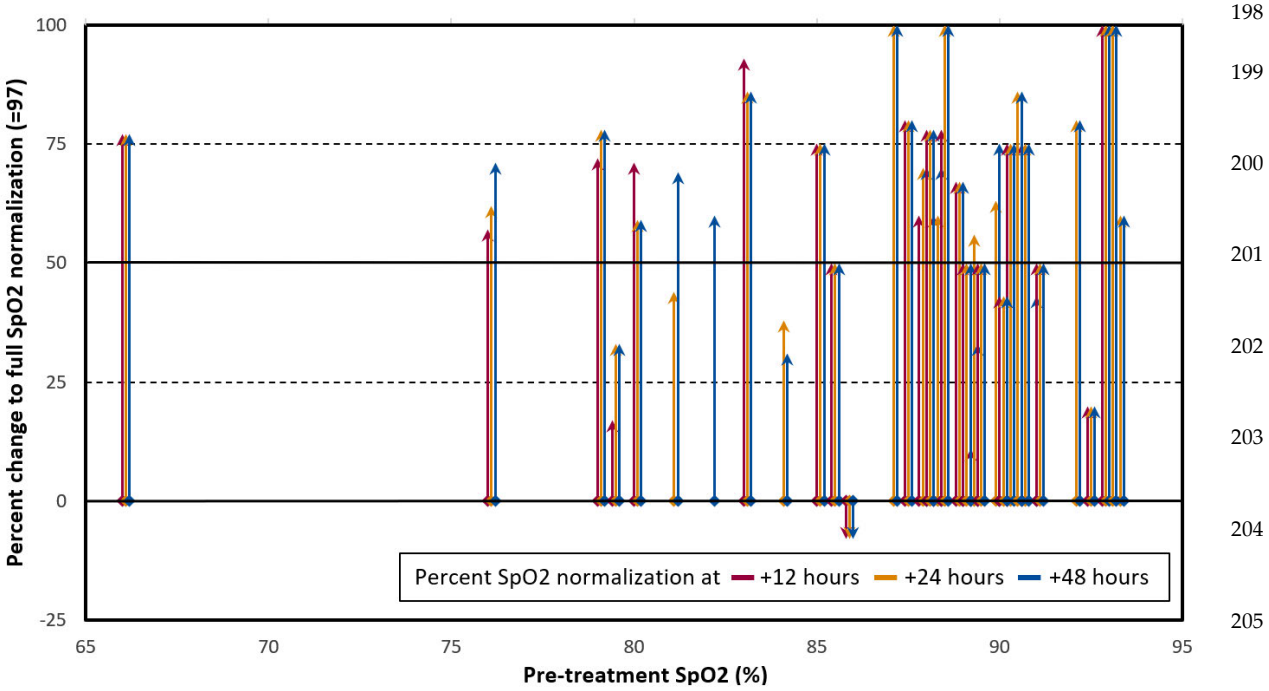

Figure 1. Changes in pre- to post-treatment SpO2 values, all on room air, for 34 severe COVID-19 patients treated with ivermectin (IVM), doxycycline and zinc, as percentages of optimal normalization to SpO2=97. Red, orange and blue lines represent, respectively, changes in SpO2 values at +12, +24 and +48 hours after first dose of IVM. Arrows were shifted to the right slightly (<1.5 x axis units) as needed for clarity. For pre-and post-treatment SpO2 values S_0 and S_1, the y axis is the percent of optimal normalization to SpO2=97, that is: $100*(S_1-S_0)/(97-S_0)$, capped at 100%. Mean (±SD) SpO2 changes (y values) were 55.1% ± 28.0% at +12 hours, 62.3% ± 26.3% at +24 hours and 64.3% ± 24.5% at +48 hours.

Figure 1 shows, for all 34 patients, SpO2 value changes from before IVM administration to post-treatment as percentages of full normalization to an optimal SpO2 value of 97 (95 is considered the minimum normal SpO2 value for a healthy child or adult by the US CDC [27]). Red, orange and blue lines show, respectively, SpO2 values at +12, +24 and +48 hours post-treatment. The mean (±SD) SpO2 changes as this specified percent of optimal normalization were 55.1% ± 28.0% at +12 hours, 62.3% ± 26.3% at +24 hours and 64.3% ± 24.5% at +48 hours. As shown in Figure 1, the bulk of the patients had 50% or

FOI 26-3132 - Document 3

more SpO2 normalization within 48 hours, while the sickest 3 (pre-treatment SpO2 ranging from 66 to 78%) improved by over 70%.

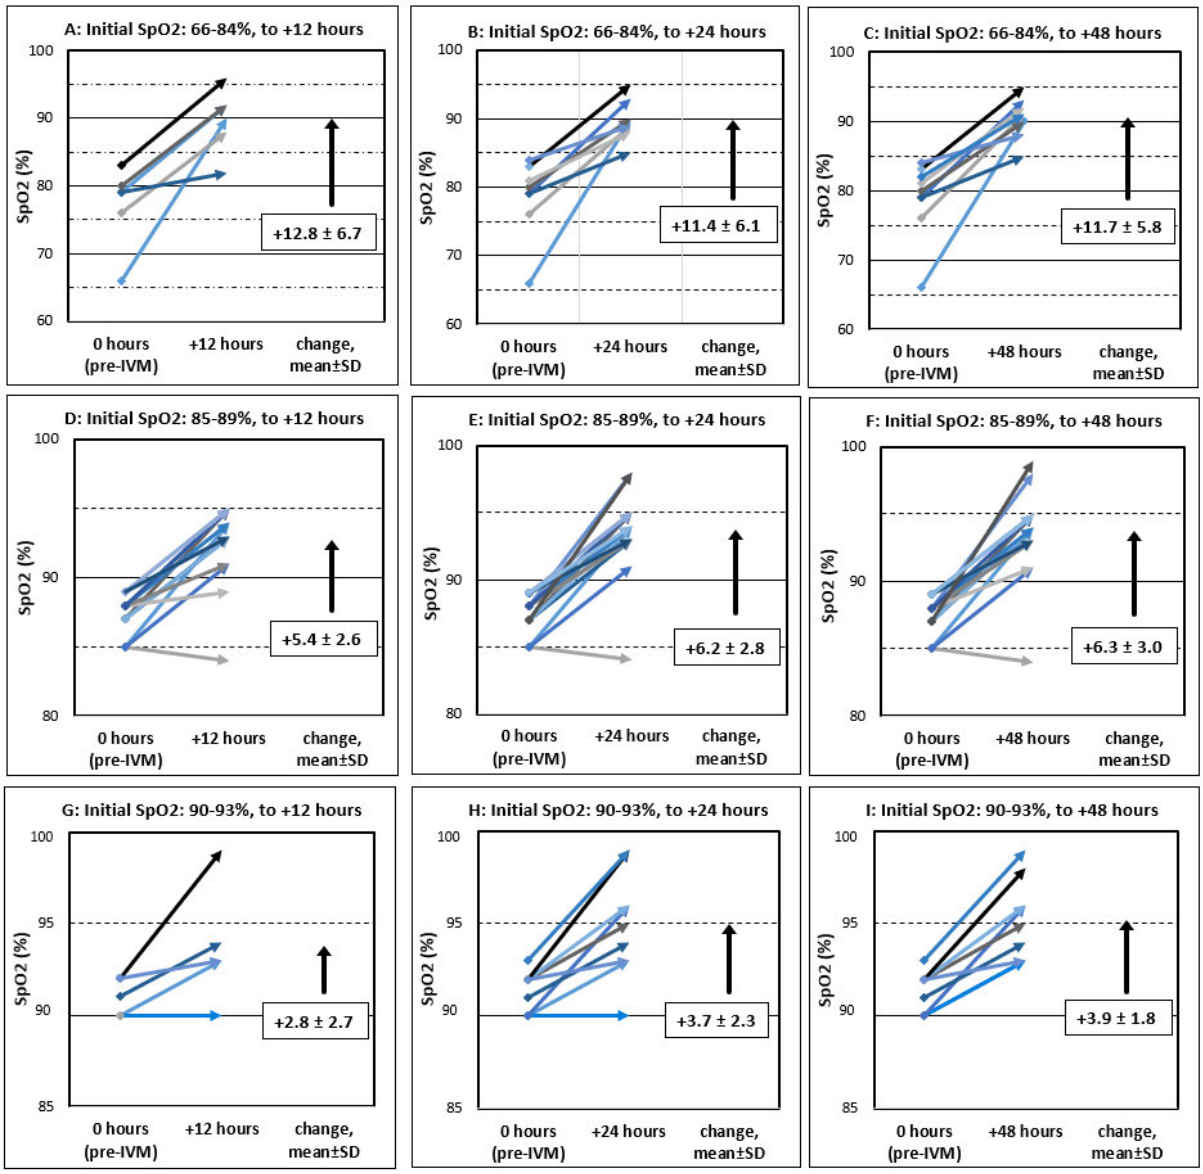

Figure 2. Pre- and post-treatment SpO2 values, all on room air, for 34 severe COVID-19 patients treated with IVM, doxycycline and zinc. Graphs A-I are in horizontal groupings by the range of pre-treatment SpO2 value and in vertical groupings by elapsed time after first dose of IVM. (The lowest SpO2 value in the stipulated range of 51-93% was 66%.) For these elapsed times of x=12, 24, and 48 hours, the SpO2 value shown for a given patient is at the latest post-treatment time ≤ x. All pre-treatment SpO2 values are from within one hour before the start of treatment.

Figure 2 shows all pre-and post-treatment SpO2 values grouped into nine graphs (A-I) by the range of pre-treatment SpO2 values and post-treatment times (after first IVM dose) of +12, +24 and +48 hours. As shown in Figure 2 and identically in Table 2, those patients with lowest, mid-range and highest pre-treatment SpO2 values had mean SpO2 increases at +12 hours of 12.8, 5.4 and 2.8, respectively (all SpO2 values in percentage units). Figure 3 shows all pre-and post-treatment SpO2 values throughout the entire observation period for each of the 34 patients. Note that these values were recorded less frequently after SpO2 had normalized.

FOI 26-3132 - Document 3

Table 2. Mean (± SD) changes in SpO2 values from pre- to post-treatment with IVM-based combination therapy.

	SpO2 (%)		
Pre-treatment	at +12 hours	at +24 hours	at +48 hours
66 - 84%	+12.8 ± 6.7	+11.4 ± 6.1	+11.7 ± 5.8
85 - 89%	+5.4 ± 2.6	+6.2 ± 2.8	+6.3 ± 3.0
90 - 93%	+2.8 ± 2.7	+3.7 ± 2.3	+3.9 ± 1.8

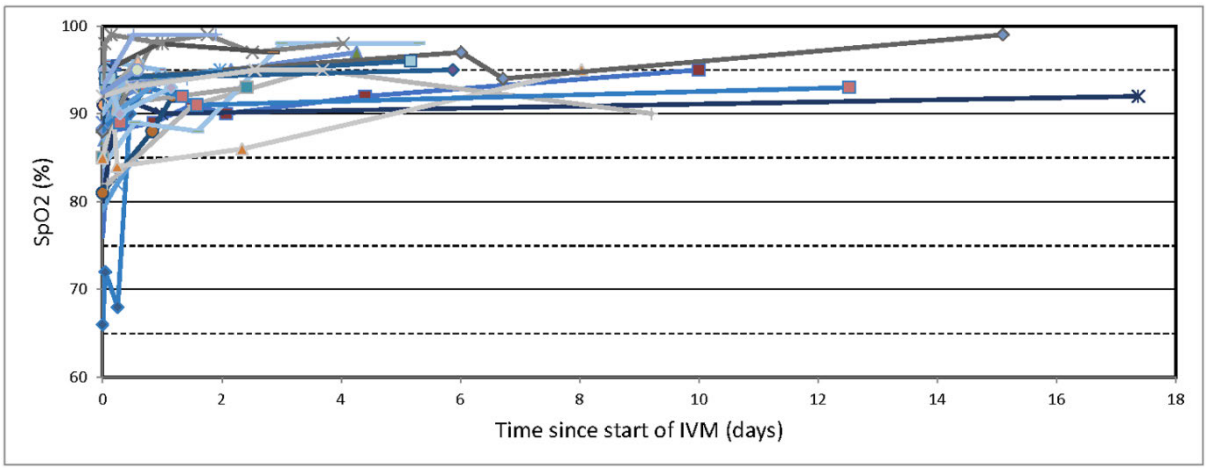

Figure 3. All SpO2 values (on room air) for the 34 severe COVID-19 patients of this study, all treated with IVM-based combination therapy including IVM, doxycycline and zinc.

Figure 4. Changes in SpO2 over 3 hours for a COVID-19 patient after administration of IVM. SpO2 values are shown (all on room air), with pulse rates (bpm) below those, at pre-treatment (A) and for 45 minutes (B), 90 minutes (C), and 3 hours (D) after first dose of IVM. This patient was diagnosed with COVID-19 by a positive result from a rapid antigen test and treated with combination therapy including IVM, doxycycline and zinc plus other oral and nebulized adjunct agents from among those itemized above.

Figure 4 shows successive SpO2 values for one patient who had a particularly rapid increase in these values after his first dose of IVM. This patient was a 25-year-old male, treated by a CPCPZ physician at a GP clinic without a supplemental oxygen capability. He received his first 12 mg IVM dose (repeated over the next four days) immediately after entering the clinic with respiratory distress and bilateral pneumonia indicated by stethoscopic examination. His COVID-19 diagnosis was confirmed by a positive result from a rapid antigen test. As shown, his SpO2 values increased from that recorded immediately before treatment (79%) to values at 45 minutes (87%), 90 minutes (92%) and

FOI 26-3132 - Document 3

3 hours (95%) post-treatment. He was discharged later that same day, and his home SpO2 readings then fluctuated between 92% and 95% over the next three days. By the fourth day after discharge, his SpO2 stabilized at 97%, his pulse dropped to 77 from prior values over 100, and he resumed working from home.

As shown in Figure 2, all but two of the 34 patients in this study had increases in SpO2 within the first 48 hours after first dose of IVM. As shown in Figure 3, this overall increase in SpO2 continued throughout the entire observation period. However, several studies of moderate and severe COVID-19 patients under standard care that track SpO2, pulmonary abnormalities, or both establish that for most patients, SpO2 decreases in tandem with an increase in the extent of pulmonary CT abnormalities from the day of onset of disease symptoms through the second week following [28-34]. Thus, the expected change in SpO2 within 48 hours after first IVM dose would be < 0, and one-tailed paired t-test calculations can assess whether SpO2 values increased significantly > 0 at each time period tracked.

Taking into account some missing post-treatment values (see Table S1), there are 25, 33 and 34 pairs of pre- and post-treatment SpO2 values at +12 hours, +24 and +48 hours, respectively. Applying these paired t-test calculations, the SpO2 increases were highly significant for each time period: t=6.28, p=8.5E-07 at +12 hours; t=8.42, p=6.36E-10 at +24 hours, and t=8.81, p=3.47E-10 at +48 hours.

4. Discussion

This study is a retrospective review of clinical data collected amid the challenges of providing treatment with limited facilities and resources to COVID-19 patients with severe disease. Under such conditions, it was not possible to obtain blood test values for all patients, including values for lymphocyte count, LDH, D-Dimer and CRP, which were thus not analyzed. On the other hand, the lack of availability of oxygen supplementation for many of the patients treated in Zimbabwe provided the rare opportunity to track changes in SpO2 values all recorded on room air before and after administration of IVM for this group of 34 severe COVID-19 patients, 74% of them presenting with SpO2 values below 90% and 29% presenting with SpO2 85% and below.

The mean (±SD) SpO2 normalization, as reported above, was 55.1% ± 28.0% at +12 hours, which rose to 62.3% ± 26.3% at +24 hours and then to 64.3% ± 24.5% at +48 hours after first IVM dose. Paired t-test calculations yield p<0.0000001 for each of the SpO2 increases, at +12, +24 or +48 hours, having occurred by chance had the IVM-based combination therapy applied had no clinical activity against COVID-19. Because the dearth of significant spontaneous improvements in SpO2 levels and respiratory function one day after a severe COVID-19 patient's presentation for medical care is a well-established norm for this disease per studies cited above, these probability values are significant and noteworthy.

This study's results, including the recoveries of all 34 patients, parallel those recently reported by Hazan et al., for which SpO2 values all on room air for 24 RT-qPCR confirmed COVID-19 patients were tracked before and +24 hours after combination treatment with IVM, doxycycline and zinc [35]. For the 19 severe COVID-19 patients in that series who had pre-treatment SpO2 values of 90% and below (minimum=77%) and had +24 hour post-treatment SpO2 values (see Table S2), the mean (±SD) SpO2 values rose from 86.7 ± 4.5 pre-treatment to 93.3 ± 2.6 at +24 hours after first IVM dose. Per our calculation of the percentage of normalization to SpO2=97, the mean (±SD) relative SpO2 increase at 24 hours post-treatment for these 19 patients was 65.2% ± 17.5%, which is close to the mean of 62.3% for the 34 patients in our study. The one-tailed paired t-test for these increased SpO2 values in these 19 patients yields t=9.34, p p<0.0000001, which as for our Zimbabwe study is highly significant.

The similar results for the COVID-19 patients in our Zimbabwe SpO2 series and the 24 patients of Hazan et al. suggest that the triple therapy of IVM, doxycycline and zinc provides efficacy regardless of which other adjunct agents were used, or may indicate that

FOI 26-3132 - Document 3

each study used different sets of adjuncts that further boosted the activity of this regimen to the degree of efficacy manifested in the clinical outcomes for each. One limitation of this study is that except for nebulized nano-silver, used for all patients at the start of the treatment regimen, other adjuncts were deployed on a case-by-case basis, per the patient's condition. Also, IVM dosages were increased during the study period based on the observations that no serious AEs were observed at higher doses, and higher doses appeared to be most effective for the patients with the most severe symptoms. A follow-up clinical study of IVM-based combination treatment of COVID-19 would benefit from a more structured specification and tracking of dosages and adjuncts used.

The distinct improvements in respiratory function for our study parallel results reported by Hazan et al. and provide a quantifiable demonstration of rapid clinical improvement in severe COVID-19 patients after IVM treatment. Such rapid improvements had been observed since the first major clinical trial in Florida, USA, of IVM treatment of COVID-19 [10]. The lead investigator of that clinical trial had observed that stabilization and then improvement in breathing function frequently occurred within 12-48 hours after IVM treatment, even for patients who had been deteriorating rapidly and had required supplemental oxygen at up to a 50% mixture [36]. That Florida study also reported a 40% reduction in mortality in the IVM-treated group compared with propensity-matched case controls. Likewise, for a larger series of 92 severe COVID-19 patients treated in Zimbabwe with IVM, doxycycline and zinc and other agents, the number of case fatalities (2) and deteriorations followed by recoveries (2) were much lower than predicted for a comparable set of patients using a well-regarded risk assessment model [25].

The SpO2 increases within a day after IVM treatment observed in this study and by Hazan et al. provide a distinct indication that IVM not only yields statistically significant clinical benefits in groups of patients as reported in most of the 20 RCTs for IVM treatment but provides rapid, directly observable resolution of pulmonary dysfunction as tracked by SpO2 values for COVID-19 patients. This finding offers clues as to the potential biological mechanism of IVM activity against SARS-CoV-2 since, for example, even an effective freeze on viral replication or rapid repair of damaged pulmonary alveoli would be unlikely to cause such rapid clinical improvements. One indicated biological mechanism of IVM activity, competitive binding with SARS-CoV-2 spike protein, as reviewed [21,37], may, through a reversal of virally induced hemagglutination, act quickly to increase pulmonary capillary flow and in turn account for normalization of blood oxygenation. An additional plausible mechanism of IVM activity is the activation of the cholinergic anti-inflammatory pathway under the control of the vagus nerve [38], which is regulated by acetylcholine and potentiated by the high-affinity binding of IVM (a positive allosteric modulator) to the alpha 7 cholinergic receptor a7nAChr [39] expressed on bronchial, vascular as well as to cytokine-producing cells (i.e., TNF, IL1 and IL6 secreting macrophages, lymphocytes and mast cells) [40].

For our study, rapid increases in SpO2 after start of IVM-based combination treatment occurred for all but two of these 34 patients and resulted in recoveries for all of them. No serious adverse effects (AEs) from IVM treatment were observed in any patient, although transient AEs such as blurred vision characteristic of higher-dose IVM administration were observed in some patients given doses as high as 100 mg. While comparative results using higher vs lower doses were not systematically tracked, the practice of increasing IVM doses for patients not initially responding to treatment had generally successful outcomes and supports the indication that higher doses provide greater efficacy.

5. Conclusions

Marked, rapid normalizations of blood oxygenation, $p<0.0000001$ (paired t-test), were obtained in each time period analyzed for the 34 severe COVID-19 patients in this study, all treated with IVM-based combination therapy. These results parallel similar

FOI 26-3132 - Document 3

rapid SpO2 increases reported by Hazan et al. for 19 COVID-19 patients having pre-treatment SpO2 ≤ 90, also at p<0.0000001, with all SpO2 values likewise on room air. For the 34 patients of our study, the mean increase in SpO2 value as a percentage of full normalization to SpO2=97 was 55.1% at +12 hours and 62.3% at +24 hours after first IVM dose, close to the mean SpO2 normalization of 65.2% at 24 hours after first IVM dose as calculated from SpO2 values reported by Hazan et al. These sharp, rapid increases in SpO2, accompanied by survivals of all patients in both the Zimbabwe and California critical series, stand in sharp contrast to the well-established typical decline in SpO2 during at least the first week after onset of moderate or severe COVID-19 symptoms. These SpO2 increases rapidly following first IVM dose establish a cause-and-effect clinical benefit for IVM-based combination treatment of this disease.

For the patients of this Zimbabwe study and the Hazan critical series, treatment at home or in clinics with basic facilities freed up hospital resources for other patients, and the treatment approach modeled in these studies could significantly relieve the pressure on overwhelmed health facilities. IVM is widely available worldwide, inexpensive, and one of the safest drugs in modern medicine, with its safety in "improving the health and wellbeing of millions" noted explicitly by the Nobel Committee in awarding its 2015 prize for the discovery of IVM [41]. These study results, therefore, support the extended deployment of IVM-based combination treatment for COVID-19, complementary to immunizations for prevention.

Additional Clinical Guidance (July 2022) 27072022.docx
image002.png
image013.png

Hi s22

The TGA has reviewed the revised Nonclinical search strategy, provided in your email of 18 August 2022. Please find attached TGA comments on the revised Nonclinical search strategy.

TGA takes the opportunity to gently remind you of the other outstanding elements associated with this possible application, as provided in the document titled 'Additional Clinical Guidance (July 2022) 27072022', emailed to Commercial Eyes on 8 August 2022 (and copy attached for reference). Please let us know if you need any further clarification or assistance to addressing these elements prior to submitting an application on behalf of your client.

Regards,
s22

Hi s22

On behalf of our client Topelia, may I please politely enquire into the progress of the LBS search strategy review for the proposed triple therapy Ziverdox?

CEPL and Topelia are more than happy to arrange a call to discuss any elements of the proposed LBS strategy at a time that suits.

Thank you in advance.

Regards,
s22

Dear Sir/Madam,

On behalf of our client Topelia Aust Ltd (Topelia), CEPL wish to seek TGA's feedback on the search strategy for a literature based submission, to support the Category 1 submission of a s47 comprising of ivermectin s47 , doxycycline s47 and zinc s47 s47 for the following indication:

- Ziverdox is indicated for the treatment of mild to moderate symptomatic patients diagnosed with COVID-19 caused by SARS-CoV-2 virus.

Please find further details about the submission and the proposed search strategy attached.

We look forward to receiving TGA feedback on the acceptability of the proposed search strategy.

Thank you in advance.

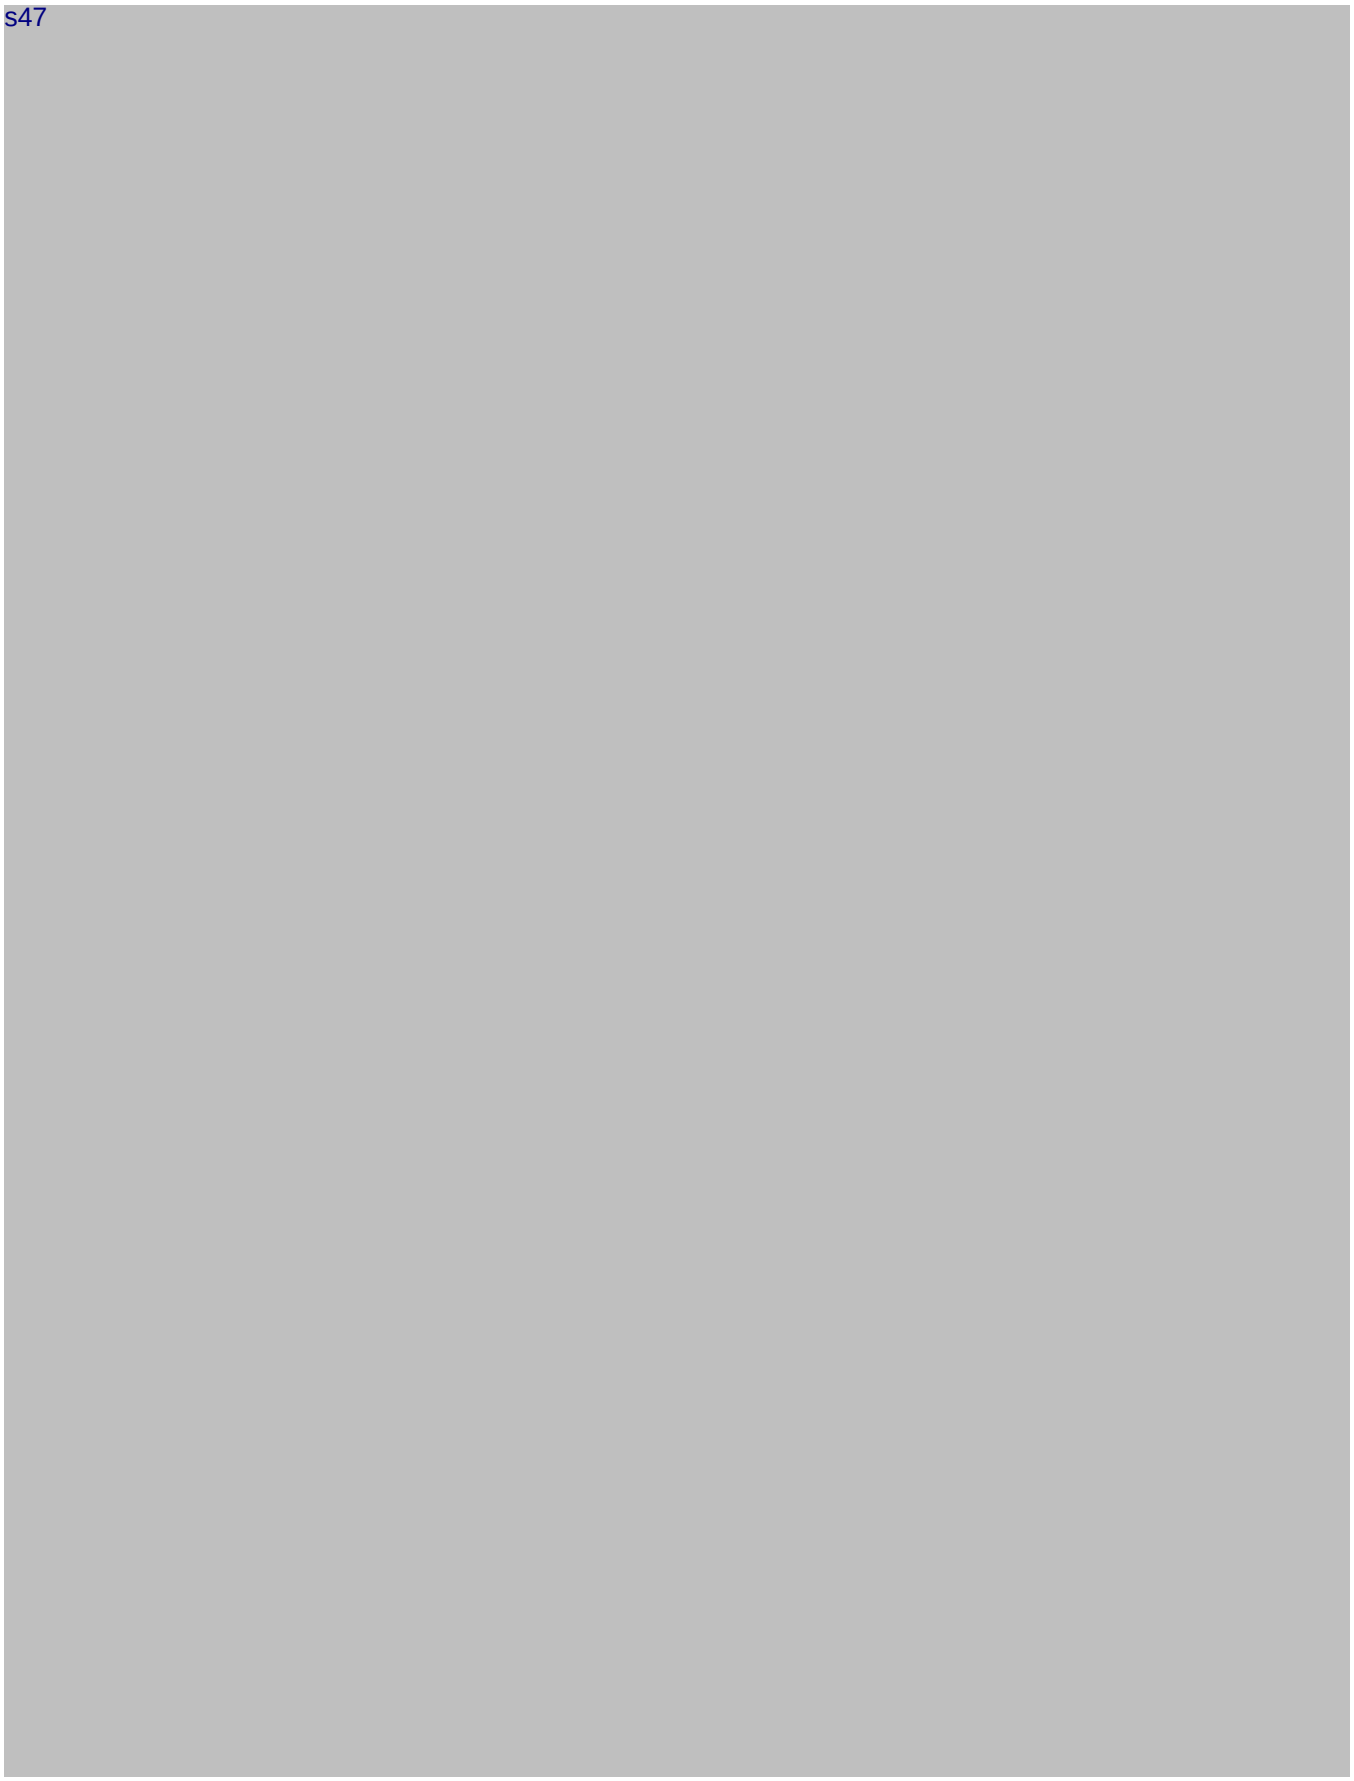
Proposed product: s47 ('ZIVERDOX')
Sponsor: Topelia Ltd
Agent: Commercial Eyes Pty Ltd
Proposed indication: *Ziverdox is indicated for the treatment of mild to moderate symptomatic patients diagnosed with COVID-19 caused by SARS-CoV-2 virus.*

The TGA reiterates the advice provided previously to s22 (email with 3 attached documents sent by TGA (Grant Pegg, dated 10 September 2021). The 3 documents that were previously provided:



- Relevant guidelines for consideration
- Comments on the Clinical study synopsis
- Considerations when applying to register medicines

Following review of your background briefing document (provided to the TGA on 25 March 2022), the TGA provides the following advice s47

image006.gif

Hi s22

The TGA has screened the updated s47 justification for the proposed ivermectin/doxycycline/zinc citrate (ZIVERDOX) product.

The scope of the additional references and updated s47 justification do not appear to have addressed the data gaps previously noted by the TGA.

The TGA notes there are some new references provided, however these appear to be not directly relevant and/or are of lower quality to support the proposed claims. In addition, there a number of recent, higher quality studies that have not been referenced (for example: JAMA 2023, 329(11), 888-897. doi:10.1001/jama.2023.1650); an application should include a balanced view of available evidence.

Please note that the TGA does not typically provide advice on the clinical study design.

The Nonclinical area has also noted that the main nonclinical issue would be the lack of pharmacology and most importantly, toxicology studies with the combination given the limited clinical experience/data with the combination. No nonclinical pharmacology studies were noted in the justification to support the sponsor's claim of synergistic antiviral activity. There are no toxicology studies with the combination to assess potential toxicological interactions between the 3 ingredients.

Regards,
s22

Dear s22

On behalf of our client, Topelia Aust Ltd (Topelia), please find attached a response to the TGA justification review dated 31 October 2022.

The s47 justification response is accompanied by a full reference list for ease of review.

Please note due to file size, the remaining attachments will be provided across other emails. The email will be identified in the Subject line as Justification for s47 - Ziverdox, Topelia Aust Ltd; Email X of 4.

Topelia Aust Ltd are welcoming of a meeting to discuss TGAs thoughts and next steps for the s47 .

Kind regards,
s22
Associate Consultant, Regulatory, Quality & Compliance

Hi s22 ,

Further to the elements raised in TGA's email of 26 September, please find attached the TGA's initial review of the s47 justification for Ziverdox.
Note that the TGA would also take into consideration additional clinical studies that come to

hand (e.g. recent study published in JAMA last week).

Good afternoon s22

Thanks for providing your justification for your s47 for this potential application.

TGA has completed an administration screen of the proposed justification. Grateful if you can please clarify a couple components of the proposed justification before the TGA continues its review. Please confirm,

1. the scope of the justification, specifically the date range of the literature references that were included in your s47 justification
2. both supporting and non-supporting literature articles were included in the development of the justification.
3. the literature articles that were referenced in the s47
4. a scientific rationale has been provided for proposed dosage of each component in the s47 based on the breadth of supporting and non-supporting literature studies using a weight of scientific evidence approach. Where non-supporting studies have been included, the justification has considered these articles and provided robust scientific reasoning as to why they were considered not relevant to the proposed s47 .

Once the TGA has received clarification of the above, the TGA can then provide you further details regarding next steps to support this potential application. Please feel free to reach out if you have any questions.

Kind regards s22

Dear Streamlined Submissions,

On behalf of our client, Topelia Aust Ltd (Topelia), CEPL hereby submit a justification for a proposed s47, Ziverdox for consideration.

Ziverdox is a proposed s47 comprising of ivermectin s47 doxycycline s47 and zinc s47 for the following indication:

- *Ziverdox is indicated for the treatment of mild to moderate symptomatic patients diagnosed with COVID-19 caused by SARS-CoV-2 virus.*

The s47 justification is accompanied by a full reference list for ease of review.

CEPL look forward to receiving TGA's feedback on the proposed fixed dose combination therapy.

Thank you in advance.

Regards,

s22

FOI 26-3132 - Document 5

Pediatric Pulmonology 43:281–287 (2008)

Effect of Zinc Supplementation on Respiratory Tract Infections in Children With Cystic Fibrosis

I. Abdulhamid, MD,[1]* F.W.J. Beck, PhD,[2] S. Millard, MD,[3] X. Chen, MD, PhD,[1] and A. Prasad, MD, PhD[2]

Summary. Zinc (Zn) has significant anti-oxidant and anti-inflammatory activity. Zn deficiency can occur in subsets of patients with cystic fibrosis (CF) especially those with malabsorption and impaired growth. Although supplemental Zn has significantly reduced infections in various disorders, its efficacy has not been thoroughly investigated in CF. We performed a double blind placebo controlled pilot study to investigate the effect of daily 30 mg elemental Zn for 1 year on the rate of respiratory tract infections (RTIs), use of antibiotics and plasma cytokines in 26 children with CF (ages 7–18 years). Plasma Zn, Cu, inflammatory cytokines and ex vivo generation of IL-2 were measured at baseline and at the end of the study. The number of days of oral antibiotics was lower in Zn treated patients compared to placebo ($P = 0.05$). However, compared to placebo, the effect of Zn was greater in patients who exhibited low plasma Zn at baseline ($P = 0.02$) than those who had plasma Zn levels identical to normal subjects ($P = 0.55$). Zn supplementation was marginally effective in reducing percentage increase in plasma IL-6 and IL-8 while increasing the percentage change in ex vivo generation of IL-2 in isolated mononuclear cell. In conclusion, oral intake of 30 mg/day of Zn reduced the number of days of oral antibiotics used to treat RTIs in children with CF. A higher daily Zn dose may be needed to decrease RTIs and modify immune responses. **Pediatr Pulmonol. 2008; 43:281–287.** © 2008 Wiley-Liss, Inc.

Key words: cystic fibrosis; respiratory tract infections; zinc; cytokines.

INTRODUCTION

Cystic fibrosis (CF) is an autosomal recessive disease caused by genetic mutations that code for cyclic AMP-activated chloride channel, the CF transmembrane regulator (CFTR).[1–3] The disease affects many organ systems, particularly the respiratory and gastrointestinal tracts. Due to pancreatic insufficiency, malabsorption of essential fatty acids, fat-soluble vitamins, and various trace elements, including zinc (Zn), can occur in subjects with CF.[4,5] The airways in patients with CF are uniquely susceptible to chronic infections with various bacterial agents, especially Gram negative organisms such as *pseudomonas aeroginosa*.[6] This infection causes the release of inflammatory cytokines, proteolytic enzymes, and oxygen radicals which leads to bronchiectasis, increased dead space, hypoxia, and hypercapnea.[7,8]

Approximately 90% of patients die of respiratory failure as a result of chronic bacterial infections, Treatment of CF lung disease is aimed at reducing airway obstruction, treating recurrent infections, improving airway clearance, and maintaining optimal nutritional status.[9–11]

Zn is an integral part of the structure and function of many biological enzymes and a regulator of ion transporters relevant to pulmonary function and disease in CF and other pulmonary disorders.[11–13] Zn is also known to exhibit powerful anti-oxidant activity in several organ systems including the lungs.[11,13] For example, Zn deficient rats developed significant lung toxicity 1 day after exposure to high oxygen concentrations and Zn replenishment prevented the hyperoxia lung damage in previously Zn deficient animals.[14]

Zn supplementation to non-CF infants and pre-school children resulted in reduced incidence of acute lower respiratory infections.[15] Zn supplementation lead to the reduction of plasma concentration of inflammatory cytokines, and oxidative stress markers in the absence of

FOI 26-3132 - Document 5

infection,[16] and decreased the duration of colds in healthy young adults.[17] It also lowered the incidence of infection and inflammatory cytokines levels in healthy elderly subjects.[18]

Using plasma and red cell Zn concentrations to reflect Zn status in CF has produced conflicting results as not all CF patients appear to exhibit low Zn status.[19] Administration of supplemental Zn to CF patients has also been non-conclusive for in one study, Zn therapy did not result in improvement of clinical status, growth velocity or pulmonary function.[20] Another study showed an association between low Zn status and impaired IL-2 activity, NK activity and thymulin activity in CF subjects, but there was no investigation as whether these parameters would be corrected following Zn supplementation.[21]

With these premises we initiated a pilot study to determine whether Zn supplementation administered to CF patients during a year long double blinded placebo controlled trial would reduce the requirement for oral antibiotics necessary during periods of active infection. We also assessed whether changes in selected plasma inflammatory cytokines and the ex vivo generation of IL-2 would be altered by oral Zn therapy. And lastly, we investigated the hypothesis that a response to Zn supplementation would be different in subjects with low plasma Zn levels compared to those expressing normal plasma Zn levels.

MATERIALS AND METHODS

Subjects and Controls

For this double blind placebo controlled study, a total of 26 children with CF exhibiting mild to moderate lung disease groups A and B were recruited from the Pediatric Pulmonary Division, Carman and Ann Adams Department of Pediatrics, Children's Hospital of Michigan (CHM), and the Pediatric Pulmonary Division, DeVos Children's Hospital, Grand Rapids, Michigan. Subject's ages ranged from 7 to 18 years old. Exclusion criteria for the study included presence of acute severe infection at the time of enrollment, renal disease, severe hepatic disease, gall bladder disease, sickle cell disease (SCD), use of oral immunosuppressive drugs (steroids and non-steroid anti-inflammatory drugs), diuretics and Zn supplements. The study was approved by the Human Investigative Committees in both institutions. Informed and signed consent was obtained from parents or legal guardians.

Study Groups

Without respect to prior Zn status, CF subjects were randomly assigned to Group A ($n = 13$) received a daily dose of 30 mg of elemental Zn as Zn gluconate (15 mg/capsule) and CF subjects assigned to Group B ($n = 13$) received placebo for 12 consecutive months. Zn gluconate and placebo preparations were capsules generously provided by Labcatal, Montrouge, France for use in this study. Both groups were given identical daily Zn-free and mineral-free multivitamin supplements for the same period (Vitamax® from SK Labs, Chesterfield, MO) supplied by the CF services Pharmacy. Patients in groups A and B were followed every 3 months and as needed in their CF clinics for routine CF care. At each visit, the patient's interval medical history, height and weight, number of hospitalizations, the use of oral and intravenous antibiotics, pulmonary function test, and physical examination findings were recorded.

Respiratory tract infections (RTIs) was defined when the patient developed more than four of the following signs or symptoms: change in sputum; new or increased hemoptysis; increased cough; increased dyspnea; malaise, fatigue, or lethargy; temperature above 38°C; anorexia or weight loss; sinus pain or tenderness; change in nasal or sinus discharge; change in physical examination of the chest; decrease in pulmonary function from a previously recorded value; or radiographic changes indicative of pulmonary infection.

Choice and duration of oral or parenteral antibiotics used for treatment of RTIs were left to the discretion of the children's treating physicians.

Ten milliliter of heparinized whole blood was collected at baseline and at the end of the study for determination of plasma Zn, Cu and the inflammatory cytokines, TNF-α IL-1β IL-6 IL-8, soluble IL-1 receptor antagonist (sIL-1RA) and soluble TNF-α receptor 1 (sTNFR1). Peripheral blood mononuclear cells (PBMC) were isolated for ex vivo generation of IL-2.[18,22] Sterile procedures were carried out on all samples to ensure no contaminants would interfere with the ELISA assays or ex vivo generation of IL-2. Plasma samples were centrifuged at 1,500*g* for 20 min at room temperature to remove cellular components before being stored in 1 ml aliquots at −20°C for ELISA assays or being admixed with trace metal free Ultrex II Nitric Acid (J.T. Baker Chemicals, Phillipsburg, NJ) and digested for Zn and copper analysis by flameless atomic absorption (AA).[18,22]

Laboratory Measurements

Aliquots of plasma samples were stored at −20°C until assayed for cytokines to ensure that both pre- and post-samples could be determined using the same high-sensitivity ELISA kits available from R&D Systems (Minneapolis, MN). Plasma Zn and Cu levels were determined by flameless AA spectrophotometry with a Zeeman background corrector (AA220Z Varian, Sugarland, TX).[18,22]

PBMCs were isolated by discontinuous density gradient using Histopaque 1077 (Sigma–Aldrich, St. Louis, MO)

FOI 26-3132 - Document 5

according to the manufacturer's protocol. Isolated PMNC were resuspended in incubation media consisting of RPMI-1640 supplemented with 10% fetal bovine serum, 1.5 gm/L sodium bicarbonate, 0.1% gentamicin, 2 mM L-glutamine and 50 μM β-mercaptoethanol. Cells were stimulated for 48 hr with 10 μg/ml PHA-p (Sigma, St. Louis, MO) at 37°C under an atmosphere of 85% air/5% CO_2. At the termination of the experiment, supernatants were harvested and assayed for IL-2 by ELISA (Quantikine ELISA, R&D Systems).

Characterization of Zn− Versus Zn+ Subjects

Zn adequate CF subjects (Zn+) were defined as those subjects with ≥90 μg/dl plasma Zn as determined by flameless AA at baseline. Subjects exhibiting inadequate Zn status (Zn−) had plasma Zn levels ≤89 μg/dl or two standard deviations below our normal database of 110 ± 10 μg Zn/dl.[18,22] Although all subjects exhibited plasma Zn levels within the clinically accepted "normal" range (70–120 μg/dl),[23] results from a number of our research studies have demonstrated that subjects exhibiting low Zn levels (<90 μg/dl) are more susceptible to infections and tend to have higher levels of plasma oxidative stress molecules and inflammatory cytokines even in the absence of outward infections.[18,22]

Statistical Analyses

Baseline data comparison between Zn adequate and Zn inadequate CF patients were determined by the Student's *t*-test. Data representing differences between pre- and post-values were analyzed using the Student's *t*-test for plasma cytokines Zn and Cu and ex vivo generation of IL-2, as well as for weight, height, hemoglobin, and FEV_1. Correlation between compliance and days of oral antibiotic usage was determined by regression analysis using Pearson r (GraphPad Instat Ver. 3.05 for Windows95/NT, San Diego, CA).

RESULTS

Overall, there were no statistical differences in the baseline parameters examined between Zn adequate and inadequate CF children with the exception of plasma Zn status (Table 1). Zn adequate CF patients also tended to have higher levels of the sIL-1RA, IL-1 β, and IL-6 and although the differences did not reach statistical significance (Table 1).

Zn supplementation administered to 12 CF patients (one subject dropped) resulted in a significant ($P = 0.05$) reduction in the number of days of oral antibiotics use per year compared to the 13 patients on placebo. However, the response to Zn supplementation was different for the Zn inadequate versus Zn adequate CF patients. Average days of antibiotic use for the Zn adequate CF subjects given Zn were not different from those given the placebo ($P = 0.55$; Table 2). This is in contrast to the response from the Zn inadequate CF subjects in which the effect of Zn supplementation was significantly greater ($P = 0.025$) compared to those given placebo (Table 2).

Compliance of Zn adequate CF subjects given Zn was less than placebo treated Zn adequate subjects (Table 2).

TABLE 1—Baseline Characteristics of Subject Population

Parameter	Zinc adequate subjects (n = 13)	Zinc inadequate subjects (n = 13)	*P*-value

TABLE 2— Number of Episodes Requiring Antibiotics, Number of Days of Oral Antibiotic Usage and Compliance in Zinc and Placebo Supplemented Subjects With Cystic Fibrosis

	Zinc adequate subjects			Zinc inadequate subjects		
Parameter	Placebo (n = 7)	Zinc (n = 5)	*P*-value	Placebo (n = 6)	Zinc (n = 7)	*P*-value
No. of episodes req. i.v. AB[1]	0.57 ± 0.53[2]	0.40 ± 0.55	0.559	0.17 ± 0.41	0.14 ± 0.37	0.915
No. of episodes req. oral AB[3]	3.28 ± 2.9	2.6 ± 0.89	0.574	3.16 ± 1.6	1.57 ± 0.97	0.049
%Compliance[4]	92.8 ± 7.6	66.7 ± 21.1	0.012	81.4 ± 18.8	70.3 ± 37.7	0.566
Avg. days/year Req. oral AB[5]	49.1 ± 36.6	37.4 ± 6.0	0.55	47.5 ± 24.3	20.5 ± 12.8	0.025

[1]Average number of episodes/year requiring intravenous (i.v.) antibiotics.
[2]Values represent Mean ± S.D.
[3]Average number of episodes/year requiring oral antibiotics.
[4]Average percent compliance.
[5]Average days/year requiring oral antibiotic use.

However, overall compliance of the two groups of Zn treated subjects was similar. Moreover, Pearson correlation coefficient indicated no correlation between compliance and number of days of oral antibiotic usage in all Zn supplemented subjects ($r^2 = 0.025$). There were no adverse events identified for any of the subjects in this study from oral or i.v. antibiotic use, Zn or placebo supplementation or any other parameter associated with this study.

Analysis of pre- versus post-values for each parameter resulted in non-significant percent change compared to baseline in selected parameters between the Zn supplemented and placebo supplemented group (Table 3). This was more likely due to the small number of patients and the large standard deviation within each group consisting of both Zn inadequate and and Zn adequate CF patients. In Zn treated CF patients, Zn supplementation was associated with less increase in plasma IL6 and IL-8, and a greater increase in plasma sIL-1ra and the ex vivo generation of IL-2 (Table 3). This may indicate an anti-inflammatory role of Zn in this group of patients.

TABLE 3— Percentage Increase (Decrease) in Selected Parameters Obtained From Zinc and Placebo Supplemented Cystic Fibrosis Subjects

Parameter	Placebo Tx (n = 13)	Zinc Tx (n = 12)	*P*-value[1]
Pl[2]. Zn (μg/dl)	8.6 ± 22[3]	6.1 ± 9.4	0.73
Pl. sIL-1ra (pg/ml)	1.9 ± 141	11.4 ± 101	0.84
Pl. sTNFR1 (pg/ml)	9.7 ± 56	8.1 ± 27	0.93

DISCUSSION

A number of investigators have reported conflicting relationships between Zn status and malabsorption, impaired growth, or pulmonary function in CF patients.[5,19,21,24,25–28] Few studies found no correlation between Zn levels and nutritional or pulmonary status[19,25] Other reports found abnormal Zn status in certain patients with CF especially those with moderate to severe growth retardation and severe pulmonary disease.[26–28] Low plasma Zn in CF was also associated with low plasma IL-2 levels, and an impairment of NK cell activity and low thymulin activity.[21] Thymulin activity, necessary for the development of IL-2 producing T lymphocytes, was dependent upon the presence of the Zn molecule being present in the thymulin peptide structure.[29] An increase in the number of CD3+ lymphocytes positive for IL-2 after stimulation has been reported in CF but was not correlated with Zn status.[30] In this present study, isolated PMNC from Zn supplemented CF patients had increased ability of generating IL-2 over the time compared to those from subjects administered placebo.

While some studies showed an association between Zn deficiency, growth retardation and malnutrition in a subset of patients with CF, our group of CF subjects did not appear to be ''Zn deficient'' but had plasma Zn levels still within clinically acceptable normal range.[23] Based on our long term studies in trace metal research, we have found that subjects with plasma levels of <90 μg/dl are more likely to suffer adverse reactions to immunological challenges such as cold, flu and infections than those subjects with plasma Zn levels above this range. In this study, Zn inadequate CF subjects exhibited lower baseline levels of plasma sIL-1ra, sTNFR1, IL-1β, IL-6, and IL-8 than their Zn adequate counterpart. One hypothesis may be that in CF subjects with low plasma Zn levels, maintainence of immunological surveillance is decreased in the absence of acute exacerbation. In CF subjects with inadequate Zn status, Zn therapy was associated with

FOI 26-3132 - Document 5

significantly fewer days of oral antibiotics and insignificant change in plasma inflammatory cytokines pre- to post-therapy than their Zn adequate counterpart. However, the small number of subjects and large SD for selected parameters are not optimal for determination of a greater beneficial effect for Zn inadequate subjects compared to their Zn adequate counterpart. Changes in plasma Zn levels, weight, height, FEV1, and Hgb in CF receiving Zn were not different from the placebo treated CF group. This suggests that the dose of Zn (30 mg/day) may not have been sufficient to affect growth rate or other parameters of lung function due to possible suboptimal absorption of Zn from the gastrointestinal tract. Slightly higher dose of Zn (no greater than 45 mg) may produce a more favorable response on anthropometric, and lung function measures. In patients with SCD in which loss of Zn due to red cell destruction and hyperzincuria leaves approximately 70% of SCD subject with mild to moderate Zn deficiency, supplemental Zn in dosages of 50–75 mg/day are required to reduce incidence of infection and the presence of endogenous plasma inflammatory cytokines.[31] Supplemental Zn at 45 mg/day has been shown to reduce the incidence of infection and reduce plasma inflammatory cytokines in the elderly population even in the absence of active infection[18] and to reduce the presence of oxidative stress markers in young adults without adverse effects or changes in copper levels.[16] Various studies in developing countries that used relatively high doses of Zn, ranging from 88 to 150 mg per week, in pre-school children for up to 15 months have reported significant reduction respiratory and gastrointestinal infections with out adverse effects.[32,33]

Several studies reported increased plasma and bronchoalveolar lavage fluid (BALF) levels of various cytokines such as IL-8 in patients with CF even in newly diagnosed infants with and with out documented airway infections.[10,34–39] One report showed increased IL-8 in plasma and BALF and increased in sera IL-8 was associated with age in CF subjects as compared to serum IL-8 from normal children which decreases with age.[35] Along with IL-8, increased TNF-α is also found in BALF samples from CF subjects and similar to IL-8, is inversely correlated to lung function FEV1.[34] BALF levels of both IL-8 and TNF-α tend to decrease with antibiotic therapy. Compared to normal controls, other dysregulations of immune function have been reported in CF subjects such as decreased plasma IL-10 in response to antigenic stimuli,[40,41] increased plasma adhesion molecules sICAM and sE-selectin,[42] and decreased IL-8 production in isolated T cells.[30] In other studies, results reflect data obtained from CF populations separated into groups of responders versus non-responders based on the cytokine studied. However, rarely has the Zn status of these patients been considered even though some subjects with CF are known to exhibit lower plasma Zn levels. Studies performed in non-CF adults and elderly demonstrate that plasma levels of inflammatory cytokines and oxidative stress markers are reduced following Zn therapy[16–18,31] and provide support for Zn as an anti-inflammatory agent in CF.

Results of our research in humans and in cell models indicate the effect of Zn in reducing inflammatory cytokines is at the mRNA level and involves inhibition of NF-κB activation.[43] HL-60 cells, (a promyelocytic cell line) rendered Zn deficient and then stimulated with LPS, produce significantly greater amounts of TNF-α, IL-1β and IL-8 than those cells that were Zn sufficient.[43] Activation of the NF-κB pathway by *P. aeroginosa* in subjects with CF and in CF animal models can lead to an overproduction of adhesion molecules, inflammatory cytokines (IL-1β, TNF-α, IL-6, and IL-8), and oxidative stress molecules, which in turn continue to provide stimulus for further NF-κB activation and the relentless vicious cycle.[44,45]

The most significant observation in this present study was the association of Zn supplementation with the reduction in the average days of oral antibiotic usage required to treat RTIs particularly in Zn inadequate subjects. It is possible that a more profound effect of Zn than inflammatory cytokine reduction was to modulate the airway environment. The effect of Zn on pulmonary function also include such events as inhibition of NADPH oxidase which generate extracellular superoxide anions[11] and the restoration of chloride secretion across the CF airway epithelia independent of changes in the CFTR as has been demonstrated in the CF mouse model.[13] In the CF mouse model, direct application of ATP and Zn was shown to trigger calcium entry via the P2X purinergic receptor channels leading to the activation of calcium-dependent chloride channels, circumventing the defective cyclic AMP dependent CFTR chloride channel.[13] Zn therapy can also modulate pulmonary sodium absorption via epithelial sodium channel (ENaC) directly and through the regulation of redox conditions.[46] The height of the airway surface liquid lining the apical side of the respiratory epithelium is tightly regulated and involves a balance between sodium absorption by ENaC and chloride secretion by the CFTR in normal children or by activation of the calcium-dependent chloride channel in CF with defective CFTR. Inducing ''near normal'' airway environmental conditions by Zn in CF would provide for suboptimal condition for infectious organisms.[47]

In summary, we have provided evidence that 30 mg/day supplemental Zn was associated with reduction in the number of days of oral antibiotics used to treat RTI and marginal reduction in the level of plasma inflammatory cytokines in children with CF. Our study has several limitations. The number of patients with CF was not large enough to enhance the potential differences between the treated groups. As a result, this study can be considered as

FOI 26-3132 - Document 5

a pilot study providing preliminary data for power analysis for future studies designed with larger number of subjects. Slightly higher doses of Zn therapy may be needed to statistically change anthropometric measures, lung function, the level of plasma inflammatory cytokines, and attenuate the severity of pulmonary exacerbations in subjects with CF. Finally, the effectiveness of Zn therapy may be optimally determined by assessing cytokine levels in BALF or sputum samples which would more directly representative of inflammation in the compartmentalized CF airways. Further investigations are needed to understand the role of Zn in mediating pulmonary infection in CF subjects.

Abstract

Researchers around the world are working at record speed to find the best ways to treat and prevent coronavirus disease 2019 (COVID-19). This study aimed to evaluate the efficacy of ivermectin for the treatment of hospitalized mild to moderate COVID-19 infected patients. This was a randomized open-label controlled study that included 164 patients with COVID-19. Patients were randomized into two groups where Group 1 (Ivermectin group) included patients who received ivermectin 12 mg once daily for 3 days with standard care and Group 2 (control group) included patients who received standard protocol of treatment alone for 14 days. The main outcomes were mortality, the length of hospital stay, and the need for mechanical ventilation. All patients were followed up for 1 month. Overall, 82 individuals were randomized to receive ivermectin plus standard of care and 82 to receive standard of care alone. Patients in the ivermectin group had a shorter length of hospital stay (8.82 ± 4.94 days) than the control group (10.97 ± 5.28 days), but this was not statistically significant ($p = 0.085$). Three patients (3.7%) in each group required mechanical ventilation ($p = 1.00$). The death rate was three patients in the ivermectin group (3.7%) versus four patients (4.9%) in the control group without any significant difference between the two groups ($p = 1.00$). Although there was no statistically significant difference in any endpoints by ivermectin doses (12 mg/day for 3 days); there was an observed trend to reducing hospital stay in the ivermectin-treated group.

KEYWORDS

COVID-19, chloroquine, ivermectin, mortality, treatment

1 | INTRODUCTION

Coronavirus disease 2019 (COVID-19) is caused by a novel coronavirus called severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which was first recognized amid an epidemic of respiratory illness cases in Wuhan City, Hubei Province, China. It was originally reported to the World Health Organization (WHO) on December 31, 2019. The WHO declared COVID-19 a global pandemic on March 11, 2020.[1,2]

COVID-19 management depends on the severity of the disease. Mild cases usually recover at home, whereas moderate and

 © 2021 Wiley Periodicals LLC

FOI 26-3132 - Document 5

severe cases should be monitored closely and sometimes need hospitalization.[3–5]

Developing an effective therapy for COVID-19 infection is a complex process. Several immunotherapies, antiviral agents, and vaccines continue to be studied and developed as potential therapies for COVID-19.[4,5]

In March 2020, the WHO declared COVID-19 a global pandemic and an increasing number of cases of COVID-19 have been reported worldwide including in Egypt. The repurposing of commercially available COVID-19 pharmaceutical drugs has contributed to the production of hundreds of trials around the world.[1–11] Egyptian protocols to treat COVID-19 infection have mainly relied on many potential drugs, including, hydroxychloroquine, remdesivir, nitazoxanide, oseltamivir, favipiravir, lopinavir/ritonavir, and ivermectin.[11]

Ivermectin, in vitro, is an inhibitor of SARS-CoV-2 which is able to lead to approximately 5000-fold reduction in viral RNA at 48 h.[10] This beneficial mechanism of ivermectin on the COVID-19 virus was not known until recently and it was thought that it behaved in the same manner as other viruses. The nuclear importation of virus and host proteins has been known to be inhibited. Virus integrase protein and importin (IMP) alpha/β1 heterodimer is responsible for nuclear import, further increasing infection are also, inhibited.[10–26]

Ivermectin may be a safe, affordable, and readily available therapy of COVID-19. Therefore, the use of ivermectin warrants the rapid implementation of controlled clinical trials to assess the efficacy against SARS-CoV-2.[5] There were observational studies suggesting a beneficial effect of ivermectin in the treatment of COVID-19. So, we aimed in this study to evaluate the efficacy and safety of ivermectin in the treatment of COVID-19.

2 | METHODS

2.1 | Study design and participants

This was a 1:1 randomized, open-label, parallel-group clinical trial of ivermectin versus standard of care for the treatment of hospitalized patients with COVID-19. The study took place between March 2020 and October 2020 at Tanta and Assiut University Hospitals, two tertiary hospitals in Egypt. The study was conducted in isolation units in both hospitals.

All adult patients from ages 20 to 65 with mildly to moderately affected COVID-19 infection confirmed by pharyngeal swab polymerase chain reaction (PCR) were included in the study. Patients who had an allergy or contraindication to the drugs used in the study, pregnant and lactating mothers, and patients with cardiac problems were excluded from the study.

2.2 | Randomization

The included patients were randomized using a computer random number generator to select random permuted blocks with a block size of eight and an equal allocation ratio. Sequentially numbered, opaque, sealed envelopes were used to ensure concealment. Three members of the study team (Soliman S, Mai Khalaf, and Eslam Saber Esmail) recruited, enrolled, and assigned participants to a computer-generated randomization sequence, held by an independent observer. During randomization, the proportional allocation of each clinical stratum was equalized in both groups. The included patients were first stratified according to their age (18–25, 26–40, 40–55, and >55), then by their gender (inside each stratum into males and females) and then their associated morbidities (absent and present). We tried to keep the randomization equalized inside each stratum as much as we could.

2.3 | Procedures

Patients and physicians were aware of the assigned treatments. The patients were divided into two groups:

Group1: (Ivermectin group) 82 patients who received a single dose of oral ivermectin tablets (12 mg) every day for 3 days added to the standard protocol of treatment according to the Egyptian Ministry of Health (MOH) protocol of COVID-19 treatment.[11] Ivermectin tablets (Iverzine tablets, Unipharma) were used in the study.

Group 2: (Control group) 82 patients received standard protocol of treatment alone for 14 days. All patients were followed up for 1 month. All participants were submitted to the following demography: age, sex, weight, and height measurements and calculation of body mass index (BMI), history-associated symptoms and co-morbidities, clinical examination, and medication history. The following blood tests were done for all the patients in the trial including CBC analysis (WBCs-lymphocytes-PLTs-hemoglobin), liver function tests, Chest X-ray, PCR for pharyngeal swab and ECG, computed tomography according to CO-RADS score.[26]

The Egyptian MOH adopted a standard of care treatment protocol for patients with COVID-19. It included paracetamol, oxygen, fluids (according to the condition of the patient), empiric antibiotic, oseltamivir if needed (75 mg/12 h for 5 days), and invasive mechanical ventilation with hydrocortisone for severe cases if PaO_2 less than 60 mm Hg, O_2 saturation less than 90% despite oxygen or noninvasive ventilation, progressive hypercapnia, respiratory acidosis (pH < 7.3), and progressive or refractory septic shock.[11] Any side effects of the studied medication were assessed using by questionnaire done by the patients or their guardians.

2.4 | Outcomes

The primary outcome was the assessment of clinical efficacy of ivermectin in the form of the analysis of all-cause mortality within 1 month after randomization and the secondary outcomes were the length of hospital stay, the need for mechanical ventilation, and the assessment of the safety of ivermectin.

2.5 | Ethical considerations

The study was approved by the Tanta University faculty of medicine ethical committee and was registered on clinicaltrial.gov with registration number (NCT04403555). Informed consent was obtained from all participants in this study. Privacy of participants and confidentially of the data were assured. Risks and benefits were declared and any unexpected risks which appeared during the course of the research were cleared to participants and the ethical committee on time.

2.6 | Statistical analysis

The primary analysis was done based on an intention-to-treat basis including all randomly assigned individuals. By the time of planning this study, there were very few pre-print pilot studies of ivermectin on humans (e.g., The study by Gorial et al.[16]) The study included all the eligible patients who agreed to participate. The calculated post hoc sample power was 0.80 based the following inputs: two-tailed sample power, 0.44 effect size, 0.05 α error probability, and 82 as the sample size in each group (the outputs were: 3.02 as noncentrality parameter δ, 1.97 as critical t, 162 as df).[21]

The normality of the variables was tested by the Shapiro–Wilks test. Data were analyzed by Statistical Package for Social Sciences (SPSS) V. 23 and were expressed in number (No), percentage (%) mean ($\bar{x}$), and standard deviation (*SD*). Student's *t*-test was used for normally distributed continuous variables and Mann–Whitney's test for not normally distributed variables. A χ^2 test (with Z test to compare column proportions) was used to study the association between categorical variables, and whenever any of the expected cells were less than five, Fisher's Exact test was used. Binary logistic regression was used to ascertain the effect of the potential I risk factors on the patients' mortality. The regression model was a simple one including one variable at each time. The included risk factors were age, gender, smoking, alanine aminotransferase (ALT), albumin, creatinine, ferritin, C-reactive protein (CRP), need for mechanical ventilation, diabetes mellitus, and ivermectin treatment. All the variables were continuous except for gender, smoking, need for mechanical ventilation, presence of diabetes, and treatment with ivermectin (each was of two categories only). Two-sided p value of less than 0.05 was considered statistically significant.

3 | RESULTS

A total number of 170 patients with mildly to moderately affected COVID-19 infection confirmed by pharyngeal swab PCR were invited to the study. Eight patients refused to complete the study, 164 patients were enrolled and they were randomized to receive ivermectin plus standard of care (82 patients) and 82 to receive standard of care alone. All the patients continued the study medications to the end of the duration of treatment and follow-up.

TABLE 1 Patients' characteristics and clinical presentation at baseline

Variable	Ivermectin (n = 82) No. (%)	Control (n = 82) No. (%)	p value (of χ^2)
Age (mean ± *SD*)	42.38 ± 16.02	39.38 ± 16.92	0.23[a]

The studied groups were matched for age and gender. The mean was 42.38 ± 16.02 year for Group 1 and 39.38 ± 16.92 for Group 2 (p = 0.231). Males represented 45.1% of Group 1 and 54.9% of Group 2 (p = 0.212) (Table 1). They had no significant difference regarding the presence of comorbidities (p = 0.160). Among Group 1, 20.7% had diabetes and 21.9% had hypertension or other cardiovascular diseases, while among Group 2, 12.2% had diabetes and 17.1% had

TABLE 2 Clinical course of the disease

Clinical course	Ivermectin (n = 82) No. (%)	Control (n = 82) No. (%)	p value
Length of hospital stay (in days) mean (*SD*)	8.82 ± 4.94	10.97 ± 5.28	0.08[a]
Need for mechanical ventilation	3 (3.7)	3 (3.7)	1.00[b]
Fate within 1 month			
Survived	79 (96.3)	78 (95.1)	1.00[b]
Died	3 (3.7)	4 (4.9)	

[a]Mann–Whitney test.
[b]Fisher's Exact test.

hypertension or other cardiovascular diseases. The clinical signs and symptoms of the disease did not show any significant difference between the two groups. Moreover, the laboratory tests did not show any significant difference between the two groups.

The ivermectin group had a shorter hospital stay (8.82 ± 4.94 days) than the control group (10.97 ± 5.28) but this was not statistically significant (p = 0.085). Three patients (3.7%) needed mechanical ventilation in each group (p = 1.00). Death among patients of the two groups did not show any significant difference either, as three patients (3.7%) died in the ivermectin group and four patients (4.9%) died in the control group (p = 1.00) (Table 2).

The univariable regression analysis showed that the patients' age, ALT, creatinine, ferritin, and CRP were independently related to the patients' mortality (p = 0.004, 0.001, < 0.001, 0.008, and < 0.001, respectively) (Table 3). Mild side effects were recorded; they were minimal in the ivermectin group with nausea in one patient and diarrhea in two patients. Ivermectin was not significantly related to the patients' mortality (p = 0.700).

TABLE 3 Univariable binary logistic regression analysis of predictors of mortality (each raw represents a separate model with one predictor)

	Univariate			
			95% CI	
Variable	p value	OR	Lower	Upper
Age	0.004	1.100	1.032	1.174
Gender	0.583	0.652	0.141	3.008

Need for mechanical ventilation	0.99	–	–	–
DM	0.07	4.156	0.874	19.75
Ivermectin	0.70	0.741	0.160	3.417

Abbreviations: ALT, alanine transaminase; DM, diabetes mellitus; CI, confidence interval; OR, odds ratio.

4 | DISCUSSION

The purpose of this randomized controlled trial was to determine the effectiveness and safety of ivermectin in COVID-19 therapy. Our study involved 164 patients who met the enrollment criteria and were enrolled and randomized to the ivermectin group (n = 82) or the control group (n = 82). The baseline demographic and clinical presentations in the two studied groups were similar without any significant difference. The laboratory parameters and the radiological findings were not significantly different either. In this study, the two groups did not show any statistically significant difference in clinical outcomes. Although there was no statistically significant difference, a trend to reducing the length of hospitalization was observed in the ivermectin. This favorable outcome of ivermectin was in accordance with Ahmed et al.[12] and Elgazzar et al.,[13] who observed that early incorporation of ivermectin to the standard of care was very successful for the treatment of COVID-19 patients with shortened hospital stay duration; and was even associated with higher viral clearance.[12] Also, a pilot study by Chaccoura et al.[22] showed a tendency to lower viral loads in the ivermectin group as well as a tendency to lower IgG titers. This result may be due to its effect on the suppression of a number of inflammatory cytokines contributing to the "storm of cytokines" and then all disease squalls.[10]

In a nonrandomized study by Gorial et al.,[16] the addition of ivermectin to hydroxychloroquine significantly shortened the length of hospital stay in comparison to hydroxychloroquine alone. Also, three recent clinical trials confirmed the beneficial impact of the addition of ivermectin to the standard of care for the outcome of decreasing hospital stay.[17] However, Podder et al.[18] and Chachar et al.[19] did not demonstrate any benefit of the addition of ivermectin to the treatment of COVID-19 in relation to our observations.

The ivermectin group did not show any significant difference either in the need for mechanical ventilation (p = 1.00) or the patients' mortality (p = 1.00) from the control group. In contrast, Elgazzar et al.,[13] showed that ivermectin treatment was associated

FOI 26-3132 - Document 5

with lower mortality during treatment of COVID-19, especially in patients with severe pulmonary involvement.

The addition of ivermectin to the treatment protocol in our study did not show any significant association with the patients' mortality by univariate binary logistic regression analysis ($p = 0.700$, odds ratio 0.471; 95% confidence interval: 0.160–3.417). However, other risk factors like the patient's age, serum ALT, creatinine, ferritin, and CRP being significantly related to all-cause mortality may be attributable to the small dose of ivermectin. Accessible pharmacokinetic evidence from clinically significant and excessive dosage trials indicates that the concentration of ivermectin needed to suppress SARS-CoV-2 in humans with known dosing regimens is unlikely to be reached in serum and tissue.[20–30] Pott-Junior et al.[24] as well as Babalola et al.[25] supported our results that higher doses of ivermectin may have a greater antiviral effect, but also showed that supra-lethal toxic doses are unnecessary to inhibit viral replication.

Owing to the scarce resources of our developing country, the limitations of research outcomes may depend primarily on the patients' health conditions, the need for intensive care unit entry, and the consequences of mortality, and not the viraemic response. Another drawback is the small ivermectin dosage which we recommend to be increased in further trials. Small sample size, lack of blindness, and lack of placebo group were additional limitations to our study.

In conclusion; the usage of ivermectin did not achieve significance for any of the endpoints. However; there was an observed trend to reducing hospital stay in the ivermectin-treated group. These findings may suggest using ivermectin as an add-on therapy to protocols used for the treatment of COVID-19. However, these results are needed to be validated in a larger prospective follow-up study.

CONFLICT OF INTERESTS

All the authors declare that there are no conflict of interests.

Pharmacokinetics and pharmacodynamics of the tetracyclines including glycylcyclines

Kenneth N. Agwuh[1] and Alasdair MacGowan[2]*

[1]Department of Medical Microbiology, Old Medical School, Leeds General Infirmary, Great George Street, Leeds LS1 2EX, UK; [2]Bristol Centre for Antimicrobial Research & Evaluation, Department of Medical Microbiology, Southmead Hospital, Westbury-on-Trym, Bristol BS10 5NB, UK

The pharmacokinetics of tetracyclines and glycylcyclines are described in three groups. Group 1, the oldest group, represented by tetracycline, oxytetracycline, chlortetracycline, demeclocycline, lymecycline, methacycline and rolitetracycline is characterized by poor absorption after food. Group 2, represented by doxycycline and minocycline, is more reliably absorbed orally, while group 3, represented by the glycylcycline tigecycline, is injectable only, with an improved antibacterial spectrum compared with the tetracyclines. Though incompletely understood, the pharmacodynamic properties of the tetracyclines and glycylcyclines are summarized.

Keywords: pharmacokinetics, pharmacodynamics, tetracyclines

Introduction

The tetracyclines including the glycylcyclines represent a large group of antibacterials, some of which were first introduced into clinical practice in the 1950s (tetracycline) while others have recently been approved (the glycylcycline, tigecycline) or are in pre-clinical development (the aminomethylcycline, PTK 0796). Given the duration over which these drugs have been developed and clinically used it will be no surprise that the available information on the pharmacokinetics of individual agents is patchy and comparisons are often difficult. There is also a lack of robust information on the pharmacodynamic properties of the class; the last member to be introduced into clinical practice, minocycline, in the early 1970s, pre-dates the development of modern pharmacodynamics concepts by more than a decade.

In general the tetracyclines can be divided into three groups based on their pharmacokinetic and antibacterial properties.

Group 1: This group consists of the older agents which have reduced absorption and are less lipophilic than newer drugs in group 2. Examples are tetracycline, oxytetracycline, chlortetracycline, demeclocycline (demethyl chlorotetracycline), lymecycline, methacycline and rolitetracycline. All can be administered orally except for rolitetracycline.

Group 2: These drugs are more or less completely absorbed and are 3–5 times more lipophilic than drugs in group 1. This may improve their tissue distribution but convincing data is absent. They are available in oral and intravenous formulations. Examples are doxycycline and minocycline.

Group 3: This group includes the developmental compounds aminomethylcyclines (e.g. BAY73-6944/PTK 0796) which are yet to enter clinical trials and the recently approved glycylcycline tigecycline. These antibiotics are active *in vitro* against many bacteria with acquired resistance to tetracyclines.

In this review we will concentrate on the pharmacokinetics of each group in turn and then discuss the pharmacodynamics of the class as a whole. The focus is primarily on the older tetracyclines as there are a number of reviews of tigecycline already published and more importantly new data will become available for this drug over the next few years. The data presented on tetracyclines should make it possible to place tigecycline in an appropriate context. With the older agents, it is important to note that the antibiotic assay methodologies used may not meet present standards; this may be partly responsible for the difference noted between studies.

Pharmacokinetics

Group 1: tetracycline, oxytetracycline, chlortetracycline, demeclocycline, lymecycline, methacycline and rolitetracycline

HPLC assays and spectrofluorometric methods are available for most of these agents[1,2] but many investigators have used microbiological assays.[3,4] A range of formulations is available, but rolitetracycline is the only one to be available as intravenous only. In many European markets these drugs are only available

			300	4–6						

in oral formulations. Topical preparations are also marketed, but are not discussed here.

Absorption, distribution, metabolism and excretion

Absorption is variable ranging from 0% to almost 90%; however, for most agents it is in the range 25–60%.[5] Serum concentrations rise slowly after oral administration with absorption occurring in the stomach, duodenum and small intestine. C_{max} (mg/L) depends on dose, but is generally in the range 1–5 mg/L (Table 1). t_{max} is in the range 2–4 h except for demeclocycline whose C_{max} is delayed until 4–6 h.

All these tetracyclines form insoluble complexes with calcium, magnesium, iron and aluminium, which markedly reduces absorption.[14] The effect of disease on the absorption of these drugs is unknown. Protein, fat and carbohydrate meals reduce the absorption of tetracycline by about 50%.[2] The volume of distribution (V) for these agents is in the order of 1.3–1.7 L/kg or a total volume of distribution of 100–130 L. These data imply some concentration in tissues; however, most data on tissue penetration are of poor quality, making firm conclusions about their relative distribution difficult. Protein binding is variable. None of these agents undergoes metabolism with the exception of tetracycline, 5% of which is excreted as the metabolite Δ-epitetracycline.[1] Unchanged drugs are excreted by renal and bilary routes. Renal elimination (CL_R) is related to glomerular filtration for most agents, the exception being chlortetracycline.[15,16] The amount of drug excreted in the urine is <50%; rolitetracycline is said to have high renal elimination. Greater than 40% appears in the faeces after biliary elimination and most drugs have some enterohepatic circulation.[5] Biliary concentrations can exceed blood by a factor of 5.[17]

Serum concentration time profiles

Tetracycline concentrations in blood follow a plateau-shaped course with a slow rise and a slower drop,[6] the serum half-life ($t_{1/2}$) being in the range 6–10 h for tetracycline, oxytetracycline, chlortetracycline and lymecycline. The half-lives of demeclocycline and methacycline are longer, 10–17 h. There has been little formal assessment of dose-linearity with these drugs, but serum concentrations clearly increase with increasing dose.[12] There is very little data on areas under the serum time curves, but 300 mg of tetracycline or lymecycline produced AUCs of 26.9 ± 6.0 and 21.9 ± 4.3 mg·h/L, respectively.[11] Five hundred milligrams of tetracycline on an empty stomach, as tablets or dissolved in water, produced average AUC in the range 55–75 mg·h/L.[2]

Special groups

There are no data on the effect of age, sex, obesity or low body weight on the pharmacokinetics of these drugs. There are no data on the effect of infection, other co-morbidities or liver impairment with the agents. Exercise increases serum concentrations and reduces renal clearance of tetracycline but the clinical significance of this is hard to judge.[18]

Renal failure is known to reduce the elimination of tetracycline[16] but not chlortetracycline where the serum half-life in patients with chronic renal failure is similar to those with normal renal function.

Group 2: doxycycline and minocycline

There is a significant published database on the pharmacokinetics of doxycycline[19–22] and minocycline[20]—therefore, these agents will be discussed separately.

Doxycycline

HPLC, biological and fluorometric assays for doxycycline have been described.[2,20,23,24] At present, only the oral formulation is available in most countries, though an iv form of doxycycline has been developed and used clinically.

Absorption, distribution, metabolism and excretion

Doxycycline is said to be almost completely absorbed with a bioavailability of more than 80%[19] with an average of ~95%.[20] However, some authors comparing intravenous (iv) and oral (po) doses of doxycycline felt absorption was lower—in the range 73–77%.[25] Absorption takes place in the duodenum.[20]

100 iv	6.9 ± 0.7	–	16 ± 2	8.8 ± 9	0.7 ± 0.1	30 ± 3	14 ± 3	14 ± 2	–	36

The half-life of absorption is 0.85 ± 0.41 h.[29] The peak concentration (C_{max}, mg/L) varies with dose being 15.3 mg/L 4 h after a dose of 500 mg orally (Table 2).[37]

Doxycycline–metal ion complexes are unstable at acid pH, therefore more doxycycline enters the duodenum for absorption compared with the earlier compounds.[38] In addition, food has less effect on absorption than on absorption of earlier drugs[10] with doxycycline serum concentrations being reduced by ∼20% by test meals compared with 50% for tetracycline.[2] The volume of distribution is 50–80 L or 0.7 L/kg (Table 2) and the protein binding is 82–93%,[19] but may be lower in some patient groups.[28] There is little good quality data on tissue penetration. In healthy volunteers, the area under the serum time curve (AUC) ratio of AUC blister/AUC serum is 54% in a suction blister fluid model.[26] All other tissue penetration depends on single time point estimations; however, penetration into sputum is 8–28% estimated over 16 h.[39] Penetration into saliva is poor while biliary concentration exceeds serum by many fold.[17,22] Penetration as assessed by a 3 h post-dose concentration measurement after a single peri-operative dose of doxycycline in orthopaedics indicated levels below that of serum in bone, skin, fat, tendons and muscle.[40] Concentrations are highest in the liver, kidney and digestive tract, that is the excretory organs.[20] There is no significant metabolism and no metabolites have been found in man.[19,20] However, in an interaction study with rifampicin, some patients had reduced doxycycline C_{max} and AUC, suggesting there may be some hepatic metabolism.[32] Doxycycline is eliminated unchanged by both the renal and biliary routes. Bile concentrations may be 10–25 times those in serum.[41] About 35–60% is excreted in urine and the remainder in faeces[12,18,30,34] (Table 2).

Serum concentration time profiles

Doxycycline is slowly absorbed orally, taking 2–3 h to reach peak concentrations. The elimination half-life is long, ranging from 12 to 25 h depending on the study (Table 2). Average AUCs for 200 mg/day oral doses range from 40–123 mg·h/L and 61–112 mg·h/L for iv doses. There is little data on dose-linearity or the effects of multiple doses on the pharmacokinetics of doxycycline.

Special groups

The pharmacokinetics of doxycycline have been studied in the elderly, undernourished patients with hyperlipidaemia, infected patients and patients with renal impairment. There are no data on the impact of sex, pregnancy, lactation or liver impairment on doxycycline pharmacokinetics.[20] The impact of age on the pharmacokinetics of 200 mg iv doxycycline was studied in 25 patients over 65 years old—mean age 76, range 65–90 years. The $t_{1/2}$ was 15 ± 9 h, AUC (mg·h/L) 194 mg·h/L and the volume of distribution 25 ± 9 L. Serum concentrations were higher than those reported in other groups with a C_{max} of 8–30 mg/L and concentrations at 10 h in the range 5–10 mg/L. The reason for these increased serum concentrations and reduced volumes of distribution is unclear.[42] Undernourished patients dosed with 200 mg iv doxycycline had lower AUC, shorter serum half-lives, serum concentrations and protein binding. Total and non-renal clearances were increased.[36] Compared with control patients, those with hyperlipidaemia had increased serum AUC and C_{max}.[31] The clinical importance and underlying pathophysiology are not determined. Exercise in young, healthy volunteers had the effect of increasing the C_{max} of 200 mg doxycycline from 4.8 ± 0.3 to 6.5 ± 0.6 mg/L and the AUC from 81 ± 5 to 106 ± 3 mg·h/L.[18] The reasons for this are unclear.

Several studies have been conducted in patients with various degrees of renal impairment and those with end stage renal disease.[28,34,41,43]

Patients with chronic renal failure have reduced urinary recovery of doxycycline and increased faecal recovery.[34,41,43] However, the serum half-life is not greatly increased, being reported in the range 20–25 h. As expected, AUCs are mostly increased for a 200 mg dose, being on average in the range 120–196 mg·h/L.[34] The C_{max} is unchanged[34] but protein binding is significantly reduced in patients with end stage renal disease.[28]

There is very limited information on the effects of haemodialysis, ∼10% of the drug was removed in a 7 h dialysis session.[43]

FOI 26-3132 - Document 5

Dose modification is probably not needed in renal impairment as the hepatic and non-hepatic gastro-intestinal elimination compensate for loss of renal clearance.

Klastersky *et al*.[44] studied the serum of doxycycline 200 mg iv, multiple doses, in patients with severe hospital infections. Peak concentrations were in the range 5–6 mg/L and troughs 1–2 mg/L, not unlike healthy volunteer data.

In more recent times, the pharmacokinetics of doxycycline in 17 patients recovering from severe *Plasmodium falciparum* malaria have been reported.[45] Patients received 200 mg of the drug orally and blood samples were drawn in the acute and convalescent phases. In the acute phase, the C_{max} (mg/L) was 3.2 (1.6–7.7); $AUC_{0–24}$ (mg·h/L) 32 (18.7–79.7); $t_{1/2}$ (h) 10.5 (6.9–17.9); and volume of distribution (L/kg) 1.4 (0.6–3.0). Equivalent values in the convalescent phase were as follows: C_{max} 4.4 (1.5–8.6) mg/L; $AUC_{0–24}$ 48.6 (18.3–69.8) mg·h/L; $t_{1/2}$ 11.6 (8.5–17.2) h and volume of distribution 0.9 (0.5–2.7) L/kg.

Minocycline

HPLC and biological assays are used to measure minocycline.[3,46] At present, there are only oral formulations available clinically as capsules, tablets, modified release capsules and suspension. An iv formulation has also been investigated.[46]

Absorption, distribution, metabolism and excretion

Minocycline is almost completely absorbed (95–100%),[20] mainly in the stomach, duodenum and jejunum. Unlike other tetracyclines, food does not appear to have an effect on either the C_{max} or AUC.[47] The kinetics of absorption of minocycline follow the same broad pattern as for tetracycline, that is after oral administration a rise to C_{max} by 2 h.[48] The C_{max} increases, with increasing dose being 0.65 mg/L after 50 mg, 2.2 mg/L after 150 mg, and 3–3.6 mg/L after a 200 mg dose[12,47–49] (Table 3). After intravenous administration, the C_{max} concentrations are 3–8.75 mg/L after a 200 mg dose.[29,51–53] Absorption is reduced by iron and antacids containing calcium and magnesium.[46] There is little data on the volume of distribution of minocycline, values of 80–115 L have been reported[53] or 1.17 L/kg.[50] Protein binding is 76%[51] and the effect of disease on protein binding has not been studied. As with other tetracyclines, there is very little good quality data on tissue penetration. However, a tissue/serum concentration ratio of >10 has been reported for liver and bile; 5–10 for duodenum, gall bladder and thyroid; and <2 for colon, bladder, prostate, uterus, breast, skin, lymph nodes and veins.[51] No minocycline has been detected in saliva and concentrations of <50% serum in CSF have been reported.[52] Minocycline is unusual for a tetracycline in that it has a variety of metabolites; up to six have been described, some of which have antibacterial activity and are found in urine. The principal metabolite is 9-hydroxyminocycline; the other two main metabolites are mono-N-demethylated derivatives. Epimerization of minocycline also results in the formation of 4-epiminocycline.[54] Little minocycline is recovered in the urine—probably 5–12% of the dose. Faecal elimination accounts for about 20–35% of the dose.[12,48,51,53] Renal clearance is about 2.2–1.2 mL/min.[50]

Serum concentration time profiles

Minocycline reaches C_{max} after 2–3 h post-oral dose and then has a prolonged serum half-life of 12–18 h.[34,48,49,53] A summary of the pharmacokinetic parameters is shown in Table 3. The AUC_{24} after a 200 mg oral dose is ∼45 mg·h/L and the equivalent $AUC_{0–\infty}$ is about 70 mg·h/L.[47,48] After a 200 mg iv dose, the $AUC_{0–\infty}$ were 70–86 mg·h/L.[50] There is little known on dose-linearity with minocycline or the effect of multiple dosing on pharmacokinetic parameters. Interesting is in one study which reported the data where the serum half-life was increased after multiple doses.[50] The reason for this is not known but may be related to saturation of excretory pathways.

Special groups

There are no data on the effects of age, sex, changes in body mass, co-morbidity or infection on the pharmacokinetics of minocycline except for a small number of studies carried out in patients with renal impairment and end stage renal disease. Renal impairment and end stage renal disease have little effect on the serum concentrations and serum half-life or AUC of minocycline[34,50,53,55] in both single dose and short multi-dosing studies. As may be expected, the urinary recovery in renal failure is <1% total dose.[34]

Group 3: Aminomethylcyclines

BAY 73-6944/PTK 0796 is a compound being investigated and is currently in pre-clinical development. In animal models it is substantially unbound in plasma at concentrations ranging from 0.5 to 10 mg/L. In the presence of liver homogenates it appears to be metabolically stable with no detectable loss of compound over 60 min.[56,57]

Table 3. Pharmacokinetics of minocycline

Dose and route	Single doe (SD) or multi-dose (MD)	Peak concentration (C_{max}) (mg/L)	Time to peak concentration (t_{max}) (h)	Half-life ($t_{1/2}$) (h)	Area under serum time curve (AUC) (mg·h/L)	Reference

CL (L/h/kg)	–	0.20 (17)	–	0.20 (9)	–	0.24 (20)
V_{SS} (L/kg)	–	8.6 (23)	–	7.2 (7)	–	9.1 (32)

C_{max}, peak concentration; AUC, area under the serum time curve; $t_{1/2}$, half-life; CL, clearance; V_{SS}, volume of distribution at steady state.

Glycylcyclines (tigecycline)

Tigecycline has been assayed by HPLC but more recently by a liquid chromatography/mass spectrometry (LC/MS) assay.[58,59] Pharmacokinetic data are available from healthy volunteer studies and also from Phase 3 clinical trials of therapy in skin and soft tissue infection and intra-abdominal sepsis, hence the data available are much more comprehensive than for the earlier drugs. As yet, there is only an intravenous formulation of tigecycline which is infused over a 1 h period.

Absorption, distribution, metabolism and elimination

There are no data on absorption of tigecycline, but its oral bioavailability is reported to be limited. A light breakfast did not have a significant effect on iv tigecycline pharmacokinetics.[60] The volume of distribution is large with initial values of volume of distribution at steady state (V_{ss}) being >10 L/kg.[61] Total volumes of distribution are ~350 L in women and 500 L in men.[58]

The more recent presentation of a dose ranging study of 12.5–300 mg as single doses or multi-dosing has added significantly to this earlier report.[62,63] For single dose exposures of 12.5, 25, 50, 75, 100, 200 and 300 mg the V_{ss} (L/kg) were 2.8, 6.4, 6.5, 7.5, 6.8, 13 and 12, respectively, indicating some dose dependency. In the multi-dose studies the V_{ss} (L/kg) for the 25, 500 and 100 mg doses were 8.6, 7.2 and 9.1, respectively (Tables 4 and 5). The reasons for these differences are at present unclear; however, in the dose range used in man 100 mg loading, then 50 mg 12 hourly, the volume of distribution is somewhere in the range 2.5–7.0 L/kg.[63] Given tigecycline's large volume of distribution there must be tissues into which it is concentrated. As yet tissue penetration data are limited; however, in 10 healthy volunteers using a cantharidin skin blister model and measuring the AUC_{0-12} in both blister fluid and serum after a 100 mg iv dose, the penetration was 74% (AUC_{0-12} blister fluid = 1.6 ± 0.2 mg·h/L; AUC_{0-24} serum = 2.2 ± 0.3 mg·h/L). The equivalent C_{max} concentrations were 0.17 mg/L in blister fluid and 0.82 mg/L in serum.[59]

Further studies in adult humans who received 100 mg iv tigecycline have indicated concentrations in lung tissue of 0.8 mg/L at 4 h post-dose, 0.2 mg/L at 8 h, 0.4 mg/L at 12 h and 0.4 mg/L at 24 h. There was significance between subject variability in measured drug concentrations. CSF concentrations in non-inflammed meninges were low being 5% 1 h post-infusion and 41% after 24 h. As may be expected, bile concentrations were high, ranging from 0.16–4.37 mg/L, with bile/serum ratios in the range 606–1997. This is consistent with biliary excretion of tigecycline.[64]

Radiolabelled tigecycline has been administered to Sprague-Dawley rats as a single infusion to study the drug distribution.[65] As expected peak radioactivity was seen at the end of infusion in all the tissues. AUC values were highest in the bone, bone marrow, salivary gland, thyroid, spleen and kidney. The tissue AUC/plasma AUC was >1 for most tissues over the 168 h of the experiments. The tissue/plasma ratios were 2046 for bone, 149 for bone marrow, 90 for thyroid, 45 for spleen and 24 for liver. The high ratio in bone may be related to calcium binding.[65]

Downloaded from https://academic.oup.com/jac/article/58/2/256/718565 by guest on 16 March 2023

FOI 26-3132 - Document 5

Tigecycline protein binding ranges from 73% at 0.1 mg/L to 79% at 1 mg/L, the reason for this atypical pattern is as yet unknown.[63] The metabolism of tigecycline in man has been studied using radiolabelled tigecycline.[66] There are two major metabolic pathways, the main route being glucuronidation and its inactive epimer producing 5–20% of the radioactivity in human serum. An N-acetyl-9-aminominocycline metabolite is also formed to a less degree.[66] At least five human metabolites have been described in urine, serum, faeces and plasma.[60] Less than 15% of tigecycline is excreted unchanged in the urine[61,67] and renal clearance accounts for <20% total clearance.[60] Radiolabelled tigecycline studies in man indicated that 59% of the radioactivity was found in faeces and 32% in urine. This presumably means that, like some other tetracyclines, there is biliary excretion and perhaps also an enterohepatic circulation.

Serum concentration pharmacokinetic profile

The serum values of the C_{max} (mg/L), AUC (mg·h/L), serum half-life (h) and clearance (L/kg/h) for single doses of 12.5, 25, 50, 75, 100, 200 and 300 mg and 25, 50 and 100 mg multiple doses are shown in Tables 4 and 5. The proposed dosing in man is a 100 mg loading dose followed by 50 mg 12 hourly. This will give a C_{max} of 0.62 ± 0.09 mg/L and an AUC at steady state of 3.1 ± 0.4 mg/L·h. The C_{max} of the 100 mg dose is 0.9 mg/L and the 50 mg in multi-dosing 0.62 mg/L. The half-life of the 100 mg dose is 22 h in the single dose study and 66 h in the multi-dose, equivalent values for the 50 mg dose are 18 and 38 h, indicating lengthening of the half-life with multiple doses. Drug clearance is usually ∼0.2 L/h/kg irrespective of the dose or number of doses. There is rough linearity with dose in terms of AUC and C_{max} values. Steady state is reached within 3 days.[62]

Using the single and multiple dose data from Phase 1 subject populations, pharmacokinetic models have been developed.[68] For single dose data a three-compartment model with zero order input and first order elimination adequately described the data, despite the presence of secondary peaks in some profiles. However a two-compartment model provided the most unbiased estimates of $AUC_{0–12}$ and is therefore most appropriate to multi-dose studies in patients.

Special groups

The effects of age, gender, excretory organ failure and infection on the pharmacokinetics of tigecycline have been studied. The effect of age and gender has been studied in healthy volunteers in three age groups, 18–50, 65–75 and >75 years old.[58] A single 100 mg 1 hourly infusion was given and the mean C_{max} was 0.85–1.0 mg/L in all groups. The lowest AUC was in males under 50 years (mean AUC 4.2 mg·h/L) and the highest in those over 75 years (means AUC 5.8 mg·h/L). The mean AUC for women was ∼5 mg·h/L in all the groups. Studies have been conducted on subjects with severe renal impairment (creatinine clearance < 30 mL/h) and those with end stage renal disease maintained by haemodialysis. These data were compared with those from healthy volunteers. A single 100 mg infusion over 1 h was administered. The C_{max} and AUC values are shown in Table 6. Haemodialysis had no effect on the pharmacokinetics of tigecycline and only 5% of unchanged drug was recovered from the urine of those with severe renal impairment compared with 16% from the healthy volunteers.[67]

Table 6. Pharmacokinetics of tigecycline 100 mg infusion in healthy subjects, those with severe renal impairment and those with end stage renal disease

	Peak concentration (C_{max}) (mg/L)	Area under the serum time curve (AUC) (mg·h/L)
Healthy volunteers	0.60	3.3
Creatinine clearance < 30 mL/min	0.6	4.7
End stage renal disease on haemodialysis	0.96	4.0

There are no published data as yet on the impact of liver impairment on the pharmacokinetics of tigecycline. A non-compartmental pharmacokinetic analysis was performed on 15 patients in the Phase 3 study in complicated skin and soft structure infections.[69] The dosing regimen was 100 mg loading dose on day 1 followed by 50 mg 12 hourly until day 14.

The patients' weights varied from 57 to 200 kg; mean 80 kg. The C_{max} was 0.63 ± 0.28 mg/L, C_{min} 0.16 ± 0.05 mg/L, AUC_{ss} (0–12 h) 3.04 ± 0.81 mg·h/L, total clearance 17.5 ± 4.2 L/h and CL/kg 0.22 ± 0.06 L/h/kg. These data are in very close agreement with data from treated patients with intra-abdominal sepsis and from healthy volunteers in Phase 1 and Phase 2 studies.[63,70]

Co-administration of digoxin plus tigecycline or warfarin plus tigecycline in healthy male volunteers had no impact on the pharmacokinetics of either agent.[71,72]

Pharmacodynamics

Pharmacodynamics is the relationship between measurements of antimicrobial exposure in body fluids with the antibacterial and toxicological effects of the drug.[73] The most important measure of drug potency is still the minimum inhibitory concentration (MIC, mg/L); however, several other antibacterial effect measures are important. These include the pattern of bacterial killing, persistent effects and data from *in vitro* and animal pharmacokinetic/pharmacodynamic models.[74,75] Pharmacodynamic indices (AUC/MIC, C_{max}/MIC, t > MIC) can be related to bacteriological outcomes and specific pharmacodynamic index sizes used to predict clinical outcomes and establish clinical breakpoints.[76]

In general the pharmacodynamics of tetracyclines is understudied in comparison with some drug classes such as β-lactams, fluoroquinolones and aminoglycosides. The pattern of the antibacterial killing effect of doxycycline, minocycline and tigecycline has been studied using time–kill curve methods. Doxycycline produces a 0.5 log reduction in viable count of *Staphylococcus aureus* over 24 h at a concentration of 2× MIC. Increasing the concentration to 16× MIC results in 1–2 log kill. Against *Streptococcus pneumoniae* doxycycline produces no killing over 24 h at 2× MIC but this increases to >4 log kill at the 16× MIC concentration. Doxycycline produces no net effect against *Escherichia coli* at 4× MIC concentration over 24 h, but a 3 log kill at MIC 8–16.[77] The patterns of killing of minocycline and tigecycline were compared against *S. aureus*

Downloaded from https://academic.oup.com/jac/article/58/2/256/718565 by guest on 16 March 2023

FOI 26-3132 - Document 5

(n = 9), *E. coli* (n = 6) and *Klebsiella pneumoniae* (n = 6) in time–kill curves at 4× MIC concentration over 24 h. Minocycline produced a –1.5 ± 1.0 log kill against *S. aureus*, –2.0 ± 0.8 log kill against *E. coli* and +0.3 ± 1.8 log growth with *K. pneumoniae*. Equivalent values for tigecycline were –2.0 ± 1.3 log kill for *S. aureus*, –0.7 ± 0.7 log kill for *E. coli* and +0.4 ± 1.5 log growth for *K. pneumoniae*.[92]

At the concentration designed to mimic those achievable in man, tigecycline 2 mg/L, 0.5–0.7 log reductions in *Enterococcus faecium* and 0.7–1.4 log reductions in glycopeptide intermediate *S. aureus* were observed over 24 h.[78]

MBCs (mg/L) are 2-fold higher than the MIC for *S. pneumoniae* and 2–4 times the MIC for *S. aureus* of both minocycline and tigecycline. In contrast with *Enterococcus faecalis* tigecycline's MBC is >16 times the MIC.[79,80] Tigecycline produces ≤0.5 log killing against *E. faecalis* with most strains in time–kill curves over 24 h;[81] however, kill is enhanced by the addition of serum.[77]

Bacterial inoculum appears to have a modest effect on tigecycline MICs which are 1–2 dilutions higher with 10- to 100-fold increases in inoculum.[82] Data for other tetracyclines are absent.

Persistent antibiotic effects have been studied with tetracyclines *in vitro* and *in vivo*; however, the significance of persistent antibiotic effects such as the post-antibiotic effect (PAE) remains to be established. Doxycycline has a PAE against *S. aureus*, *S. pneumoniae* and *E. coli* which increases with increasing concentrations of exposure. At 2× MIC to 4× MIC concentrations the PAE for *S. aureus* is 0.7–1.2 h, *S. pneumoniae* 2.2–2.8 h and *E. coli* 1.0–1.4 h.[77] Tigecycline has been reported to have a longer PAE than minocycline against *S. aureus* and *E. coli* by an average 0.6–2 h at 8× MIC concentrations.[83]

In vivo using a murine model, tigecycline at a dose of 3 mg/kg single dose, C_{max} 0.42 mg/L, AUC 0.68 mg·h/L, and $t_{1/2}$ 0.25 h had PAE of 8.9 h against *S. pneumoniae* and 4.9 h against *E. coli*.[79] Tigecycline's PAE against *E. faecalis* is 1–4.5 h at 1–20 × MIC concentrations using time–kill *in vitro* studies.[81]

There is very little data on the use of *in vitro* pharmacokinetic or animal pharmacokinetic/pharmacodynamic models to describe the antibacterial effects of tetracyclines. Using a hollow fibre *in vitro* model to simulate free drug serum concentrations of oral minocycline 200 mg/day in man, the 24 h antibacterial effect was a –1.8 ± 0.2 log reduction in count by 24 h against UK EMRSA-16.[84]

Similar data to those of Bowker *et al*.[84] were reported by Garrison and Neumiller[85] in their *in vitro* model where tigecycline at concentrations associated with human dosing produced a 1.5 log drop in viable counts at 24 h. Tigecycline produced a greater antibacterial effect against fluoroquinolone-resistant *S. pneumoniae* than levofloxacin and against vancomycin-resistant enterococci than vancomycin.[84]

Van Ogtrop *et al*.[79] studied minocycline and tigecycline in a murine neutropenic thigh infection model against a number of strains of *S. pneumoniae*, *S. aureus* and *E. coli*; tigecycline's MICs were 0.06–0.12, 0.12–0.5 and 0.12 mg/L, respectively. The dose of tigecycline for a 24 h static effect was 0.8–5.9 mg/kg/day with *S. pneumoniae* but 25 times greater for *S. aureus* and *E. coli* (4.3–23 mg/kg/day) despite similar MIC values. Against *K. pneumoniae* the bacteriostatic dose was higher yet at 65–151 mg/kg/day. These data with that from time–kill curves suggest that the drug exposures to clear different bacterial species with tigecycline may be different, with *S. pneumoniae* requiring the lowest exposures, *S. aureus* and *E. coli* higher and *K. pneumoniae* higher yet. In this murine model AUC and $t >$ MIC could be related to antibacterial effect using non-linear regression analysis. The drug exposure to produce 80% of maximal effect was calculated as a free drug time greater than MIC of more than 50% of the dosing interval for tigecycline.[79]

Table 7. Successes and failures in man with iv doxycycline according to bacterial species and expected MIC_{50}

Species	MIC_{50} (mg/L) of representative strains	Success	Failure
S. pneumoniae	0.1	16	1
Group A streptococci	0.2	2	0
S. aureus	0.3	4	0
E. coli	12.0	3	2
Klebsiella/Enterobacter spp.	25.0	5	7
Proteus spp.	>50.0	2	9

More recently, based on likely drug exposures in man, tetracyclines have been classified as AUC driven agents.[73] As yet no AUC/MIC static effect targets have been published for any tetracyclines or tigecycline; such data from animal or *in vitro* models would be of help in determining clinical breakpoints.[76]

There are four studies relating tetracycline serum concentrations, pathogen MIC and species to clinical outcomes. Klastersky *et al*.[44] used iv doxycycline to treat a group of about 50 patients with a variety of infections including urinary tract infection, pneumonia, wound infection and septicaemia. Peak serum doxycycline concentrations were in the range 5–6 mg/L and trough concentration was 1–2 mg/L. Table 7 shows the successes and failures by species and the MIC_{90}s of representatives of those species performed by the authors. Of those bacteria which had an MIC of ≤0.3 mg/L (26) 25 infections were cured while if the MIC was ≥12 mg/L (30) 12 infections were cured.

In a different indication, Q fever endocarditis, 16 patients were studied over 1 year. *Coxiella burnetii* MIC, doxycycline serum concentrations and serological response (phase 1, *C. burnetii*) antigens were correlated. Those patients with a serum doxycycline to MIC ratio of ≥1 showed a more rapid decline in phase 1 antibodies than those with values between 0.5 and 1. Serum AUC values were not calculated and it was obviously difficult to generalize from this infection to others.[86]

The relationship between tigecycline AUC, MIC and microbiological outcome has been explored using data from three trials in complicated skin and soft tissue infection.[87,88] Two different dose regimens were used: 100 mg load plus 50 mg 12 hourly and 50 mg load plus 25 mg 12 hourly. The serum $AUC_{0–24}$ at steady state was median 5.16, range 2.81–9.36 mg/L (high dose) and median 2.33, range 1.49–4.98 (low dose). The pathogens isolated were divided into several groups, the most useful for the analysis being all Gram-positive pathogens (n = 36). One patient who failed tigecycline had a mesh graft for a hernia repair which was not removed. This patient was, very reasonably, excluded from outcome analysis. If the AUC/MIC value was <25, 5 patients failed therapy and 10 were cured, if the AUC/MIC was >25, no patients failed and 20 were cured. Classification and regression tree (CART) analysis identified an AUC/MIC of 12.3 for both

Downloaded from https://academic.oup.com/jac/article/58/2/256/718565 by guest on 16 March 2023

FOI 26-3132 - Document 5

microbiological and clinical responses. In a further analysis including patients with polymicrobial infection and MICs of tigecycline up to 16 mg/L the probability of cure was >0.9 if the AUC/MIC was >30.[87,88]

Given an AUC/MIC breakpoint of ~12–18 for infection mainly caused by *S. aureus*, the pharmacodynamic breakpoint would be ≤0.25 mg/L,[89] which is in close agreement with the breakpoint suggested from animal models of *S. pneumoniae*, *S. aureus* and *E. coli* infection.

A similar analysis was performed on patients in three trials of complicated intra-abdominal infection (n = 71). Patients received 100 mg iv tigecycline and then 50 mg twice daily, and the median AUC was 5.6 mg·h/L. APACHE score predicted microbiological and clinical outcomes and an AUC/MIC of 6.96 was significant in CART analysis for both microbiological and clinical outcomes. An AUC/MIC of >30 was associated with >90% chance of success in the final model.[90] These data were used to try to develop a pharmacodynamic breakpoint for *E. coli*. Several AUC/MIC targets were used, 6.96, 8.4 and 11.1; there was a 95% probability that the true AUC/MIC target was between 5.7 and 11.5. For an MIC of 0.5 mg/L, the target attainment rates for AUC/MIC ratios of 6.96, 8.4 and 11.1 were 94%, 83% and 54%, respectively.[91]

Conclusions

Tetracycline and glycylcycline pharmacokinetics and pharmacodynamics represent a relatively under-investigated but interesting area of antimicrobial chemotherapy. Until recently our understanding was poor and little progress had been made until tigecycline entered clinical development. We are still unclear as to the relative importance of serum versus tissue levels in predicting outcomes for the tetracyclines and glycylcyclines but this may be important given their large volumes of distribution. Much work could be done to improve our pharmacokinetic/pharmacodynamic knowledge of these agents, and as tigecycline enters clinical use it is to be hoped that this experience will add to our knowledge in the area.

A Case Series of 100 COVID-19 Positive Patients Treated with Combination of Ivermectin and Doxycycline

MT ALAM[a], R MURSHED[b], E BHIUYAN[c], S SABER[d], RF ALAM[e], RC ROBIN[f]

Abstract:

Background: A definitive treatment of SARS CoV-2 is yet to arrive and the human death toll rises exponentially globally. In this health emergency, it might be useful to look into the old therapies which could be effective against the virus. In vitro research showed Ivermectin could decrease the concentration of coronavirus 4000 to 5000 folds in living lung tissue.

Aim: In this prospective study a combination of Ivermectin and Doxycycline will be evaluated therapeutically to treat COVID-19 patients.

Methods: 100 COVID-19 patients were enrolled in this study with a predefined inclusion and exclusion criteria. RT- PCR of the SERS-CoV-2 will be done at designated government hospitals. The clinical features and response to treatment were noted according to a dedicated protocol.

Results: In this study male and female were 64 and 36 respectively, the age ranged between 8 to 84 years. Retesting was done between 4 and 18 days of starting medication. All patients tested negative and their symptoms improved within 72 hours. There were no noticeable side effects.

Conclusion: Combination of Ivermectin and doxycycline was found to be very effective in viral clearance in mild and moderately sick COVID-19 patients. Medical societies and institutions should undertake larger multi center studies to validate and recommend this combination therapy to include in national guidelines.

Keywords: Covid-19, Doxycycline, Ivermectin

Background:

One hundred years after the Spanish flu pandemic in 1918-20, the whole world is again facing devastation due to the Covid-19 (SARS CoV-2) pandemic. This virulent virus SARS CoV-2 has high infectivity, morbidity and remarkable fatality rate. No specific treatment or vaccine has been invented to save mankind yet. Scientists, physicians and concerned multidisciplinary professional including political leaders are united to explore a quick effective treatment and vaccine before it is too late. Empirical applications of some drugs have been assumed to work with success, but without having a clinical trial, they cannot be validated. Until anything comes up, it might be useful to repurpose old therapies which could be effective against the virus.

In the beginning of April 2020, Caly et al. from Monash University, Australia published their research article stating that a single dose of Ivermectin (an anti-parasitic drug) could decrease the concentration of coronavirus in vitro. In the lab, Caly et al. bathed Vero-hSLAM cells with Ivermectin at a concentration of 5μM from 2 hours post-infection SARS-CoV-2 isolate Australia/VIC01/2020 until the conclusion of the experiment. SARS-CoV-2 RNA was determined by RT-PCR at days 0-3 in both supernatant and cell pellet experiments. The authors noted 93-99.8% reduction in viral RNA for Ivermection versus DMSO control at 24h in the supernatant (released virions) and cell associated viral RNA (total virus) respectively. They also describe by 48 hours about 5000 fold reduction of viral RNA and maintenance of effect at 72 hours.[1]

They concluded that the human dose needed to be ascertained in further studies. In the current SARS-CoV-2 pandemic, this news was a ray of hope.

FOI 26-3132 - Document 5

Methodology:

Study design

Observational /Cross-sectional study

Study Population

All RT-PCR SARS- CoV-2 positive patients fulfilling the selection criteria. Mild and moderate cases purposively selected from Bangladesh Medical College.

Selection criteria

Inclusion Criteria

- Subjects within age group 5 years and above
- With either sex, male or female
- Confirmed cases of Covid-19 by RT-PCR test
- Patients who are classified as asymptomatic,
- Mild and moderate cases with typical symptoms
- Patients who are not already treated with any other antiviral drugs

Exclusion criteria

- Patients who are severe and critically ill.
- Patients with chronic liver diseases
- Patients with pregnancy and on lactation
- Children less than 5 years of age or less than 15kg weight.

Procedure

100 patients RT-PCR confirmed cases of SARS CoV-2 met the selection criteria and was enrolled in the study. They were given a combination treatment of Tab Ivermectin and Cap Doxycycline along with supportive treatment. The dose of ivermectin was 0.2 mg/kg single dose. Doxycycline 100 mg daily was given to patients aged 8 years and above for 10 days. Patients were given the choice to go to a COVID 19 designated hospital but they went home and continued treatment. Follow up was done every day for all symptomatic patients over telephone about remission of symptoms. RT-PCR test was repeated with sample of nasal swab for all patients according to availability of testing centers between 4 to 18 days. Six weeks after testing negative, we plan to follow up on the patient about their health conditions.

Result:

This observational study, consisting of 64 males and 36 females was conducted from April to May 2020 (Figure 2) in Bangladesh Medical College. The oldest patient was 84 years and the youngest one was 8 years with most patients between the ages of 21 to 40 years (Figure 3). Patients were divided in 3 groups: Mild (73), Moderate (20) and Severe (7), based on their symptoms. From the severe patients, three had fever more than 103 Fahrenheit for seven days with severe cough and lung infiltrates , three had severe loose motion and one had uncontrolled diabetes. Out of the rest, 20 patients had moderate symptoms of mild fever (100 Fahrenheit) and mild cough. Moreover, 73 had mild symptoms of malaise, sore throat, loss of smell, loss of taste, and body ache. Fifty percent symptomatic improvement of mild to moderate patients was seen between 3rd to 5th day after starting treatment. All 7 severe patients' symptoms subsided by 50 percent by 7th day of treatment. Retesting was done between 4 to 18 days of starting medication (Figure 4). Twenty five patients underwent retesting between 4th to 8th days, 51 between 9th to 13th days and 24 between 14th to 18th days from starting medication. All of the patients tested negative. None needed intensive care admission and no deaths were reported.

Discussion:

An elderly female colleague with co-morbidities, who tested positive for SARS-CoV2, was referred to the Medicine Out Patient Department. As she was asymptomatic, she was advised isolation but she wanted to be treated without Hydroxychloroquine and Azythromycin fearing cardiac toxicity. She was informed about the recent findings on Ivermectin and agreed to take an oral combination of 200mcg/kg single dose of Ivermectin along with Doxycycline 100mg orally daily for 10 days. She tested negative in seven days.

This observation correlates with the findings of Caly et al.[1] We had given the standard single dose of Ivermectin that is normally given for the treatment of scabies and head lice although a very high dose was used in vitro. Doxycycline, a trusted antibiotic, anti-malarial, anti-typhus, and anti-viral which also decreases cytokine production without any cardiac toxicity has been a good combination in our small observational study[2]. We only treated asymptomatic and mostly mildly symptomatic patients.

Ivermectin was discovered in 1975 and came into medical use in 1981.[3,4] It is on the World Health Organization's List of Essential Medicines.[5] Ivermectin is a FDA approved drug, it is used for prevention, treatment, and control of river blindness (onchocerciasis) in populations where the disease is common. It is also used for treatment of Strongyloidosis, enterobiasis, Trichuris trichura, Loa Loa, Scabies, human lice, malaria and is also known to have wide-spectrum antiviral activity against number of viruses under in-vitro conditions. [6,7,8,9] SARS-CoV-2 is a single stranded RNA virus which is closely related to SARS coronavirus (SARS-CoV). Recent study on Ivermectin against SARS-CoV-2 under in-vitro conditions revealed that it can inhibit the viral replication. The single treatment of this drug was able to reduce the virus up to 5000-fold in Vero-hSLAM cells bathed with Ivermectin within 48 hours. However, no further reduction was reported with further increase in time period i.e up to 72 hours. Moreover, no toxicity was seen with the drug at any point of time[10]. Mechanism by which Ivermectin responded against the SARS CoV-2 virus is not known and was believed to be working similarly as it acted on other viruses. It was known to inhibit the nuclear import of viral and host proteins. Integrase protein of viruses and the importin IMPα/β1 heterodimer was responsible for IN nuclear import which further increases the infection. As most of the RNA viruses are dependent

FOI 26-3132 - Document 5

upon IMPα/β1 during infection, Ivermectin acts on it and inhibits the import with the increase in antiviral response [1,10].

Fig 1 shows a schematic of Ivermectin's proposed antiviral action on coronavirus. IMPα/β1 binds to the coronavirus cargo protein in the cytoplasm (top) and translocates it through the nuclear pore complex (NPC) into the nucleus where the complex falls apart and the viral cargo can reduce the host cell's antiviral response, leading to enhanced infection. Ivermectin binds to and destabilizes the IMPα/β1 heterodimer thereby preventing IMPα/β1 from binding to the viral protein (bottom) and preventing it from entering the nucleus. This, likely, results in reduced inhibition of the antiviral responses, leading to a normal, more efficient antiviral response[1].

Ivermectin is well tolerated by uninfected humans. It is primarily metabolized in the liver by CYP450-3A47 and has a plasma half-life of 16 hours and is almost exclusively excreted in faeces with minimal clearance by the kidneys. Therefore, it does not require dose adjustment for people with renal failure. There have been some reports of a mild anticoagulation effect. However, this is usually not significant enough to alter coagulation parameters such as the prothrombin ratio.

Side effects of oral Ivermectin are rare and usually minor. These include transient tachycardia, flushing, nausea and lightheadedness. More severe neurological side effects are theoretically possible in rare susceptible individuals. Moreover, FDA describes some of the side-effects that may be associated with Ivermectin include skin rash, vomiting, diarrhea, stomach pain, facial or limb swelling, neurologic adverse events (dizziness, seizures, confusion), sudden drop in blood pressure, severe skin rash potentially requiring hospitalization and liver injury (hepatitis) [11]. The safety of Ivermectin in pregnant women has not been studied and such use is not recommended. Studies in animals have shown an increase in birth defects. Safety and effectiveness in children below 5 years and under 15 kg and pregnant women have not been established. Ivermectin passes into breast milk and use during breast feeding is not recommended[12]. No significant drug interactions with Ivermectin are recognized.

In vitro studies showed Doxycycline to exert anti inflammatory effects at low (20 - 40mg/day) and high (100 or 200mg/day) doses with inhibitory action on metalloproteases and modulating effects of pro inflammatory cytokines IL 6, IL 8 and tumor necrosis factor alpha. The anti inflammatory properties of Doxycycline and other components of tetracycline has been demonstrated for several inflammatory airway diseases, including, acute respiratory distress syndrome. Thereby, low Doxycycline doses have been shown to be more effective than high doses to prevent induction of pro inflammatory cytokines (such as IL 6) in inflammatory diseases[13]. Doxycycline is rapidly and almost completely absorbed after oral administration and has half life of 16-18 hours. Based on the available evidence, we believe Tetracyclines may be effective agents in the treatment of Covid-19 due to their ability to chelate Zinc compounds on matrix metalloprotienases (MMP) on which coronaviruses rely heavily for survival, cell infiltration, cell to cell adhesion and replication, many of which has Zinc as part of their MMP complex.[14] It is a safe and inexpensive drug with a minimal toxicity[14]. Doxycycline is largely excreted unchanged both in the bile and urine and the dose does not require adjustment in patients with renal failure, because of their enterohepatic circulation this drug may remain in the body for a long time after cessation of therapy. Doxycycline can produce GI irritation most commonly after oral administration. Tolerability can be improved by administering it with food. Doxycycline can be safely used in children aged 8 years and above[15]. Currently global scenario is not stable as there is no effective drugs could be prescribed under sufficient evidence based clinical trials. Already efficacy and effectiveness of Hydroxychloroquine is questionable[16,17,18.] As Doxycycline is safe to use in treatment of ARDS it alone could be a better option for Covid-19 treatment.

FOI 26-3132 - Document 5

Conclusion:

It is too early in this pandemic to claim major successes of the effectivity of our combination therapy (Ivermectin and Doxycycline) as our number is small and there is no control group. Nevertheless, the results encourage us to continue the clinical study for people of the world in this improbable crisis as each and every life counts.

We urge the different medical societies and International organizations to take up this unique observation and quickly give it a trial and clearance because these drugs are FDA approved for many years with excellent safety and efficacy reviews. At the very least, using them in the first few days of being positive with or without symptoms may save the admissions of those 20% who suffer and the unnecessary deaths on ventilators. We can also stop the community transmission by asymptomatic carriers by treating the asymptomatic COVID-19 positive patients. Above all it is a very cheap combination, and if fast tracked by a quick trial would cost pennies and save a lot of lives, specifically designed for resource-poor settings.

Abstract

Rationale

Due to the cluster and associated comorbidities in residents of long-term care facilities (LTCFs), COVID-19-associated morbidity and mortality are significantly increased. Multiple therapeutic options, including hydroxychloroquine (HCQ) and azithromycin (AZI), were tried initially to treat moderate to severe COVID-19 and high-risk patients in LTCFs, but they were abandoned due to unfavorable reports. As a less toxic option, we initiated treatment with doxycycline (DOXY) very early in the course of illness. DOXY has antiviral, cardioprotective, immunomodulatory, and anti-inflammatory properties, but the efficacy of early intervention with DOXY in high-risk COVID-19 patients in LTCFs is unknown.

Objective

The goal of this retrospective study is to describe the clinical outcomes of high-risk COVID-19 patients with moderate to severe symptoms in LTCFs after early intervention with DOXY.

Design

Case-series analysis

Setting

LTCFs in New York

Participants

This observational study examines 89 patients who were diagnosed with COVID-19 from March 18 to May 13, 2020.

Exposure

All patients who were diagnosed with COVID-19 received DOXY and regular standard of care

Alam M M, Mahmud S, Rahman M M, et al. (August 11, 2020) Clinical Outcomes of Early Treatment With Doxycycline for 89 High-Risk COVID-19 Patients in Long-Term Care Facilities in New York. Cureus 12(8): e9658. DOI 10.7759/cureus.9658

within 12 hours of the onset of symptoms. Additionally, four patients received meropenem, three patients received Zosyn, two patients received linezolid, and two patients received Bactrim DS. Four patients were on chronic ventilator support. No patients received any steroids or any other antiviral or immunomodulatory agents. The majority of the patients received zinc and calcium supplements as well.

Main outcomes and measures

Assessed measures were patients' characteristics, fever, shortness of breath (SOB), cough, oxygen saturation/pulse oximetry (POX), radiologic improvements, laboratory tests, DOXY side effects, hospital transfers, and death.

Results

Eighty-nine (89) high-risk patients, who developed a sudden onset of fever, cough, SOB, and hypoxia and were diagnosed with COVID-19, were treated with DOXY (100 mg PO or intravenous (IV) for seven days) and regular standard of care. Eighty-five percent (85%) of patients (n=76) demonstrated clinical recovery that is defined as resolution of fever (average 3.7 days, Coeff = -0.96, p = 0.0001), resolution of SOB (average 4.2 days), and improvement of POX: average 84% before treatment and average 95% after treatment (84.7 ± 7% vs. 95 ± 2.6%, p = 0.0001). Higher pre- and post-treatment POX is associated with lower mortality (oxygen saturation (Spo2) vs. Death, Coeff = -0.01, p = 0.023; post-Spo2 vs. Death, Coeff = -0.05, p = 0.0002). Within 10 days of symptom onset, 3% of patients (n=3) were transferred to hospital due to clinical deterioration and 11% of patients (n=10) died. The result was followed for 30 days from the onset of symptoms in each patient.

Conclusion

Early treatment with DOXY for high-risk patients with moderate to severe COVID-19 infections in non-hospital settings, such as LTCFs, is associated with early clinical recovery, decreased hospitalization, and decreased mortality.

Introduction

The COVID-19 pandemic placed an unprecedented and overwhelming burden on the U.S. healthcare system. Since the first case of COVID-19 in the U.S., there have been over two million COVID-19 cases and 122,000 deaths as of June 25, 2020 [1]. One-third of these deaths are nursing home residents or workers [2]. Data from small studies conducted in China [3] and France [4] present the clinical outcomes of COVID-19 patients who were treated with hydroxychloroquine (HCQ) and/or azithromycin (AZI). However, since HCQ and AZI are both cardiotoxic, there are concerns about the development of arrhythmia in patients treated with these drugs [5]. With limited treatment options, our group first treated high-risk COVID-19 patients in long-term care facilities (LTCFs) with doxycycline (DOXY) and HCQ [6]. DOXY has anti-inflammatory [7], immunomodulating [8], cardioprotective [9-10], and antiviral [11] activities. Subsequently, other studies noted the harmful side effects and mortality associated with HCQ administration [12].

Based on current evidence and reference articles that detail COVID-19 pathophysiology and DOXY's mechanisms of action, DOXY may be an effective drug in the treatment of COVID-19. As a result, we began treating high-risk patients with only DOXY and supportive care. The

efficacy of early DOXY intervention in high-risk COVID-19 patients in LTCFs is unknown. In this observational study, we collected data retrospectively, and we are presenting our clinical observations and outcomes of DOXY for high-risk patients with moderate to severe COVID-19 infections in LTCFs.

Materials And Methods

This case series assessed the clinical outcomes of eighty-nine (89) high-risk patients in LTCFs who developed a sudden onset of fever, cough, shortness of breath (SOB), and hypoxia between March 18 and May 13, 2020. High-risk patients were defined as patients who had at least one comorbidity such as hypertension (HTN), diabetes, coronary artery disease (CAD), congestive heart failure (CHF), chronic obstructive pulmonary disorder (COPD), obesity, or ventilator-dependency. These patients were diagnosed with COVID-19 and they were treated with an early course of DOXY (100 mg PO or IV for seven days) and regular standard of care. Since all patients were closely monitored by healthcare workers, COVID-19 symptoms were immediately noticed; DOXY was started within 12 hours and RT-PCR COVID-19 swab was collected. Assessed measures were patients' characteristics, fever, SOB, cough, oxygen saturation/pulse oximetry (POX), radiologic improvements, laboratory tests, DOXY side effects, hospital transfers, and death. Clinical recovery was defined as a resolution of fever, resolution of SOB, and improvement of POX (⩾93%). Follow-up chest X-rays (CXR) were ordered if clinically indicated.

The statistical analysis was done using Microsoft Excel 2016 (Microsoft Corporation, Redmond, Washington) with statistical application packages and IBM SPSS v23 (IBM Corp., Armonk, NY). The two-tailed T-test was used for between-group intervals in parametric data (e.g. POX). Binary logistic analysis and regression were used to assess the association of risk factors with the outcome. The patients' outcomes were recorded 30 days after symptoms onset.

All patients or patients' families gave informed consent before DOXY treatment was started, and oversight medical boards and corporate clinical services approved this observational study.

Results

Table *1* summarizes the characteristics, clinical features, lab and radiology results, outcomes, and side effects of DOXY of all 89 patients who were started with early DOXY treatment. The median age is 78 years, and the range is 43-101 years. One hundred percent (100%) of patients (n=89) tested positive for COVID-19 through reverse transcription-polymerase chain reaction (RT-PCR) and 85% of patients (n=76) showed clinical recovery. Eleven percent (11%) of patients died (n=10) and 3% of patients (n=3) were transferred to hospitals due to clinical deterioration.

Assessed Measures	LTCF Residents (n=89)	Percentage
Median Age, Years (Range)	78 (43-101)	
Male	50	56%
Female	39	44%
Clinically Recovered*	76	85%
Transferred to Hospital	3	3%
Death	10	11%
Hypertension (HTN)	62	70%

Diabetes	30	34%
Coronary Artery Disease (CAD)	41	46%

TABLE 1: Characteristics, clinical outcomes, clinical features, lab and radiology results, side effects of doxycycline, and other antibiotics of all 89 high-risk COVID-19 patients who started seven-day doxycycline treatment in long-term care facilities

*Clinical recovery defined by resolution of fever (3.7 days), resolution of SOB (4.2 days), and average POX improvement 95%

**Four percent (n=4) of ventilator-dependent patients recovered and the ventilator setting returned to baseline.

***Chest X-ray not ordered, not required, or pending.

BUN: blood urea nitrogen; CRP: C-reactive protein; LFT: liver function test; LDH: lactate dehydrogenase; POX: pulse oximetry

Table *2* summarizes the characteristics, clinical features, lab and radiology results, outcomes, and side effects of DOXY of the remaining 76 patients who successfully completed the seven-day DOXY treatment. One hundred percent (100%) of patients demonstrated clinical improvement. After DOXY treatment started, resolution of fever and SOB occurred at an average of 3.7 days and 4.2 days, respectively. Average POX before and after treatment was 84% and 95%, respectively.

Assessed Measures	LTCF Residents (n=76)	Percentage
Median Age, Years (Range)	79 (43-101)	
Male	42	55%
Female	34	45%

TABLE 2: Characteristics, clinical outcomes, clinical features, lab and radiology results, side effects of doxycycline, and other antibiotics of 76 high-risk COVID-19 patients who completed seven-day doxycycline treatment in long-term care facilities

This table includes all patients who completed a full course (7 days) of DOXY therapy and excludes any patients who died and who were transferred to hospital and did not complete the seven-day course.

*Clinical recovery defined by resolution of fever (3.7 days), resolution of SOB (4.2 days), and average POX improvement 95% after treatment.

**Four percent (n=4) ventilator-dependent patients recovered and the ventilator setting returned to baseline.

***Chest X-ray either not ordered, or not required or pending.

BUN: blood urea nitrogen; CRP: C-reactive protein; LFT: liver function test; LDH: lactate dehydrogenase; POX: pulse oximetry

There was a statistically significant difference in POX before (pre-POX) and after (post-POX) treatment (n = 89, 84.7 ± 7% vs. 95 ± 2.6%, p = 0.0001). In the multivariate analysis model, the resolution of fever was associated with a reduction in mortality (Coeff = -0.96, p = 0.0001). Higher pre-POX and post-POX were also associated with decreased mortality; lower pre- and post-treatment POX is associated with increased mortality (pre-oxygen saturation (Spo2) vs Death, Coeff = -0.01, p = 0.023; Post-spo2 vs Death, Coeff = -0.05, p = 0.0002). Other variables, such as initial CXR with pneumonia, BUN, creatinine, liver enzyme levels, CRP, ferritin, LDH, D-Dimer, troponin, and procalcitonin, were not associated with mortality. Overall mortality at 30 days in our cohort was 11% (n=10). Clinical improvement was noted in 76 patients. Additionally, 3% (n=3) required transfer to a hospital while the rest of the patients were treated in the nursing home facility.

Discussion

COVID-19 is a positive-sense, single-stranded ribonucleic acid (RNA) virus [13], with a lipophilic outer shell that allows the pathogen to easily infiltrate lung tissue [14]. The coronavirus is believed to recognize and bind to cluster of differentiation 26 (CD26)/dipeptidyl peptidase-4 (DPP4) markers expressed on the cell surface, serving as an entry point for viral invasion [15]. COVID-19 infects the upper and lower respiratory tract, causing the release of pro-inflammatory cytokines such as interleukin 1β (IL-1β), tumor necrosis factor (TNF), and IL-6 [16]. COVID-19 induces mast cell proliferation within the respiratory submucosa [17] and activates the NF-kB pathway [18], further increasing the inflammatory response. As a result, individuals with COVID-19 present with fever, cough, and SOB. Severe infection can progress to acute respiratory failure and vascular thrombosis. COVID-19 is additionally correlated with acute cardiac injury and increased troponin I levels [19].

DOXY, an analog of tetracycline, is lipophilic and can also easily penetrate the lung epithelium [20]. Chemically modified tetracyclines (CMTs) can also induce apoptosis of mast cells [21]. The drug downregulates inflammatory markers demonstrated to have a role in COVID-19 pathophysiology. Evidence shows that DOXY downregulates the expression of DPP4 through the inhibition of the NF-kB pathway [22], impeding the virus's ability to enter cells and consequently decreasing the viral load. Along with its anti-inflammatory and immunomodulatory properties, DOXY is considered to be cardioprotective. During reperfusion after myocardial injury, matrix metalloproteinases-2 (MMP-2) are released. DOXY's inhibition of the MMP-2 pathway rescues left ventricular function [23]. As a result, in patients with acute ST-segment elevation myocardial infarct (STEMI) and left ventricular dysfunction, DOXY reduces adverse left ventricular remodeling [24]. DOXY's cardioprotective characteristics may improve clinical recovery in COVID-19 patients with acute myocardial injury.

DOXY is also thought to have antiviral activity. In-vitro assays of cultured cells inoculated with the dengue virus suggest that DOXY inhibits the virus's serine protease, disrupting viral replication, and viral entry into cells [25]. Another study demonstrates that when cells infected with murine retrovirus were treated with DOXY, there was a 70% decrease in retroviral load [26]. Tetracyclines can potentially treat other viral infections as well, such as viral encephalitis, West Nile virus, and human immunodeficiency virus (HIV) [27]. Further research reveals that elevated levels of intracellular zinc inhibit viral replication of COVID-19 [28] and that DOXY facilitates this inhibition by acting as a zinc ionophore, transporting, and increasing intracellular concentrations of zinc. Recently, a study demonstrated that in-vitro, DOXY itself

has antiviral activity against COVID-19 at a concentration of 5.6 µM [29].

DOXY has anti-inflammatory, immunomodulatory, cardioprotective, and antiviral properties. No observational study has yet been done using an early regimen of DOXY to treat moderate to severe high-risk COVID-19 patients in an LTCF. This case series demonstrates that early DOXY treatment in a non-hospital environment has good clinical recovery (85%, n=76), minimized hospital transfers (3%, n=3), and reduced death (11%, n=10).

A limit to this study is that there was no control group. We thus compared the data from this population to that of a similar reference patient population in an LTCF in Washington. This study performed an epidemiological investigation regarding 129 confirmed cases of COVID-19. Of the 129 confirmed cases, 63% (n=81) were LTCF residents (median age = 81 years, range = 54-100 years), 26% (n=34) were healthcare workers (median age = 42.5 years, range = 22-79 years, and 11% (n=14) were visitors (median age = 62.5 years, range = 52-88 years). Fifty-six point eight (56.8%) LTCF residents, 35.7% visitors, and 5.9% of healthcare personnel were hospitalized. Comorbidities among LTCF residents included HTN (69.1%), cardiac disease (56.8%), diabetes (37%), obesity (33%), and pulmonary disease (32.1%). Of the total population, 65.1% (n=84) were women. While no deaths occurred among staff members, 27.2% of LTCF residents and 7.1% of visitors died [30]. Comparing this study's data to our data using naive indirect comparison, early DOXY treatment may reduce hospital transfers and decrease mortality.

Conclusions

In this cohort of high-risk LTCF residents with moderate to severe COVID-19 infections who were treated with an early course of DOXY, improvement in oxygen saturation and resolution of fever were factors associated with lower mortality. The median time of all deaths in these high-risk patients was within the first 10 days in the course of illness. In the majority of our cohort, early initiation of DOXY treatment was associated with improved clinical outcomes, decreased hospitalizations, and decreased mortality. Larger randomized control trials are required to study the effect of DOXY treatment in moderate to severe COVID-19 infections.

The effects of high-dose ivermectin regimens on *Onchocerca volvulus* in onchocerciasis patients

Kwablah Awadzi, Simon Kwaku Attah, Ebenezer Thomas Addy, Nicholas Obuobisa Opoku and Benjamin Theophilus Quartey *Onchocerciasis Chemotherapy Research Centre (OCRC), Hohoe Hospital, Hohoe, Ghana*

Abstract

Ivermectin, at the standard dose of 150 μg/kg bodyweight, does not kill the adult worms of *Onchocerca volvulus* and does not disrupt embryogenesis or spermatogenesis. Repeated standard doses, if maintained, arrest microfilarial production but result in only a mild-to-modest macrofilaricidal effect. We investigated whether high doses would effectively kill the adult worms, and whether cessation of microfilarial production could be reproduced by an equivalent, single, high dose. One hundred men participated in a double-blind placebo-controlled trial and received increasing doses of ivermectin from 150 μg/kg to 1600 μg/kg bodyweight. Nodules were excised at day 180 and examined by histopathology. Total doses of ivermectin up to 1600 μg/kg were not significantly more effective than 150 μg/kg. Moreover, they did not reproduce the marked inhibitory effects of the repeat standard-dose regimens on embryogenesis, nor the modest effect on adult worm viability, at comparable total doses. These effects may be functions of multiplicities of dosages rather than of the total dose. Our findings also suggest that repeated high-dose regimens are unlikely to be more effective than a similar number of 150 μg/kg doses. This deficiency of ivermectin requires that the search for macrofilaricides remains a top priority.

Keywords: onchocerciasis, *Onchocerca volvulus*, chemotherapy, ivermectin, efficacy, drug regimens, adult worms

Introduction

Ivermectin is the drug of choice for the treatment of onchocerciasis. When given at the standard dose of 150 μg/kg bodyweight it does not kill the adult worms and does not disrupt embryogenesis or spermatogenesis. The main effects are a potent microfilaricidal action and a block to the release of stretched microfilariae (mf) from the adult female worms followed by their degeneration *in utero* (WHO, 1995).

Initial attempts to investigate the macrofilaricidal potential of ivermectin have led to the repeated administration of 100–150 μg/kg bodyweight. These dose regimens have varied in frequency and duration and total doses have ranged from 600 μg/kg to 1800 μg/kg bodyweight. Indirect evidence of the effect on the adult worms obtained by studying the kinetics of skin mf numbers showed that there was a permanent decline in mf production (GREENE *et al.*, 1991). This has been quantified, using model calculations, at ~30% per treatment (PLAISIER *et al.*, 1995).

Other investigators have defined the nature of this decline directly by examining the adult worms. A regimen of 100 μg/kg bodyweight given every 2 weeks to a total dose 600 μg/kg bodyweight had no adulticidal effect (DUKE *et al.*, 1991a). Three studies in Guatemala investigated the effects of 150 μg/kg given monthly for 4, 8 or 12 doses (Guatemala I), as a single dose compared with 4 doses given every 6 months (Guatemala II), and (in Guatemala III) as 4, 8 or 11 doses given every 3 months (DUKE *et al.*, 1990, 1991b, 1992). The major effect of these regimens was a reduction in the proportion of female worms producing mf. The effect was most marked in Guatemala III where mf production ceased 4 months after 8 or 11 doses. Other findings included an increase in the proportion of unfertilized or uninseminated worms and of female worms with degenerate mf. There were fewer male worms per nodule and an increase in the number of nodules without male worms in Guatemala I and Guatemala III. However, macrofilaricidal activity was not impressive. A mild increase in both adult male and female worm mortality (12% and 22%, respectively) occurred only with 12 monthly doses (total dose 1800 μg/kg). A modest increase in mortality among female worms occurred in groups given 8 (25·5%) or 11 (32·6%) 3-monthly doses (total dose 1200 μg/kg or 1650 μg/kg).

In Sierra Leone, 4 × 150 μg/kg and 5 × 150 μg/kg bodyweight of ivermectin (given 6-monthly to a total dose of 600–750 μg/kg) were compared with 150 μg/kg and placebo (CHAVASSE *et al.*, 1992). A single dose of ivermectin did not affect embryogenesis and produced many degenerating mf. Multiple doses severely depressed embryogenesis. There was a significant trend with increasing doses towards fewer worms with multicellular embryonic stages and stretched mf and there were fewer gravid worms. Oocytes were produced normally but there was an increase in the proportion of abnormal forms with dose. Embryogenesis was arrested at the single-cell stage possibly because of reduced fertilization. A probable cause for this was ineffective insemination of the female worms as shown by the much lower proportion of seminal receptacles containing sperm (CHAVASSE *et al.*, 1993). There was no significant reduction in the number of live male worms per nodule.

The repeat standard-dose regimens have shown that ivermectin given 3- or 6-monthly to a total dose of ⩾600 μg/kg markedly suppressed mf production and produced minor to modest macrofilaricidal effects at total doses of ⩾1200 μg/kg bodyweight.

An important consideration in the selection of repeat standard-dose regimens in the investigation of the macrofilaricidal potential of ivermectin was the lack of information on the safety of the drug at higher doses. In an initial investigation, we reported the safety of single, increasing doses of ivermectin from 150 μg/kg through 800 μg/kg bodyweight given with or without a 'clearing' dose of 150 μg/kg bodyweight (AWADZI *et al.*, 1995). This study was eventually extended to a total dose of 1600 μg/kg bodyweight. The aim was to determine whether high doses of ivermectin effectively kill the adult worms. An additional interest was whether the marked effects on embryogenesis achieved by 5 to 12 repeated standard-dose regimens could be duplicated or augmented by an equivalent, single, high dose. This paper compares the parasitological effects of the standard- and high-dose regimens.

Patients and methods

Patients were healthy men, infected with *Onchocerca volvulus*, from the forest region of south-eastern Ghana. The study took place between January 1994 and October 1995 at the Onchocerciasis Chemotherapy Research

Address for correspondence: Dr Kwablah Awadzi, Onchocerciasis Chemotherapy Research Centre, Hohoe Hospital, P.O. Box 144, Hohoe, Ghana; fax +233 21 668871, e-mail awadzi@ghana.com

The effects of high-dose ivermectin regimens on Onchocerca volvulus in onchocerciasis patients 16/3/2023, 5:53 pm
FOI 26-3132 - Document 5

Centre (OCRC) at Hohoe (Ghana) located 80 km south of the project area. Vector control measures had begun in the area 7 years earlier and transmission of onchocerciasis had been interrupted. Verbal consent was obtained from each patient after all the procedures involved had been explained in detail. The study was approved by the Ethics Committee of the Ministry of Health, Ghana, and the WHO Secretariat Committee for Research Involving Human Subjects (SCRIHS).

The details of the conduct of this randomized, double-blind, placebo-controlled trial and the clinical and laboratory safety aspects have been presented previously (AWADZI *et al.*, 1995). During this phase 75 patients were treated. In brief, systemic clinical, ophthalmological and laboratory tests were conducted before, during and after drug administration. Ophthalmological examinations included perimetry, slit-lamp examination of the anterior segment, colour photography and fluorescein angiography. Systemic and ocular reactions to treatment were quantified (AWADZI, 1980; HERO *et al.*, 1992). Laboratory tests included the determination of mf densities in skin snips and standard biochemical and haematological tests. Ivermectin or matching placebo tablets were administered on days 1 and 4; ivermectin dosages were increased in successive groups of patients from 150 μg/kg to 800 μg/kg. With the high-dose regimens some patients received a 'clearing' dose of 150 μg/kg on day 1 followed by the high dose on day 4 while others received the high dose on day 1 followed by placebo on day 4. Clinical and laboratory tolerances were determined on data collected through day 30.

Besides the 75 patients reported on previously there were 6 other patients included as controls for a study of the immunopathogenesis of the Mazzotti reaction carried out in parallel over the first 72 h; they received placebo tablets on day 1 followed by 150 μg/kg of ivermectin on day 4. Subsequently, 19 additional patients were treated as a single group to bring the total number enrolled to 100. Nine of these patients received 800 μg/kg of ivermectin as a single dose and 12 others received the same dose repeated after 13 days. There was no reaction to the second 800 μg/kg dose. Follow-up for all patients took place on days 30, 90, 180 and 365 when all clinical and laboratory examinations were repeated. At day 180, all palpable nodules were aseptically excised using 1% xylocaine. Some nodules were examined using in-vitro tests (BENNETT & PAX, 1986; COMLEY *et al.*, 1988; STROTE *et al.*, 1993) while the rest were processed for histopathology. Nodules for histology were freed from excess host tissue, washed in saline and fixed in 4% (w/v) buffered formaldehyde and embedded in paraffin. From each nodule in the plane of the largest diameter, at least 10 sections of 4-μm thicknesses were cut, stained with haematoxylin and eosin and examined by microscopy. Adult worm viability and reproductive activity were assessed as described previously (BUTTNER *et al.*, 1988).

Statistical analysis

The treatment groups were ordered according to the total dose of ivermectin received. The distribution of nodule characteristics, adult worm viability and of female worms in various reproductive stages were compared using the χ^2 and trend tests. Microfilarial counts were logarithmically transformed before analysis. Skin mf counts are the adapted sums of the densities at the iliac crests and calves. Ocular counts are the adapted sums for both eyes. The means of these counts were compared using analysis of variance (ANOVA); comparison of group means was done where significant differences occurred using the t test and pooled SD. The kinetics of skin mf numbers in each group was studied by comparing the mean counts of adjacent visits (paired t test). The null hypothesis was rejected when P was less than 0·05.

Results

Categorization of patient groups

One patient could not be traced after the day 180 follow-up and was eliminated from the study. The data presented relate to the 99 patients who were available at all time points up to day 365. Owing to the numbers of patients in the individual treatment groups whose nodules had been examined by histology, it was necessary to combine the groups in a meaningful way to permit reasonable statistical analyses to be undertaken. The final allocation of patients created 5 treatment groups (based on total dose range) as follows:

Group 1. 150 μg/kg (control);
Group 2. 400 μg/kg preceded by 150 μg/kg or placebo (400–550 μg/kg);
Group 3. 600 μg/kg preceded by 150 μg/kg or placebo (600–750 μg/kg);
Group 4. 800 μg/kg preceded by 150 μg/kg or placebo (800–950 μg/kg); and
Group 5. 800 μg/kg preceded by 800 μg/kg (1600 μg/kg).

Nodule characteristics and adult worm viability

The results presented are of those nodules examined by the standard method of histopathology. Data from tests *in vitro* are not presented as the method is still being assessed as an alternative to histopathology. A total of 225 nodules from 60 patients were examined. These yielded 495 adult female and 190 adult male worms. The numbers of nodule donors and of the nodules examined, the basic characteristics of the nodules and the effect on adult worm viability for each treatment group are shown in Table 1.

There were no significant trends regarding the number of live female or male worms per nodule, the male:female ratio or in the number of nodules with live mf. There was however a significant trend to a reduction in the number of nodules without male worms with increasing doses of ivermectin (χ^2 for trend = 5·78; $P = 0·02$). With increasing doses of ivermectin, there was no significant trend in mortality among female and male worms in the treated groups. Overall, 32·7% of all female worms and 9·5% of all male worms were dead/moribund and 17·0% of the female worms were calcified.

Among 255 female worms obtained from 107 nodules excised from 25 untreated patients at the beginning of vector control in south-eastern Ghana, 26% were dead/probably dead and 12% were calcified while 4% of 79 male worms were dead/probably dead (BUTTNER *et al.*, 1990). Although there were increases in the proportions of dead and calcified adult worms in this study population as compared with pre-control data, none of the differences was significant ($P > 0·05$ for all comparisons). Thus, 7 years of successful vector control had not invalidated the suitability of the adult worm population for clinical trials. An unusual finding that was probably unrelated to therapy was the tendency to a reduction in the proportion of calcified adult female worms with increasing doses of ivermectin.

Adult worm reproductive activity

The number and distribution of female worms in different reproductive stages are shown in Table 2. The main findings were an increase in the proportion of female worms with nearly empty uteri, and a reduction in the proportion with young embryos and coiled mf with increasing doses of ivermectin. There was no significant trend with dose in the proportion of worms with young oocytes only, with stretched mf, or with degenerate stretched mf. There was no marked effect on embryogenesis. Between 95% and 100% of live male worms contained intact spermatozoa with no differences between the groups (data not shown).

[a]Of those with stretched mf.

Skin and ocular microfilariae

The skin and ocular mf counts over 1 year are shown in Table 3. An earlier presentation summarized the results at days 3, 7 and 11 (AWADZI *et al.*, 1995). Within each group there was a rapid reduction in counts reaching a nadir at day 30. This value was maintained over the next 3 months after which successive increases occurred at days 180 and 365. This pattern of kinetics of skin mf numbers reflects an initial potent microfilaricidal effect and a subsequent recovery from the effects of the block to mf release. Comparison of the group geometric means revealed no significant differences initially, at day 90 or at day 365. The groups were however significantly different at days 30 and 180. At day 30 the differences were due to a greater reduction in 3 of the 4 high-dose groups (namely Groups 2, 3 and 5) when compared to the 150 µg/kg group; the 800–950 µg/kg group was the exception. At day 180, only the 2 highest dose groups (800–950 µg/kg and 1600 µg/kg) produced greater reductions than the 150 µg/kg group. These groups appeared to have a greater suppression of skin mf at this time than the lower dose groups but the effect was minor (maximum difference 1·6% reduction) and transient (lasted less than 6 months) and by 1 year the mean skin mf densities were again similar in all groups.

Sixty-three of 99 patients had mf in the anterior chamber of the eye. The counts were highly variable between patients (1–86 mf in both eyes). The initial group geometric mean counts were low and varied from mean (95% confidence interval) 1·3 (0·2–3·5) to 3·5 (1·7–6·7). Comparison of the group geometric means revealed no significant differences at any time. The data for all the groups were therefore pooled. Within each group there was a delay in reduction of mf counts till day 30 or 90. Small numbers of mf (2–11) persisted in 9 patients at 1 year. Overall, the treatment groups maintained at 1 year a 96% reduction on initial counts for both skin and ocular mf.

Discussion

The 'ideal' drug for the treatment and control of onchocerciasis should be safe, macrofilaricidal, effective in a single dose, uniformly effective in all endemic areas, cheap and stable. It should readily merge into existing health care delivery strategies and be compatible with drugs already in use for common endemic diseases. Ivermectin would have satisfied all these requirements but for the lack of a potent macrofilaricidal effect. This potential was explored in many studies that relied on giving repeat standard-dose regimens. The dominant effect of these regimens was however on the reproductive activity of the female worms. The effects observed include an increase in the number of females with unfertilized ova, depression of the rate of new embryonic development, a decrease in the proportion of females producing mf, a decrease in the number with degenerate mf and a cessation of microfilarial production. An important explanation for these findings was a failure of insemination of the female worms. Among the mechanisms suggested are a reduction in the number of nodules with male worms, an abnormality of spermatogenesis, a disinclination of the male worms to mate, a block to the passage of sperm by mf degenerating in the uteri and impairment of oogenesis.

Although not the ideal situation, a permanent sterilization of the adult worms, or even a prolonged suppression of mf production over many years, could form a rational basis for a control programme pending the coming of the ideal drug. So far, a sustainable suppression of mf production has depended on multiple dosing with ivermectin over several years (KLÄGER *et al.*, 1996).

One rationale for our study was that, if the total dose administered was the major factor in the embryo suppression characteristic of the repeat-dose regimens, then the administration of a safe, single high dose that achieved similar effects would greatly simplify the use of ivermectin in the control of onchocerciasis. The preferred outcome, however, was that the high dose would kill the adult worms.

In order to assess the effects on the adult worms, pooling of the data was necessary owing to the number of patients providing nodules for histopathology in the individual groups. Pooling involved the combination of those who had received a 'clearing' dose of 150 µg/kg with those who had not with respect to a given high dose. Since this dose has no macrofilaricidal activity, it is unlikely that results of adult worm viability would be unduly influenced by this procedure. Other related data (skin mf densities, ocular mf counts) were similarly regrouped to permit parallel comparisons to be made.

There was no increase in mortality among the adult worms with increased dosage with ivermectin. In all groups there were worms in various stages of reproductive activity and included worms with multicellular stages and stretched mf. Although there was a significant trend towards an increase in the number of female worms with nearly empty uteri and a reduction in the proportion of female worms with young embryos and coiled mf with increasing dose, this did not materially affect the production of stretched mf.

An indirect assessment of the effects on the adult worms was obtained by a study of the kinetics of skin mf numbers over time. This revealed differences between the groups only at day 30 and day 180. At day 30 the 150 µg/kg group was at a slight disadvantage as 6 of the members had acted as controls for the Mazzotti reaction and were treated 3 days after the other patients. On the other hand the 1600 µg/kg group (800 µg/kg × 2) had a slight advantage in that the second dose of 800 µg/kg was given on day 13 while the other groups had completed

therapy on day 4. The findings at day 180 suggest a more complete clearance of mf with the highest doses, but the similarity of mf loads in all groups at 1 year indicates that the effect is of little importance. The clearance of ocular mf was also similar in all groups.

In summary, single doses of ivermectin as high as 800 μg/kg (more than 5 times the standard dose) or of 1600 μg/kg given in 2 doses (more than 10 times the standard dose) are as safe as the standard dose but are not clearly superior in their antiparasitic effects. Moreover, they do not reproduce the marked inhibitory effects of the repeat standard-dose regimens on embryogenesis, nor the mild-to-modest effect on adult worm viability, at comparable total doses. This suggests that it is the multiplicity of dosages rather than the total dose that is the factor that determines the effects. This study also reconfirms that the ceiling of therapeutic activity of ivermectin against *O. volvulus* is reached with 150 μg/kg (AWADZI *et al.*, 1985). A further extension of this assertion is that multiple high-dose regimens are unlikely to be more effective against the adult worms than a similar number of doses of the standard regimen. This deficiency of ivermectin requires that the search for macrofilaricides for onchocerciasis remains a top priority.

Acknowledgements

We are grateful to Merck Sharp & Dohme Research Laboratories for the supply of ivermectin and placebo tablets. This investigation received financial support from the African Programme for Onchocerciasis Control–Onchocerciasis Control Programme in West Africa–UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases. We are also grateful to Professor D. W. Büttner of the Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany, for nodule histological data that are generally in agreement with those presented in this paper.

Received 11 July 2003, Revised 5 January 2004, Accepted 7 January 2004

If ivermectin-based programmes for the control of human onchocerciasis are to be successful, the drug must remain effective for as long as necessary. In an open, case–control study, an attempt was made to determine if the persistent, significant, *Onchocerca volvulus* microfilaridermias seen in some individuals who had received at least nine treatments with ivermectin were the result of the development of drug resistance in the parasite. Twenty-one of these 'sub-optimal' responders (cases) were matched, by age, weight, number of treatments, locality and skin microfilarial counts, with seven amicrofilaridermic responders and 14 ivermectin-naive subjects. The number of treatments taken, any potential drug interactions and significant underlying disease were determined from detailed clinical and laboratory studies. Each subject was treated with ivermectin during the study, so that plasma concentrations of the drug could be determined for 72 h from the time of dosage. The microfilarial and adult-worm responses to this treatment were assessed from skin microfilarial counts (obtained before the treatment and at days 8, 90 and 365 post-treatment), day-90 embryogrammes, and the results of fly-feeding experiments. Parasite-sensitivity criteria for various time-points were derived from earlier data on skin microfilaridermias and the effects of ivermectin on the adult worms. The results indicate that the significant microfilaridermias that persist despite multiple treatments with ivermectin are mainly attributable to the non-response of the adult female worms and not to inadequate drug exposure or other factors. The possibility that some adult female worms have developed resistance to ivermectin cannot be excluded. These results justify the routine monitoring of treatment efficacy in any ivermectin-based programme of disease control.

In onchocerciasis-endemic areas with ongoing transmission, the human host often harbours various stages of the filarial parasite *Onchocerca volvulus*, the causative agent of the disease. These include the infective larvae, the migrating and developing pre-adult forms, the adult male and female worms and the microfilariae (mff). Many adult worms are readily accessible in subcutaneous nodules (onchocercomata) whereas the millions of mff that they produce, and that cause most of the pathology in onchocerciasis, reside predominantly in the skin and eye. The infective third-stage larvae (L_3), the form transmitted by the blackfly (*Simulium*) vector to the human host, develop in the vector from the mff taken up from the skin. Human onchocerciasis has been a major cause of disfiguring skin lesions, visual impairment and blindness, with attendant socio–economic problems. The World Health Organization (WHO) estimated that $>99\%$ of the global totals of those infected and those blind as a result of the disease live in the tropical belt of Africa (WHO, 1995). Because of this, the Onchocerciasis Control Programme in West Africa (OCP) and the African Programme for Onchocerciasis Control (APOC) were set up, with the common aim of eliminating onchocerciasis as a disease of public-health importance (Webbe, 1992; Benton, 1998).

In the absence of a protective vaccine, the control of onchocerciasis depends on measures directed against the vector and on chemotherapy. The drugs (diethylcarbamazine and suramin) that were available at the inception of the OCP had serious drawbacks that limited their mass administration and use in public-health programmes for the control of onchocerciasis. Thus, initially, the OCP relied on control of the vector, using insecticides to attack the larval stages of blackflies in their aquatic habitat. With the introduction of ivermectin, however, an additional tool became available. Ivermectin is a safe drug that has a potent effect against the mff and also temporarily blocks release of the mff by the adult female worms. Since a single, first dose of 150–200 μg ivermectin/kg has no effect on the vitality or reproductive potential of the adult worms (WHO, 1995), the release of mff begins again post-treatment and mff gradually repopulate the skin. In order to keep the skin free of mff, repeated administration of ivermectin, one or more times a year, is therefore required. Unlike the first dose, repeated treatments with ivermectin impair the ability of the female worms to produce mff (Chavasse *et al.*, 1992; Duke *et al.*, 1992; Plaisier *et al.*, 1995; Klager *et al.*, 1996) and also have a variable effect on adult-worm vitality (Duke *et al.*, 1992; Gardon *et al.*, 2002). The combined effects of multiple treatments on the mff and the adult worms result in the disappearance of mff from the skin (Guderian *et al.*, 1997), a reduction in the uptake of mff by the vector (Chavasse and Davies, 1990; Cupp *et al.*, 1992), a reduction in transmission (Boussinesq *et al.*, 1997; Boatin *et al.*, 1998) and hence a reduction in the incidence of onchocerciasis (Boussinesq *et al.*, 1995).

In the control of onchocerciasis, ivermectin is used either as the sole agent or as an adjunct to vector control. If ivermectin-based programmes, such as the APOC, are to be successful, the drug must remain effective against the mff and the adult worms for as long as it takes to control or eliminate the disease. The worrying possibility that *O. volvulus* could develop resistance to ivermectin has been considered (Awadzi, 1993; Shoop, 1993; Boussinesq and Gardon, 1999; Dadzie *et al.*, 2003), and the WHO has urged that methods be established to detect the development of such resistance, and to study the underlying mechanisms (WHO, 1995).

In 1987, the OCP introduced large-scale distribution of ivermectin, beginning in the Pru and Lower Black Volta (LBV) river basins in Ghana. Vector control began in the LBV basin in 1975 and was stopped in 1996. In the Pru basin, vector control started in 1988 and continues to date. Field surveys carried out in 1997, at Chingakrom and

FOI 26-3132 - Document 5

Agbelekame I in the LBV basin and at Asubende, Faomang and Hiampe in the Pru River basin, revealed individuals with persistent, significant microfilaridermia (PSM). Others subjects from the same communities, who had similar microfilarial loads in 1987 and had subsequently been exposed to the same environmental factors and received an identical number of treatments to those found with PSM, were skin-snip-negative (unpubl. obs.). As a working, 'field' definition, individuals who still had at least 10 mff/snip in 1997, after nine or more treatments with ivermectin, were labelled as 'sub-optimal responders' (SOR) in 1997. Subjects who were snip-negative in 1997 although known to have been positive in 1987 were considered 'responders'. The potential factors that could result in sub-optimal response, and the possible approaches to their investigation, are summarized in Table 1.

The primary objective of the present investigation was to determine whether sub-optimal response was due to parasite factors. This involved the exclusion of subject- and pill-related factors and the assessment of the parasite response on re-challenge with ivermectin under standard, hospital conditions. In addition, parasite material was collected from sub-optimal responders, responders and a population not previously exposed to ivermectin, to determine, in a subsequent study, if genetic differences could account for any observed differences and provide a plausible explanation for the possibility that the mff and/or the adult female worms of *O. volvulus* have developed resistance to ivermectin.

SUBJECTS AND METHODS

Subject Selection and Study Design

Lists of potential study subjects were extracted from the OCP database in line with the working field definitions of SOR and responder. Overall, 26 SOR suitable as subjects — 12 males and five females from the LBV basin and nine males from the Pru basin — were identified. Their ages ranged from 15–67 years and they had had 14.5–213 mff/snip when last examined. In case an inadequate number of these SOR could be recruited, a 'standby list' of two male and two female subjects with counts of nine mff/snip was also created. 'Responders', who were matched for sex and approximate age (15–67 years) with the SOR, were

TABLE 1. *The possible reasons for sub-optimal responses to ivermectin, and their investigation*

Factor	Investigative approach
THE PILL	Stability, storage, transportation, distribution
THE SUBJECT	
Failure to consume drug	Detailed history of intake, adverse events to each dose, review of records
Adverse interactions with other drugs or herbs	Activities in temporal relationship to ivermectin intake
Inadequate drug exposure	Pharmacokinetic study
Underlying disease (immunosuppression)	Clinical and laboratory examinations
THE PARASITE	
Patent new infections	Review of epidemiological data. Evidence of exposure to intense transmission
Abnormal response (tolerance or resistance)	Response of microfilariae and adult worms on re-challenge, measured using skin snips, fly feeding, and/or embryogrammes. Demonstration of a plausible genetic basis, using individual parasites from multi-dosed responders, sub-optimal responders and the ivermectin-naive

FOI 26-3132 - Document 5

identified from the same localities: eight male and nine female subjects from the LBV basin and 19 male and six female subjects from the Pru basin. (A much higher number of responders than SOR was selected because it was assumed that those who were already snip-negative would be less likely to volunteer for the study, as many would derive no direct benefit from their participation.) In 2000, the Directorate for Onchocerciasis Control of the Ghanaian Ministry of Health located 28 subjects from the lists who were willing to participate in the study: 15 SOR and 13 responders. The study was an open, case–control investigation. The SOR (the cases) were matched, by age, body weight and number of treatments with responders from the same localities and with 14 subjects from the Tordzi river basin, an area without previous ivermectin distribution or vector control. The Tordzi subjects, henceforth referred to as the 'ivermectin-naive', had physical characteristics similar to those of the SOR and responders and levels of microfilaridermia that were broadly similar to those of the SOR.

Between May 2001 and July 2002, the subjects were treated with ivermectin in Hohoe Hospital, Hohoe, Ghana, so that post-treatment plasma concentrations of the drug and the responses of the subjects and their parasites to the treatment could be carefully monitored (see below). At the beginning of the hospital-based study (i.e. 3–4 years after the multi-dosed subjects had been categorized in the field as SOR or 'responders'), seven 'responders' were found to have become snip-positive and only a single microfilaria was found in snips taken from four sites on one of the SOR (who was subsequently skin-snip-negative). As a result of these observations, a working 'hospital' definition was developed, in which the SOR were the 21 subjects from the select lists who were snip-positive on admission (irrespective of the intensity of their microfilaridermia), and the seven subjects who were snip-negative on admission were termed 'responders'.

Ethical Aspects

In 2001, before screening procedures were initiated in the study villages, informed consent was obtained from each villager volunteering to be a subject. A document detailing the conduct of the study was available in English and two local languages. This was read out to the volunteers who, after exhaustive discussions, gave verbal consent to participate in the investigation. The process was documented, on a form for each subject, by a project technician or co-ordinator and by an impartial witness from the community. Each consent form was countersigned and dated by the principal investigator or a co-investigator. The Ghanaian Ministry of Health and the WHO Secretariat Committee for Research Involving Human Subjects approved the study protocol. The subsequent hospital-based study was conducted in compliance with good clinical practices and in accordance with the Declaration of Helsinki (2000 revision).

Determination of Baseline Clinical Characteristics

In 2001, while in their villages, the subjects had been asked about the number of ivermectin treatments taken, the adverse events to each dose and the use of any other drug or herbal preparation in the few days before or after ivermectin intake.

Later, while hospitalized in Hohoe, the subjects lived under standard conditions; they had a common diet and the use of alcohol, tobacco, herbal medications and non-prescribed drugs was banned. A more detailed medical history was taken from each subject and a general physical examination performed. The subjects' eyes were examined as described previously (Awadzi *et al.*, 1997), with the exclusion of fundus photography and fluorescein angiography. Haematocrits, haemoglobin concentrations, platelet and total leucocyte counts, absolute counts of granulocytes, lymphocytes and monocytes (and the related percentages of all the

FOI 26-3132 - Document 5

leucocytes) were recorded. Each subject was screened for glucose-6-phosphate-dehydrogenase (G6PDH) deficiency and his plasma concentrations of sodium, potassium, chloride, bicarbonate, alanine aminotransferase (SGOT), aspartate aminotransferase (SGPT), lactic dehydrogenase, gamma-glutamyl transferase, alkaline phosphatase, total and conjugated bilirubin, albumin, total protein, sugar, cholesterol and triglycerides were determined in a 'fasting' blood sample. Stool and urine samples were checked for helminth and other parasites, using Kato–Katz smears and filtration through Nucleopore® filters (Nucleopore, Pleasanton, CA), respectively.

Skin snips were taken shortly before the treatment. In the field and in the hospital, skin snips were taken from both iliac crests and both calves with a Walser-type corneo-scleral punch. Punches were sterilized between subjects, in an autoclave. Each snip was weighed and then incubated for approximately 24 h in isotonic saline in a flat-bottomed well of a microtitre plate. Any mff in the well were then counted on an inverted microscope. The microfilarial density at each snip site was expressed as the number of mff/mg skin, the count for each subject (mff/4 mg skin) being the sum of the densities (in mff/mg) at each of the iliac crests and each of the calves.

Determination of Baseline Entomological Indices

During the bite of an infected human by a female blackfly seeking a bloodmeal, mff are taken up from the dermis. The mff undergo temperature-dependent morphological changes, transforming into infective L_3 that may be deposited in the skin of another human during the next bloodmeal. Microfilariae cannot be taken up from the skin if they have been cleared by treatment, and ingested mff may not develop into infective larvae if they have been damaged or modified by the treatment. Thus, by allowing the appropriate blackflies to feed on trial subjects under controlled conditions before and after treatment, the sensitivity of the mff to the administered drug can be determined. The use of newly emerged flies ensures that any mff found in the fly could only have been taken up during the experiment.

For the present, hospital-based investigation, pupae of *S. damnosum* s.l. were collected, from breeding sites at Obosomase and Krobo on the River Pra, and reared to adults in emergence cages. On admission and before treatment, the legs of each subject were exposed to 30 newly emerged female blackflies, which were allowed to feed undisturbed for 30 min. Some of the blood-fed flies were killed and dissected immediately, to determine their uptake of mff (VmfU) from the skin (Wirtz *et al.*, 1986). The rest of the flies were maintained, at 18–22°C on 10% sucrose solution, for 10 days. All the flies found dead on days 1–9 were immediately dissected and those that survived until day 10 were killed and also dissected, so that the first-, second- and third-stage larvae of *O. volvulus* they contained could be counted, separately (Wirtz *et al.*, 1986).

All of the *O. volvulus* recovered from the flies were preserved, dried on microscope slides (Toe *et al.*, 1997), at room temperature (20–28°C). They were eventually shipped to a specialized laboratory for genetic investigation (the results of which will be reported elsewhere).

Determination of Pharmacokinetic (PK) Parameters

On 'day 1', after admission to the Hohoe hospital, the baseline investigations, and an overnight fast, each subject was treated with ivermectin (as 3-mg tablets donated by Merck & Co., Inc., Whitehouse Station, NJ). All subjects received a single dose of 150 μg/kg. Breakfast was delayed for 2 h after taking the ivermectin tablets. A 10-ml sample of venous blood was collected, in a tube with heparin as anticoagulant, before treatment and 1, 2, 3, 4, 6, 8, 10, 12,

FOI 26-3132 - Document 5

24, 36, 48 and 72 h post-treatment. These samples were centrifuged (2000 × *g*, 15 min) within 30 min of their collection, so that the plasma could be separated off and kept frozen at −70°C until assayed. Plasma concentrations of ivermectin were determined by reversed-phase HPLC (Edwards *et al.*, 1988). The area under the curve of plasma concentration *versus* time to the last experimentally determined concentration (AUC) was determined by the linear trapezoidal rule. Maximum plasma concentrations (C_{max}) and the times at which they were achieved (T_{max}) were noted directly.

Monitoring during Hospitalization and at Follow-up Visits

Adverse events were recorded throughout the admission period and graded as described previously (Awadzi, 1980). Skin snipping and fly feeding were repeated on day 8 for all the SOR, the ivermectin naive and the one subject (known as the 'late convert') who was categorized as an SOR in 1997 and a responder in 2001. All of the subjects were discharged on day 9 but re-admitted on days 90 and 365, for follow-up. At each follow-up visit, the subjects were asked about their general health, whether they had used any drugs or herbal preparations since last seen and, if so, for what purpose. They were given physical and ocular examinations and the skin snipping and fly feeding were repeated on the same groups as at day 8 (except that the 'late convert' was spared fly feeding on day 365). None of the responders (who had been found skin-snip-negative in the field in 1997 and in the hospital in 2001) was subjected to any further skin snipping or fly feeding after the initial examination.

During the day-90 visit, all the skin nodules that could be detected on each subject were excised aseptically, using 2% xylocaine as the local anaesthetic. Each extracted nodule was placed in sterile Eagle's minimum essential medium (MEM) supplemented with 10% foetal calf serum and antibiotics, and examined under a dissecting microscope. Samples of the extruded contents of any damaged nodules were taken, and examined, as wet smears, for embryos. The adult male and female worms in the nodules were harvested by collagenase digestion (Schulz-Key *et al.*, 1977). All the fragmented and calcified worms were noted and then discarded. An inverted microscope was used to check the culture medium around each nodule, and the genital tracts of intact or damaged female worms, for mff. Preferentially, embryogrammes were made from intact female worms and examined, as described by Schulz-Key *et al.* (1980). Embryogrammes were described as 'active' if developmental stages up to mff were present and 'inactive' if the adult females contained empty uteri or one-cell embryos only.

The mff obtained from the skin snips were either stored dry in microtitre plates, after isopropanol treatment, or in 2-ml cryotubes containing 1 ml isopropanol each. Each of the adult male and female worms recovered and each of the deposits from the embryogrammes was fixed in 1 ml isopropanol or 1 ml ethanol, in a 2-ml tube. This preserved material, like that from the fly-feeding experiments, was shipped to a specialized laboratory for genetic investigation.

End-points and Criteria of Parasite Sensitivity to Ivermectin

PRIMARY END-POINTS

The primary end-points used were the sensitivities of the mff and the adult worms. Sensitivity of the mff was measured as the reduction in the skin count between day 0 (pre-treatment) and day 8, supported by the entomological findings. The sensitivity of the adult worms was evaluated from the embryogrammes and the counts of mff in the skin-snips taken on days 90 and 365.

In order to determine the expected response of the mff at various time-points, the skin-snip results from all the blinded studies conducted in Hohoe Hospital between 1991 and 1998 in which single doses of ivermectin of at least 150 μg/kg were administered were

FOI 26-3132 - Document 5

pooled. [Efficacy against the mff and adult worms is not improved by increasing single (Awadzi *et al.*, 1995, 1999) or multiple (Gardon *et al.*, 2002) doses of ivermectin beyond the standard dose of 150–200 μg/kg.] All of the pooled data came from skin-snips taken, in the same way and by the same individual, as in the present study. The skin counts recorded for individual patients on days 8, 90 and 365 post-treatment were categorized, as percentage reductions in the pre-treatment counts, and summarized (Table 2). On the basis of these data, the mff in a subject of the present study were considered sensitive to ivermectin if (1) the level of the microfilaridermia on day 8 showed a reduction of at least 60% compared with the initial level and (2) no blackflies fed on the subject on day 8 contained L_3 when dissected 10 days later.

The prime indicator of a sensitive adult female worm, in SOR or responders, was an inactive embryogramme on day 90 (all worms from the ivermectin-naive were expected to have active embryogrammes on day 90). Additional criteria were day-90 and day-365 counts of mff in the skin that did not exceed 6% and 40% of the day-0 counts, respectively (Table 2). In subjects without nodules and the ivermectin-naive, the sensitivity of the adult worms had to be based entirely on the counts of mff in the skin.

SECONDARY END-POINTS

The secondary end-points were the PK parameters (AUC, C_{max}, and T_{max}), which, owing to inter-subject variability (Awadzi *et al.*, 1994), were described in terms of medians and inter-quartile ranges (IQR). Values of AUC and C_{max} at or below the lower quartile were assumed to indicate reduced bio-availability. For T_{max}, values at or below the lower quartile indicate a

TABLE 2. *Changes in the counts of microfilariae in the skin (pooled data from patients hospitalized in Hohoe, Ghana) with time after first treatment with ivermectin*

Feature	Ivermectin dose (μg/kg) 150	Ivermectin dose (μg/kg) 200–800*	Criterion of adequate parasite response

EOI 26-3132 - Document 5

relatively rapid appearance of ivermectin in the systemic circulation. These PK parameters were examined in the subjects who showed less-than-expected reductions in their microfilaridermias or had active embryogrammes, to determine if inadequate exposure to ivermectin was a factor in their sub-optimal response. In subjects with normal parasite responses it was presumed that an adequate exposure had occurred.

Data Management

Throughout the study, each subject was considered separately. The results observed were compared with the (previously defined) expected values, so that decisions could be made about the subject and the parasites that he harboured. Pooled data were used only in the determination of cut-off points for the PK parameters. Most of the data are presented in a tabular format and for individual subjects; they are equivalent to case reports. The baseline data are presented for all subjects. The sensitivities of the adult worms, as based on the embryogrammes and skin counts, are summarised for the SOR who had nodules and for the ivermectin-naive. As the subsequent summaries are limited to those subjects whose parasites showed an abnormal response to ivermectin, no post-treatment data are tabulated for any subject (whether a responder, SOR or ivermectin-naive subject) whose parasites responded as expected. Some SOR of special interest are mentioned in the text. The entomological results from this study and the results of the genetic investigation of the parasitic material collected will be presented in detail elsewhere.

RESULTS

The procedures for subject selection and examination, the target criteria for parasite sensitivity and the final reclassification of subjects participating in the trial are summarized in Figures 1 and 2.

The 42 subjects who agreed to participate in the investigation were all males and all completed the hospitalized treatment and follow-up. The essential background features, as assessed at the beginning of the hospital study, are presented in Tables 3 and 4. The SOR from the LBV basin tended to have higher levels of microfilaridermia, more mff in the anterior chamber of the eye and a greater number of nodule sites than the subjects from the Pru river basin (Table 3). Only two responders came from the LBV basin whereas five came from the Pru basin (Table 4). All the ivermectin-naive subjects had nodules and skin counts that were generally higher than those in the SOR, but only three had mff in the anterior chamber of at least one eye (Table 4).

All the participants were in good general health and their haematological and biochemical tests did not reveal any underlying disease. *Mansonella perstans* was found in all the participants from the LBV basin except number 09, in three participants from the Pru basin (numbers 18, 22 and 24) and in subject 32 from the Tordzi basin. Light infections with hookworm (24–792 ova/g faeces) were found in 20 subjects.

Adverse Events

The adverse effects of ivermectin were mild. The most common was bodily pain (eight subjects), followed by headache (seven), then arthralgia, pruritus, gland pain or limb swelling (six cases each), and muscle aches (five). Acetaminophen was given to six subjects for bodily pain, headache, gland pain, joint pain and/or muscle aches, and to two other subjects for low backache unrelated to the treatment. Severe itching of the legs occurred in 18 subjects following fly feeding and was relieved by the local application of calamine lotion.

Parasite Sensitivity to Ivermectin

The skin mff in all but five subjects were found sensitive to ivermectin. The exceptions were subject 07 from the LBV basin (who

FOI 26-3132 - Document 5

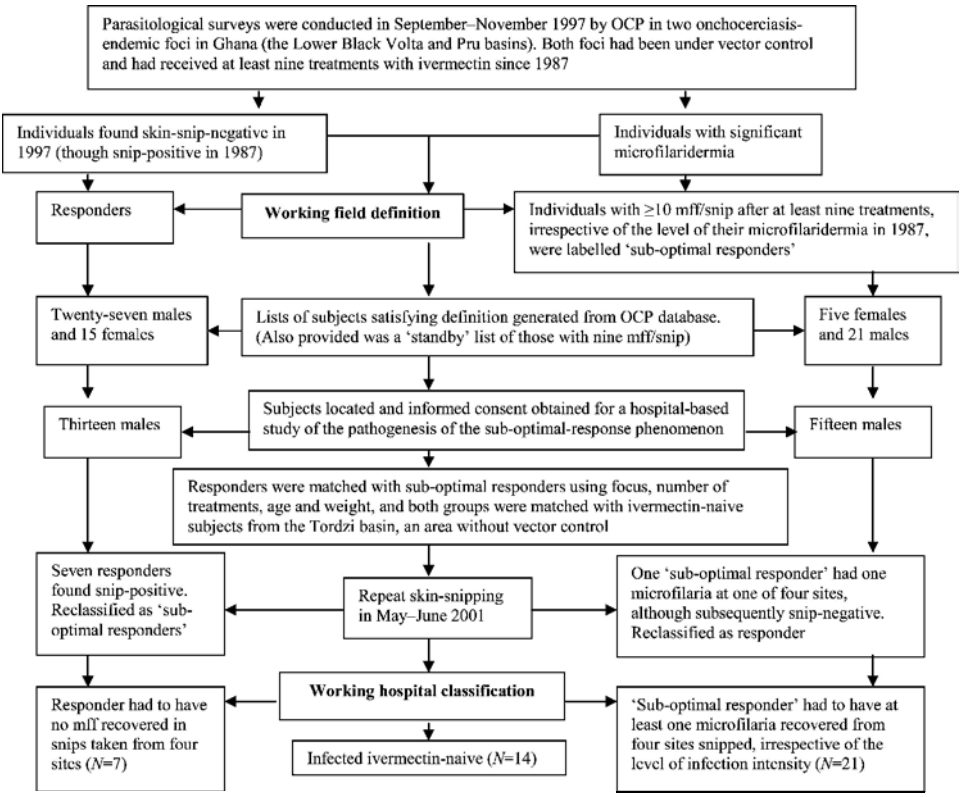

FIG. 1. The approach used to investigate the causes of persistent microfilaridermias despite multiple treatments with ivermectin — subject selection and classification. OCP, Onchocerciasis Control Programme in West Africa; mff, microfilariae.

only showed a 55.4% reduction on day 8, compared with his initial count), subject 16 from the Pru basin (whose skin count increased from 2.0 mff/4 mg on day 0 to 2.4 mff/4 mg on day 8) and subjects 29 and 49 from the Tordzi basin (whose counts increased from 0.6 to 4.7 and 59.3 to 77.4 mff/4 mg, respectively). Infective larvae (L_3) were also found in the blackflies that had fed 10 days earlier (on day 8 post-treatment) on subject 49.

The characteristics of the nodules and the adult female worms, the results of examination of the embryogrammes, and the skin counts on days 90 and 365 (expressed as percentages of the initial counts) are summarized, for the SOR with nodules and the ivermectin-naive, in Table 5. All the embryogrammes of the worms obtained from the nine subjects from the LBV basin (but none of those of the worms from the Pru-basin subjects) were 'active'. The adult worms obtained from six out of seven subjects from the Tordzi basin had active embryogrammes.

The day-90 count of skin mff was below 6% of the initial count in all subjects except numbers 07, 10 and 12 from the LBV basin, number 24 from the Pru basin, and numbers 29, 35 and 36 from the Tordzi basin. By day 365, the adult worms in all but two subjects from the LBV basin (the exceptions being numbers 01 and 06) and those in one subject (number 15) from the Pru basin and one (number 40) from the Tordzi basin were showing a poor response to the drug, with levels of microfilaridermia that were $>40\%$ of those recorded initially. In fact, six out of nine subjects from the LBV basin had more intense microfilaridermias on day 365 than

EOI 26-3132 - Document 5

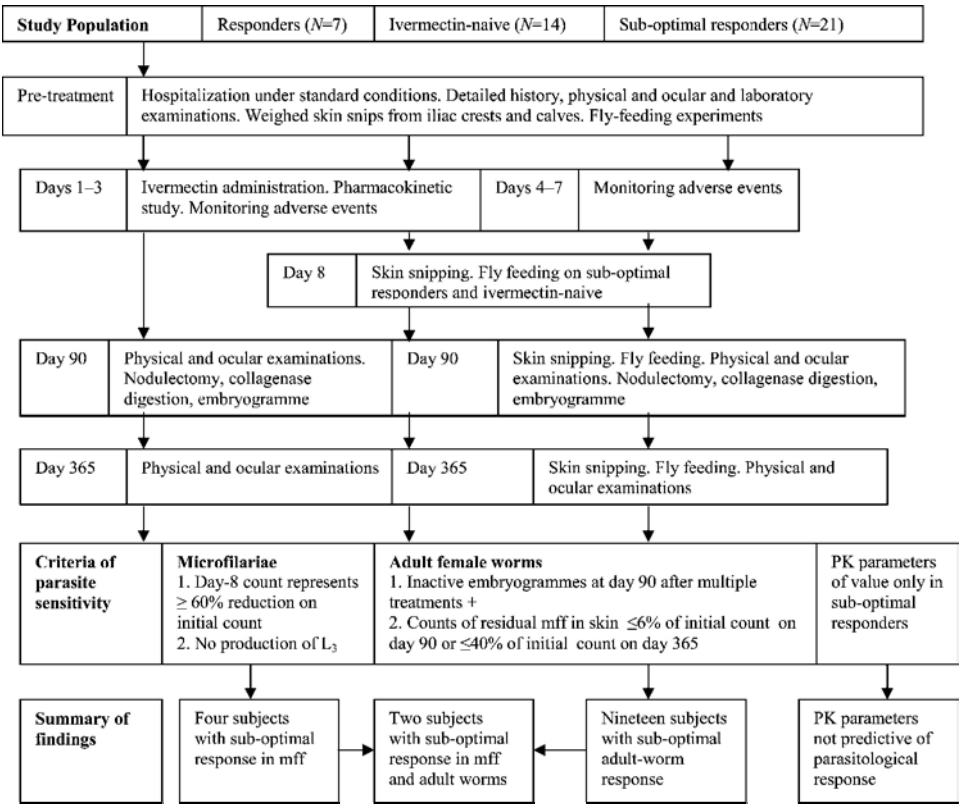

FIG. 2. The approach used to investigate the causes of persistent microfilaridermias despite multiple treatments with ivermectin — the examinations, the criteria for parasite sensitivity, and the main observations made. L_3, Third-stage larvae; PK, pharmacokinetic; mff, microfilariae.

they did when first admitted (data for five of these six subjects are shown in Table 5; the other had no nodules).

Among the SOR without nodules (i.e. numbers 03, 08 and 11 from the LBV basin and numbers 16–20 from the Pru basin), subject 03 was skin-snip-negative on day 90 but had a day-365 count (29.2 mff/4 mg) that was more then four times higher than his initial count (6.2 mff/4 mg). Subject 08 was snip-negative on days 90 and 365 whereas subject 11 was negative on day 90 but had a day-365 count that was 46.7% of his pre-treatment one. Subjects 16, 17, 19 and 20 were snip-negative on days 90 and 365 but subject 18 was snip-positive on both of these days, with counts that were 12% and 136.1% of the initial counts, respectively.

Summary of Parasite Responses to Ivermectin

There were 21 subjects (12 from the LBV basin and nine from the Pru basin) who were classified as SOR at the beginning of the trial. On re-challenge, the results from only six of these SOR — one (number 08) from the LBV basin and five (numbers 17, 19, 20, 21 and 24) from the Pru basin — indicated that their mff and adult worms were sensitive to ivermectin. The 21 subjects with abnormal microfilarial and/or adult-worm responses — two of whom (numbers 07 and 29) had abnormally responsive mff **and** adults — comprised 11 SOR from the LBV basin, four SOR from the Pru basin and six ivermectin-naive subjects from the Tordzi basin (Table 6).

Pharmacokinetic Parameters

The qualitative assessments of AUC indicated considerable inter-individual variation in the extent of drug exposure. The AUC values obtained, from 40 of the subjects, had a median of 397 ng/ml.h (IQR = 202–856 ng/ml.h). The C_{max} values (obtained from 41 subjects) had a median of 22 ng/ml (IQR = 14–36 ng/ml) and the T_{max} data (obtained from 41 subjects) had a median of 4 h (IQR = 3–6 h). The AUC and C_{max} values for all of the subjects from the LBV basin were within or above the IQR whereas those for all of the subjects from the Pru basin fell below this range. Two of the subjects from the Tordzi basin (numbers 29 and 40) had AUC and C_{max} values within or above the IQR, two (numbers 35 and 49) had AUC and C_{max} values below the range, and two (numbers 36 and 39) had either an AUC value or a C_{max} value that was below this range. The T_{max} values for five subjects from the LBV basin, three from the Pru basin and two from the Tordzi basin were also below the corresponding IQR.

DISCUSSION

Taken together, the present results indicate that the PSM observed despite multiple treatments were most probably the result of the adult female worms failing to respond adequately to ivermectin.

The present evaluation of adult-worm response was based predominantly on the level of reproductive activity of the female worms, as demonstrated in embryogrammes. The embryogrammes of the worms from the LBV were highly active; since the major effect of multiple treatments with ivermectin is the suppression of the production of mff (Chavasse *et al.*, 1992; Duke *et al.*, 1992; Plaisier *et al.*, 1995), this level of reproductive activity shown by the adult female worms was abnormal. In nine out of 11 subjects from the LBV basin, there was a rapid increase in the counts of skin mff between days 90 and 365 following the re-challenge with ivermectin, with day-365 counts that were >40% (in six cases >100%) of the initial values (Table 6). Although the embryogrammes of the worms harvested from all of the SOR from the Pru basin were inactive, three of these SOR had abnormally high counts of skin mff on both days 90 and 365 (one subject) or just day 90 (one subject) or day 365 (one subject); these three SOR presumably harboured adult worms with active embryogrammes but in unknown locations. In six out of seven subjects from the Tordzi basin, embryogrammes were active, as expected following a first dose of ivermectin. Although the counts of skin mff were higher than expected in three of the Tordzi subjects on day 90 and in two others on day 365, they never exceeded the initial count. This contrasts with the findings for the subjects from the LBV basin but is in line with the pooled data summarized in Table 2. The level of reproductive activity of the adult female worms in most SOR from the LBV basin was therefore at least as high, if not higher, than that observed in subjects receiving their first dose of ivermectin.

The mff from all but two of the SOR were sensitive to ivermectin (the exceptions being subject 07 from the LBV basin and 16 from the Pru). The good response to ivermectin of the mff in nearly all of the SOR excludes the possibility that PSM are the result of an incompetent immune system in the host (Ali *et al.*, 2002), and exonerates the mff as important contributors to the phenomenon. Subject 49, who was ivermectin-naive, had a more intense microfilaridermia on day 8 than on day 0, and L_3 developed in the blackflies that fed on him on day 8. Here, the mff fulfilled all the previously defined criteria of a lack of sensitivity to ivermectin. By day 90, however, the level of microfilaridermia in subject 49 had fallen well within expected limits (Table 6). A possible explanation of these observations is that the response to ivermectin of the mff was simply slower than usual, although this in itself implies that the mff were abnormal *ab initio*.

FOI 26-3132 - Document 5

Six subjects originally classified as SOR were found to have ivermectin-sensitive mff and adult worms. This led to a final re-classification in which three subjects from the LBV basin and 10 from the Pru basin were considered responders and 11 subjects from the LBV basin and four from the Pru basin were classed as SOR. The change in the category of six subjects, from SOR to responders, was not the result of a change in the sensitivity of their parasites but reflects the very stringent definition of a 'normal' response employed in the present study. This required that no mff be present in four skin snips taken from areas where the maximum concentrations of mff usually occur (i.e. the iliac crests and calves). Inevitably, some subjects with low numbers of mff in their skin were initially classed as SOR, pending the results of the re-challenge with ivermectin.

The main aim of the ivermectin treatment given to the SOR during the present study was to determine the drug sensitivity of the mff. The sensitivity of the adult worms in the same subjects had already been established by the multiple doses given previously, and was unlikely to be influenced by another single dose. Thus, inactive embryogrammes, coupled with a rapid reduction in the level of microfilaridermia, provide evidence of past and persisting sensitivity of *O. volvulus* adult worms and mff to ivermectin. These were the findings in all six subjects who were reclassified as responders. These six subjects shared some other common characteristics: they appeared to have no (numbers 08, 17, 19 and 20) or very few (numbers 21 and 24) nodules, they had relatively few mff in their skin when admitted (0.12–4.2/mg), they had no mff in the anterior chambers of their eyes, and all except one (number 21) were skin-snip-negative on days 90 and 365 (Tables 3 and 5). These features — which are shared to some extent by the original responders (Table 4), in whom all embryogrammes were found to be inactive — could constitute a working definition of the phenotype of a responder to multiple treatments with ivermectin. No mff were found in any post-challenge skin snips from the 'late convert' (i.e. the original SOR who was re-classified as a responder on admission to the Hohoe Hospital) and none was taken up by any blackfly that fed on him. The same observations would presumably have been made on all the other responders, had they been checked.

The establishment of the exposure of all the participants to at least nine treatments with ivermectin between 1987 and 1997 was essential to the initial definition of a sub-optimal response. Examination of the treatment records provided by the OCP and the Ghana Onchocerciasis Control Unit established that all the eligible inhabitants of the Pru basin had taken 11–14 annual doses by 2000, with the exception of one (subject 24) who had only received nine doses. The data on the treatment rounds in the LBV basin pre-1994 were not as good. The senior author of this article was present, however, at the first treatment round in the LBV basin, and detailed questioning of each of the present subjects from this area (regarding the timing of the doses relative to local and national events) and their descriptions of the adverse effects of each dose over time provided enough evidence to credit each one with the intake of at least nine treatments by 1997. Further treatments were given to the inhabitants of the LBV basin in 1998, 1999 and 2000, with the exception of the subjects from Agbelekame I, who missed the 1998 round.

Detailed personal histories did not reveal any activity, undertaken in the few days before or after an ivermectin treatment, that could have produced an adverse interaction. The results of the clinical and laboratory examinations failed to reveal any underlying disease in any subject. Coincidental infection with *M. perstans* and hookworm were found in several subjects but were unlikely to modify the response of the *O. volvulus* to ivermectin. The PK parameters revealed the expected large inter-individual variation in

FOI 26-3132 - Document 5

circulating plasma concentrations of ivermectin. The main inference from the PK data is that all the LBV subjects had adequate exposure to ivermectin. The significance of the low AUC and C_{max} values in the SOR from the Pru basin is difficult to determine since lower and even undetectable levels of ivermectin (data not shown) were recorded in three of the six subjects (numbers 17, 19 and 24) who were initially classified as SOR but subsequently re-classified as responders. Since the parasites in the latter subjects showed an adequate response to the re-challenge with ivermectin, the PK data recorded in the present study seem to be unreliable predictors of pharmacological response.

The observations listed above make it unlikely that host-related factors were involved in the poor response seen in each SOR. An examination of the 'pill'-related factors also provided no evidence that these played any part in the phenomenon.

The possibility that active embryogrammes and/or high residual numbers of mff in the skin could be the result of new infections was examined in a review of the epidemiological data for the Pru and LBV basins. These data indicated that the residual levels of infection and transmission over the study period were very low. The mean annual transmission potential (ATP), for example, was 45. The ATP is the theoretical total number of infective larvae that would be received in 1 year by an individual stationed at a capture point for 11 h/day and is calculated by adding the corresponding monthly transmission potentials. An ATP of <100 is considered to be a satisfactory result of a blackfly-control programme (WHO, 1995). Thus, in the absence of subject migration into areas of high transmission, new infections were unlikely.

With the elimination of pill and host factors and new infections as the cause of apparent PSM, the only factors that remain relate to parasite tolerance or resistance (Table 2). From the present results, the development of tolerance or the selection for resistance to ivermectin in the adult female worms seems the most likely cause of PSM. It is envisaged that an examination of the genetic profiles of the individual parasites obtained from the various categories of subjects (responders, SOR and the ivermectin-naive) may shed some light on the problem.

In summary, clinical, PK, entomological and parasitological indicators were used to study the responses of individuals and their parasites to ivermectin. Of the 42 subjects from three river basins in Ghana, 21 were found to have *O. volvulus*, predominantly adult female worms, that failed to respond adequately to previous doses or to the first dose of ivermectin; in a small minority of these subjects, the mff also failed to respond adequately. It has been speculated that non-responsive adult worms would have a greater influence on the effective use of ivermectin than non-responsive mff (Grant, 2000). The extent of this phenomenon and any influence it may have had on the control of onchocerciasis in the areas subjected to multiple treatments are unknown. The discovery of sub-optimal response among the ivermectin-naive population supports the concept of a 'first-dose sub-optimal response', possibly related to parasite factors (tolerance). The current results justify the routine monitoring of the efficacy of treatment in any ivermectin-based control programme. Optimally, this should begin when the first pill is given to the first subject.

The results of the present investigation have been discussed informally elsewhere, within the context of current onchocerciasis-control programmes, and more extensive studies have been proposed to define better the sub-optimal-response phenotype and its relationship with ivermectin treatment and any associated changes in parasite genotype.

ACKNOWLEDGEMENTS. The authors thank Merck for supplying the ivermectin tablets. This investigation received financial support from the African Programme for Onchocerciasis Control, the Onchocerciasis Control

ABSTRACT

Introduction: In vitro studies have shown the efficacy of Ivermectin (IV) to inhibit the SARS - CoV- 2 viral replication, but questions remained as to In-vivo applications. We set out to explore the efficacy and safety of Ivermectin in persons infected with COVID19.

Methods: We conducted a translational proof of concept (PoC) randomized, double blind placebo controlled, dose response, parallel group study of IV efficacy in RT - PCR proven COVID 19 positive patients. 62 patients were randomized to 3 treatment groups. (A) IV 6mg regime, (B)IV 12 mg regime (given Q84hrs for 2weeks) (C, control) Lopinavir/Ritonavir. All groups plus standard of Care.

Results: The Days to COVID negativity [DTN] was significantly and dose dependently reduced by IV (p = 0.0066). The DTN for Control were, = 9.1+/- 5.2, for A 6.0 +/- 2.9, and for B 4.6 +/-3.2 . 2 Way repeated measures ANOVA of ranked COVID 19 + / - scores at 0, 84, 168, 232 hours showed a significant IV treatment effect (p=0.035) and time effect (p <0.0001). IV also tended to increase SPO2 % compared to controls, p = 0.073, 95% CI - 0.39 to 2.59 and increased platelet count compared to C (p = 0.037) 95%CI 5.55 - 162.55 × 10^3/ml. The platelet count increase was inversely correlated to DTN (r = -0.52, p = 0.005). No SAE was reported.

Conclusions: 12 mg IV regime may have superior efficacy. IV should be considered for use in clinical management of SARS-Cov-2, and may find applications in community prophylaxis in high-risk areas.

Keywords: Ivermectin, COVID-19, RCT, Efficacy, Safety, Days-to-Negative.

INTRODUCTION

The Corona Virus Disease 2019 (COVID 19) pandemic caused by the Severe Acute Respiratory Syndrome Corona virus -2 (SARS-CoV-2)[1] led to a World Health Organization declared global pandemic on March 11, 2020[2]. As of December 22, 2020, more than 77.7 million people on all continents had being infected and more than 1.7 million people had died globally[3]. Prolonged morbidity after recovery from acute COVID 19[4] and astronomical hospital costs[5], has left hospitals swamped and health workers exhausted. In addition, the global economy is in a depression[6] with massive job losses, furloughing and social movement restrictions.

There have been concerted attempts to seek preventive and interventional modalities to arrest the spread of the contagion by public health measures such as masking, social distancing, self isolation and hygiene, or more recently by vaccines[7,8]

There are also pharmaceutical/ therapeutic agents with antiviral properties, being repurposed to urgently treat or serve as chemoprevention for COVID 19. One such drug is Ivermectin, which has exhibited broad spectrum anti-parasitic, anti-bacterial and antiviral properties against many RNA viruses[9,10]. Ivermectin is extensively used, with good safety profile in Nigeria and other African nations in treating ocular onchocerciasis[11]. Of more current import, Ivermectin was shown to exhibit a 5000-fold reduction in SARS-C0V-2 viral RNA in vitro in Vero-h/SLAM cells in a study from Australia.[12]

There are several mechanisms by which Ivermectin may inhibit SARS-CoV-2 in COVID 19 patients, including by inhibition of RNA -dependent RNA polymerase (RdRP) required for viral replication,[13] abolition of importin-α/β1 heterodimer nuclear transport of SARS-CoV-2 from the cytosol to the nucleus, and inhibition of viral mRNA and viral protein translation[14] .

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint

However, there has been skepticism as to whether the virucidal IC50 of Ivermectin against SARS-CoV-2 of 2.4uM (obtained in vitro) could be feasible or attainable in humans or patients with COVID 19. This is because a 10-fold dose of Ivermectin (120mg) simulations-based kinetics in cattle still did not yield peak drug levels (Cmax) approaching the IC50 for in vitro SARS-CoV-2 inhibition[15]. In yet another simulation, based on human pharmacokinetics of different potential antiviral SARS-CoV-2 repurposed drugs, Ivermectin was one of the drugs predicted to have 10-fold concentrations higher than their reported 50% effective concentration [EC50].[16] There is thus conflicting report on simulations from cattle and human pharmacokinetics in the effective anti-SARS-CoV-2 concentration attainable by Ivermectin dosing. Ivermectin has a long half life ($t^{1/2}$) of 81-91 hours, and is highly lipophilic with a high volume of distribution (Vd), indicating preferential lung and tissue accumulation.[17]

Pharmacodynamically, Ivermectin dose-dependently inhibits lipopolysacharide (LPS) induced release of inflammatory cytokines (interleukins) in mice and improved LPS-induced survival.[18] Collectively, there are were multiple pharmacodynamic and pharmacokinetic basis that suggest a potential utility and efficacy of Ivermectin in COVID 19.

We therefore tested the hypothesis that Ivermectin will exert a clinically and therapeutically beneficial effect in mild to moderate COVID 19 patients in a randomized double blind controlled clinical trial in Nigerian COVID 19 patients with RT- PCR proven SARS-CoV-2 positivity.

METHODOLOGY.

The study was a proof of concept (PoC), double blind, randomized controlled trial, of a parallel group, dose-response design. There were 3 treatment groups to which COVID 19 positive patients were randomized. One group received Ivermectin 6mg (given every 84 hours) twice a week, another group received Ivermectin 12mg (given every 84 hours) for 2 weeks, and the third group received lopinavir / ritonavir daily for 2 weeks.

The study protocol received ethical review and approval of the Institutional Review Board of the Lagos University Teaching Hospital (LUTH), Lagos, Nigeria. The protocol was also reviewed and approved by the Nigerian Agency for Food and Drug Administration and Control (NAFDAC) in Lagos.

The patient inclusion criteria were COVID 19 PCR proven positive patients, who gave informed, written consent to participate in the study, and were either asymptomatic or had mild/moderate symptoms.

Study exclusion criteria were COVID 19 negative patients, patients who had COVID pneumonia or requiring ventilator therapy, renal failure, thromboembolic complications, or unconscious by reduced Glasgow Coma Scale.

There were 62 patients randomized to the 3 treatments. COVID 19 PCR testing was undertaken at baseline (pretreatment time 0 hour) and after dosing at 0 hours, 84 hours, 168 hours, 232 hours and 336 hours.

The baseline demographic, clinical, laboratory and virological data of the 3 patient groups is summarized on Table 1.

RT - PCR

COVID 19 test was by RT polymerase chain reaction (PCR) testing for 3 genes. Using a geneexpert machine and testing simultaneously for three genes

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint

(Orf, EN, N) A positive COVID 19 test requires all the 3 genes to be present, and a negative test requires all the genes to be functionally absent.

The Cycle threshold (Ct) of the gene tester of more than 40 was regarded as negative, and values below 40 are positive where the Ct value bears an inverse logarithmic relationship to the SARS -CoV-2 viral load.[19,20]

Routine biochemistry, hematology, arterial oxygen saturation (Pa02) temperature and clinical data were gathered, and prognostic ones were recorded at the aforementioned times.

RESULTS.

This study was undertaken between May and November 2020. A general description of the study population and the spread over three arms is found in Table 1. Sixty-three patients with positive PCR result were randomised into three arms of the study. There was one withdrawal, thus sixty-two patients completed the study. The average age was 44.1years (SD14.7), ranging from 20-82. There were 43 males and 19 females. The patients had mild to moderate clinical symptoms and none of them required ventilator, although five required intranasal oxygen, 3 in the 12mg arm (B) and two in the control arm (C). One third of the patients reported with a fever and cough, while 44% and 18% respectively reported with headache and difficulties with breathing. 12% reported with anosmia/ageusia. The commonest comorbidities were Diabetes Mellitus (DM) (2) and Hypertension (9), while some had combined hypertension and DM. Some patients required concomitant medications such as dexamethasone, enoxaparin, and supplemental oxygen.

The effectiveness of randomization was assessed, and the results are displayed in Table 1. In all, twenty-one patients were each randomised into the 6mg (A) and 12mg (B) Ivermectin arms while twenty went into the control arm (C).

There was no significant difference in the distribution of the age, sex and symptoms, comorbidities, blood counts, prothrombin time, liver function and

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint

It is made available under a CC-BY 4.0 International license .

kidney function tests. There were however slight differences in the baseline Cycle threshold (Ct) values, being lower in the A arm than the other two arms with regards to the ORF and N genes, but similar for the EN gene. The distribution of other supplemental medications taken by participants, aside from Ivermectin, was broadly similar. These included Zinc, ascorbic acid, vitamin D and Azithromycin.

Changes in variables over time was assessed.

The time to SARS-CoV-2 negativity is described in Figures 1A and B and Table 2. Ivermectin significantly and dose-dependently reduced time to negativity compared to the control group. The mean days-to-negative in the control arm was 9.15 (CI 5.68 to 12.62) while for combined Ivermectin arms it was 5.33 (CI 4.33 to 6.32). Average days-to-negative in the combined Ivermectin arms (any Ivermectin) was thus shorter by 3.83 days (95% CI 6.54 to 1.11) compared to controls P=0.0066. (Student t-test.)

Mean days-to-negative for the 12mg arm was however shortened by 4.5 days, and by 3.15 days for the 6mg arm compared to controls. These differences were significant by ANOVA P>F =0.0179.

The distribution of the days-to-negative are depicted in Figure 1A. Figure 1B depicts a Kaplan Meier (KM) curve comparing time to negative (failure) for the three arms. Log rank test for equality of survival functions gave P>chi = 0.0363. Figure 1C depicts KM curve comparing 'Any Ivermectin' with controls. P>chi=0.019.

Cox proportional hazard model enabled computation of Hazard Ratio (HR) using the control arm as base. HR for the 6mg arm was 1.68, (P=0.120, CI 0.87 - 3.25) while for the 12mg arm, HR was 2.38 (P=0.011, CI 1.22 - 4.65). This suggests that the 12 mg treatment arm will cause the patient to progress 2.38 times faster than the control group. Although there is a HR of 1.68 for the 6mg arm, it did not achieve statistical significance.

The HR for "Any Ivermectin" was 1.96, P= 0.024, CI 1.09 -3.51.

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY 4.0 International license .

A 2-way 2 factor Repeated Measure Analysis of Variance (RAMOVA) concerning SARS-CoV-2 PCR assays was carried out to compare means and variances of each of the three treatments at the different time points to obtain treatment effect, Time effect and Time Treatment interaction. A plot of the Means and Standard Error of the Means of 20 patients in each of group A, B, C is shown in Figure 2. There was a significant treatment ($p=0.035$) and time effect ($p < 0.0001$) of Ivermectin on COVID 19 ranked scores compared to controls.

The likelihood of negativity by day five was explored. The Ivermectin arm was 3.45 times more likely to go negative by or before day five, P=0.0271, 95% CI 1.12-10.63. This effect is slightly mitigated by sex (adjusted OR 3.44 P>z 0.031 CI= 1.12 -10.6) but more significantly by age (OR 2.77 P>z 0.113 CI= 0.79 to 9.8).

Changes in clinical and laboratory parameters at baseline and at seven days (or as otherwise stated) were observed for the three arms and recorded in Table 3. Day seven was used as a midway point in the trial. Of note was that there was a moderate increase in SpO2 in the Ivermectin arm, although this did not attain significance (P=0.098). The difference from baseline to highest attained SpO2 during the study for each participant is also depicted in Figure 3A, in which baseline figures are compared with highest attained SpO2. (P=0.073)

Because the drug Ivermectin is essentially metabolized in the liver via CYP34A, changes in liver enzymes such as SGOT (serum glutamic-oxaloacetic transaminase,) SGPT (Serum glutamic pyruvic transaminase) and Alkaline Phosphatase were analysed. Both arms of treatment showed reduction in SGOT and SGPT and moderate increases in Alkaline phosphatase. None of these were statistically significant.

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY 4.0 International license .

There were also no significant differences in changes in kidney function tests such as Blood Urea Nitrogen and Creatinine between the three groups.

There was a notable significant increase in platelet counts in the ivermectin arm relative to the control arm (P=0.037). See Figure 3B. There was also a moderate but not significant relative increase in lymphocyte count. The overall Platelet Lymphocyte Ratio (PLR) was not significantly changed (Table 2). In Figure 3C, we note a statistically significant (P=0.0055) negative correlation between days-to-negative and increase in platelet count. The higher the change in platelet count, the fewer the days-to-negative. Pearson's r= -0.53, R^2=0.28

There were slight increases in prothrombin time across all arms, more so in the control arm. Rate of increase was not significantly different across arms.

There were no significant changes over time, across the three groups in clinical parameters such as Respiratory rate, Heart rate, Temperature, and symptoms such as cough and dyspnea as assessed by Likert scales.

There was no significant overall effect of age on days-to-negative by linear regression analysis (r =0.046 p = 0.728). However, those in the 30-40-year age band had a lower time to negative relative to others.

No adverse effects of Ivermectin was reported in response to questioning or spontaneous report.

Symptomatic improvement was seen in all patients, with resolution of fever dypnea and other signs. There was no mortality and the patients remained well on follow up.

DISCUSSION

Our findings show a statistically significant and dose dependent effect of Ivermectin to reduce the time to SARS-CoV-2 negativity in RT-PCR COVID 19 positive patients (p =0.0066) and significant treatment (p=0.035) and

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY 4.0 International license .

time effect (p <0.0001) of Ivermectin on COVID 19 ranked scores compared to controls by RAMOVA. A Hazard Ratio of 2.38 in the 12mg arm suggests that negativity events such as described above are likely to occur more than twice as fast with Ivermectin. In addition, Ivermectin appears to be 3.45 times more likely (P=0.0271, 95% CI 1.12-10.63.) to induce negativity by day 5 compared to controls. Collectively, these results demonstrate a likely beneficial treatment effect of Ivermectin, to reduce the duration of illness, elicit faster recovery and diminution of qualitative indices of SARS-CoV-2 viral load compared to the usual treatment.

These results are consistent with those of Ahmed et al[21] who demonstrated a significant reduction in time to COVID 19 virological clearance with Ivermectin of 3 days on average, albeit at a higher dose of 12mg daily for 5 days in Bangladesh. Similar findings were reported by Elgazzar and colleagues in Egypt[22].

Our results demonstrate a dose-response in the effects of Ivermectin 6mg and 12mg twice weekly in time to SARS-CoV-2 negativity. The time (mean +/- SD) to negativity (days) in the treatments were; 6mg; 6+/-2.95 , 12 mg; 4.65 +/- 3.19 , and the controls 9.15+/- 7.26, p =0.02 ANOVA. When both Ivermectin groups were combined (with a new mean 5.34 +/- 0.07 days n=41) the mean difference SEM from placebo control, of - 3.81 +/- 1.34 days was statistically significant p = 0.0066, 95% CI -1.13 to - 6.49 days.

These collectively suggest that the 12 mg dose achieved a faster SARS-CoV-2 virological clearance compared to the 6 mg dose, and that using these standard doses of Ivermectin employed in onchocerciasis treatment caused a 3.8 days faster virological clearance, and clinical amelioration compared to controls on lopinavir/ritonavir.

The findings also provide Proof of concept (Poc) of Ivermectin efficacy against SARS-CoV-2 at the doses that were initially considered inadequate based on pharmacokinetic simulations[15,17]

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY 4.0 International license .

The progressive reduction in COVID 19 positivity in the Ivermectin-treated group over time, as well as the treatment effect were sustained with no time-treatment interactions (Figure 2. Table 2). This was associated both with symptomatic improvements as well as Ivermectin-induced reversal of abnormal COVID 19 prognostic parameters. Ivermectin treatment was associated with a strong trend to an increase in arterial oxygen saturation (SPO2%) compared to controls (See Figure 3A) p= 0,073 and 95% CI of -0.39 to 2.59. Pulse oximetry at the finger digits, has recently been shown to exhibit racial divergences with a higher likelihood of overrating SPO2% and leading to "occult hypoxemia" occurring more in black people in comparison to whites[23] thus, the real change in SPO2 with Ivermectin may have been masked.

Platelet count is another prognostic index in COVID 19 with thrombocytopenia reflecting platelet consumption in SARS-CoV-2 as part of sepsis-induced coagulopathy, even before frank Disseminated Intravascular Coagulation (DIC) manifests as hemorrhage or thrombosis[24]. Ivermectin treatments (combined 6mg and 12 mg dose) caused an increase in platelet count relative to the control group patients with a 95% CI for the difference of 5.55 to 162.55 x 10^9/L p= 0.037 ANOVA, F =4,88, df -24. (See Table 3). Further, there was an inverse correlation (r = - 0. 52 , R^2 = 0. 28, p = 0.005) between the Ivermectin induced increase in platelets and the time to SARS-CoV-2 negativity in the patients (See Figure 3C). These platelet results indicate an Ivermectin effect to reverse a negative prognostic factor, and the increase in platelets is associated with a faster resolution and inhibition of SARS-CoV-2 virological proliferation.

The baseline prothrombin time appeared slightly prolonged in all the patients (>0.15 seconds), but no effect of treatment in any group was apparent. The concurrent trend to Ivermectin improvement of COVID 19- associated arterial

medRxiv preprint doi: https://doi.org/10.1101/2021.01.05.21249131; this version posted January 6, 2021. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY 4.0 International license .

hypoxemia, concomitant with a reduction in prothrombotic hematological coagulopathy (reversal of platelet consumption) may be a consequence of ivermectin anti-inflammatory reduction in COVID-19 hypercytokinemia ("cytokine storm'), and is entirely consistent with reduction in mortality and especially in patients with SARS-CoV-2 pulmonary complications.[25-28] Meta analysis revealed that IL-6 and associated cytokines are correlated with SARS-CoV-2 severity in patients[29] which are under Janus Kinase (JAK-STAT) signaling pathway.[30] Given the known effect of Ivermectin to inhibit IL-6, TNF-alpha in vivo and in vitro, and its suppression of NF-kappa B translocation in mice,[18] a formal controlled study of the effect of Ivermectin on hyper-cytokinemia is now indicated in COVID 19.

There were no significant changes in hepatic and renal functions given that Ivermectin is hepatically metabolized. The gender of participants did not exert any effects on the pharmacodynamic effects of Ivermectin in time to COVID 19 negativity. However, the likelihood of negativity by day 5 was mitigated by age from 3.45 to 2.77.

Ivermectin was remarkably well tolerated and there was no adverse drug event reported spontaneously or in response to inquiry.

In conclusion, Ivermectin exhibited a dose-dependent significant inhibitory effect on SARS-CoV-2. This study provides support for the translation of the in vitro findings of Caly et al[12] at doses that were initially thought to be suboptimal in humans. The 12mg twice weekly regime appears to confer a superior efficacy. Ivermectin modified prognostic factors such as arterial oxygenation and platelet and hematological indices of SARS-CoV-2 infections.

The mechanisms of the benefits were not established in this study, but an effect on JAK-STAT and NF-kappa B related cytokines should be studied in patients.

Further study of Ivermectin 12mg in the pre-exposure prophylaxis and prevention of community transmission of SARS-CoV-2, such as spoke-and-wheel or targeted hotspots treatment, is now warranted, especially as an interim measure in countries that cannot immediately roll out vaccination programs.

Cellular host factors for SARS-CoV-2 infection

Jim Baggen, Els Vanstreels, Sander Jansen and Dirk Daelemans ✉

The coronavirus disease 2019 (COVID-19) pandemic has claimed millions of lives and caused a global economic crisis. No effective antiviral drugs are currently available to treat infections of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The medical need imposed by the pandemic has spurred unprecedented research efforts to study coronavirus biology. Every virus depends on cellular host factors and pathways for successful replication. These proviral host factors represent attractive targets for antiviral therapy as they are genetically more stable than viral targets and may be shared among related viruses. The application of various 'omics' technologies has led to the rapid discovery of proviral host factors that are required for the completion of the SARS-CoV-2 life cycle. In this Review, we summarize insights into the proviral host factors that are required for SARS-CoV-2 infection that were mainly obtained using functional genetic and interactome screens. We discuss cellular processes that are important for the SARS-CoV-2 life cycle, as well as parallels with non-coronaviruses. Finally, we highlight host factors that could be targeted by clinically approved molecules and molecules in clinical trials as potential antiviral therapies for COVID-19.

Coronaviruses are positive-strand RNA viruses belonging to the subfamily *Orthocoronavirinae* within the family *Coronaviridae* (International Committee on Taxonomy of Viruses) and are subdivided into four genera—*Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus* and *Deltacoronavirus*. Coronaviruses cause intestinal and respiratory infections in a variety of birds and mammals, including livestock and domestic animals.

Seven human coronaviruses (HCoVs) have been characterized, four of which cause mild respiratory infections (HCoV-229E, HCoV-NL63, HCoV-OC43 and HCoV-HKU1). The emergence of two highly pathogenic betacoronaviruses in 2002 (severe acute respiratory syndrome coronavirus (SARS-CoV)) and 2012 (Middle East respiratory syndrome coronavirus (MERS-CoV)) revealed that new pathogenic coronaviruses can emerge in the human population by zoonotic transmission (reviewed in ref. [1]). In late 2019, a pathogenic coronavirus SARS-CoV-2 was first detected in Wuhan, China, causing an outbreak of severe pneumonia. This human pathogen is thought to have originated in horseshoe bats and was probably transmitted to humans through an intermediate host that remains to be identified[2]. Owing to its high contagiousness and the occurrence of asymptomatic carriers, SARS-CoV-2 rapidly spread across the globe and continues to claim human lives and obstruct social and economic activity, while vaccination programs are ongoing. The pandemic has prompted countless efforts to develop vaccines and antiviral therapies, but also many fundamental studies to better understand coronavirus biology. As cellular proviral host factors are potential antiviral drug targets, numerous studies have analysed host factor dependencies of coronaviruses, in particular SARS-CoV-2.

In this Review, we provide an overview of proviral host factors for SARS-CoV-2. After explaining the coronavirus life cycle, we discuss the cellular receptors and proteases that are required for SARS-CoV-2 entry. As only few of the identified proviral host factors have been assigned to specific post-entry stages of the life-cycle, these stages are not discussed separately. Instead, we summarize the wealth of information on proviral SARS-CoV-2 host factors that has been produced by genome-wide functional genetic screens and interactome analyses and discuss their roles in cellular processes. Finally, we highlight host factors that may serve as targets for antiviral therapies against COVID-19.

The coronavirus life cycle

The SARS-CoV-2 virion is an enveloped and pleomorphic particle with a diameter of around 60–100 nm (ref. [3]). The helical nucleocapsid contains the ~30 kb single-stranded RNA genome packaged by the nucleocapsid (N) protein[4]. It is surrounded by the viral envelope, which contains the spike (S), membrane (M) and envelope (E) proteins. Coronavirus entry into cells is mediated by S, a homotrimeric class-I fusion protein (reviewed in ref. [5]). The dual role of S is to bind to cellular receptors on target cells and to fuse viral and cellular membranes, triggered by proteolytic cleavage of S by host proteases. Coronaviruses enter cells either through endocytic pathways or by directly fusing with the plasma membrane, depending on the availability of cellular proteases (reviewed in refs. [6,7]) (Fig. 1). After fusion, the nucleocapsid is released into the cytoplasm, after which the genomic RNA uncoats by dissociation from N and is subsequently translated.

Coronaviruses have capped and polyadenylated genomes that contain multiple open reading frames (ORFs), flanked by 5′ and 3′ untranslated regions. The SARS-CoV-2 genome contains at least 11 ORFs[8], encoding 16 non-structural proteins (nsp1–16), 4 structural proteins (S, E, M and N) and a set of putative accessory proteins (ORF3a, ORF3b, ORF6, ORF7a, ORF7b, ORF8 and ORF9b)[9]. Although coronavirus accessory proteins are non-essential for replication in vitro, these proteins are believed to be required for virulence in vivo (reviewed in ref. [10]). Viral gene expression starts with the translation of *orf1a* and *orf1b* directly from the positive-strand RNA genome pp1a is encoded by ORF1a, whereas pp1ab is formed by continuous translation of ORF1a and ORF1b through a programmed −1 ribosomal frameshift (regulated by host proteins such as SHFL), which determines the stoichiometry between pp1a and pp1ab. These polyproteins are processed by viral proteases that are located within nsp3 (PL^{pro}) and nsp5 (M^{pro} or $3CL^{pro}$), yielding the 16 replication proteins nsp1–16 (ref. [11]). nsp1 shuts down host translation and promotes host mRNA degradation, whereas nsp2–16 establish the viral replication–transcription complex (RTC). nsp2–11

KU Leuven Department of Microbiology, Immunology and Transplantation, Laboratory of Virology and Chemotherapy, Rega Institute, Leuven, Belgium. ✉e-mail: dirk.daelemans@kuleuven.be

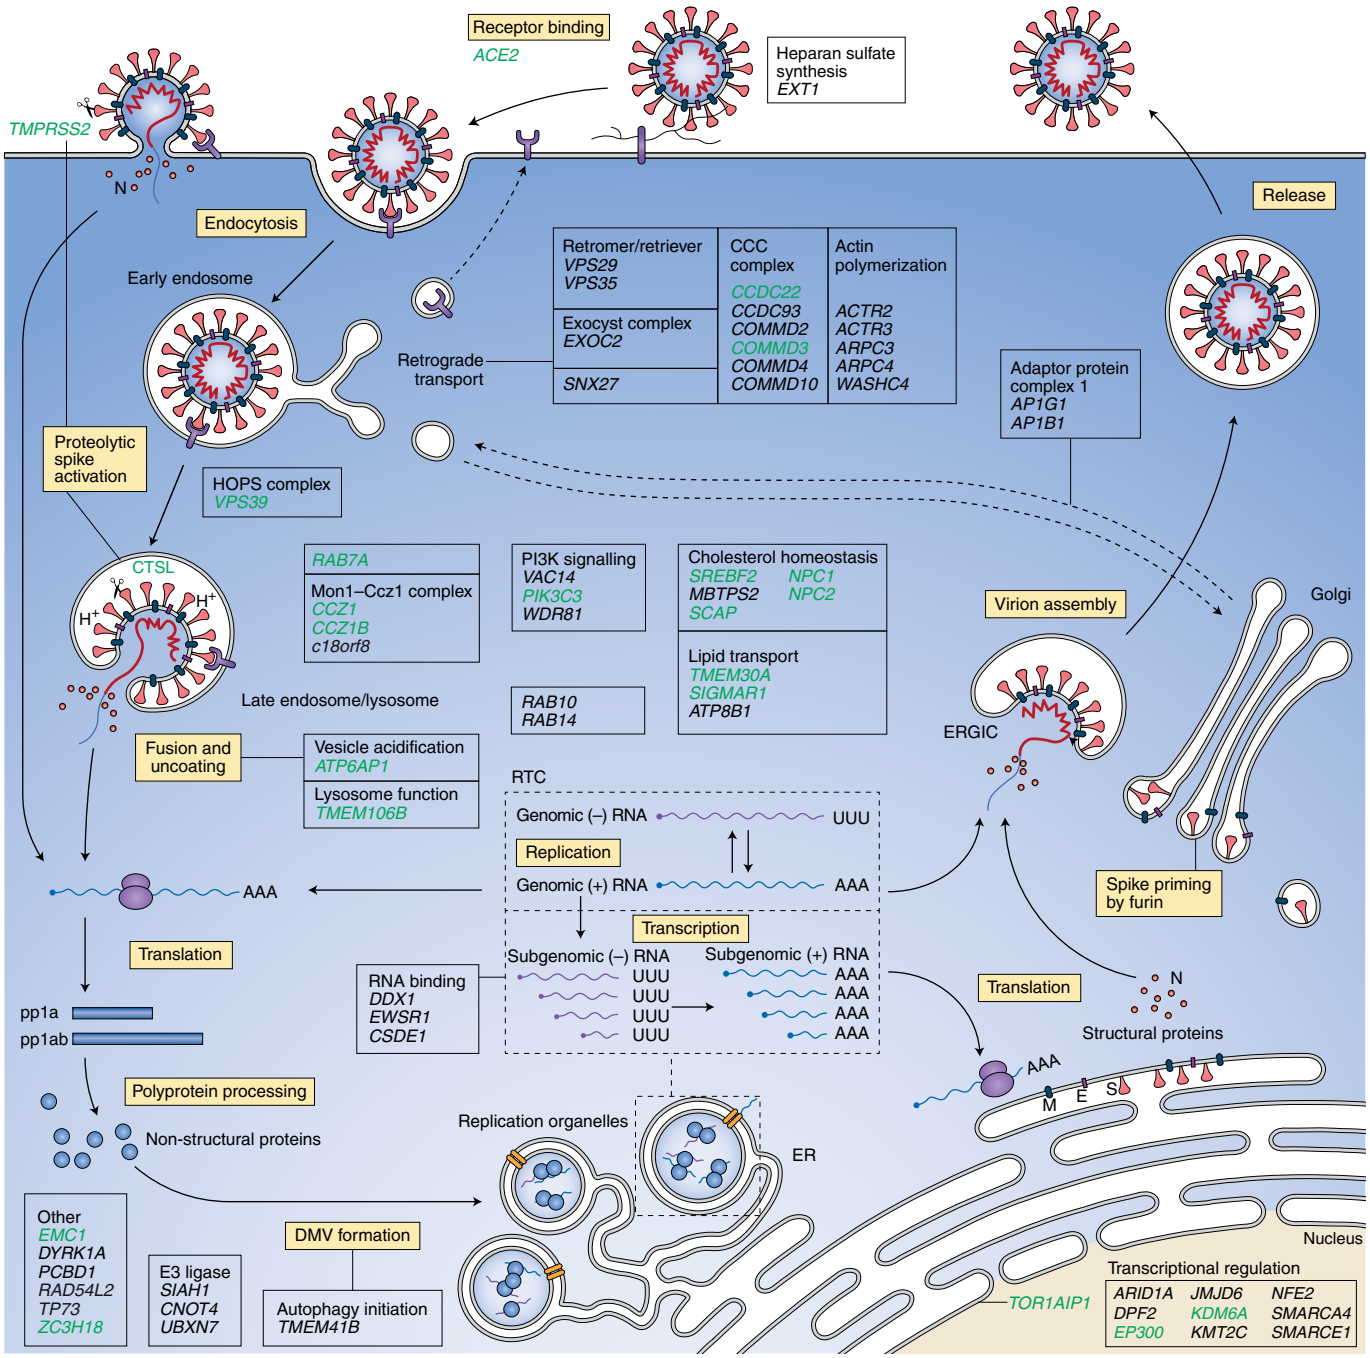

Fig. 1 | Key proviral host factors in the SARS-CoV-2 replication cycle. After SARS-CoV-2 particles attach to the target cell by interacting with receptor(s), cleavage of the S protein by cell-surface proteases (such as TMPRSS2) is thought to trigger fusion with the plasma membrane. Alternatively, SARS-CoV-2 can enter cells through endocytosis, after which fusion is induced by low pH and S cleavage by endosomal/lysosomal proteases (cathepsins). The N protein dissociates from the viral positive-strand (+) RNA genome, which is directly translated to form polyproteins pp1a and pp1ab. These polyproteins are autocatalytically processed into the non-structural proteins nsp1–16, which establish RTCs and remodel cellular membranes to form replication organelles. These organelles are continuous with the ER and provide an optimal environment for viral RNA replication, which mainly occurs inside DMVs. Genome replication starts with the synthesis of a negative-strand (–) copy that functions as a template for the synthesis of new positive-strand RNA genomes, which may enter more rounds of translation or are incorporated into new virions. Discontinuous transcription of the positive-strand genomic RNA yields subgenomic negative-strand RNAs, which function as templates for the synthesis of subgenomic positive-strand RNAs that encode structural and accessory proteins. Nascent viral RNAs exit DMVs through a transmembrane pore to reach sites of translation or virion assembly. Genomic positive-strand RNA, encapsidated by N, as well as the structural proteins S, M and E, assemble at the ERGIC, at which new virions form by budding into the lumen. Finally, progeny virions are released from the host cells. The yellow boxes indicate the different steps of the viral life cycle. The genes that were both identified as proviral SARS-CoV-2 host factors in at least two independent studies (either through pooled functional genetic screening or through individual genetic validation) and individually validated in at least one study (Supplementary Table 1) are shown. Genes that were individually validated in multiple studies and in different cell lines are highlighted in green.

FOL 26-3132 - Document 5

modulate the intracellular environment to favour viral replication, whereas nsp12–16 contain the core enzymatic functions required for RNA synthesis, including the RNA-dependent RNA polymerase (RdRp; nsp12) (reviewed in ref. [12]).

RNA replication starts with the synthesis of full-length negative-strand copies of the viral genome. These serve as templates for the production of new positive-strand genomes, which are translated to form more non-structural proteins or are packaged into newly formed virions. Moreover, discontinuous transcription of the genome generates a set of negative-strand subgenomic RNAs, which serve as templates for the synthesis of positive-strand subgenomic RNAs (reviewed in ref. [13]). These are translated to form the structural proteins and accessory proteins. RNA replication occurs in replication organelles (formed by nsp3, nsp4 and nsp6), which provide an optimal environment for replication and are thought to shield viral RNA from detection by cytosolic innate immune sensors[14]. These organelles are endoplasmic reticulum (ER)-derived perinuclear interconnected membrane structures that contain double-membrane vesicles (DMVs), in which RNA synthesis occurs[15]. Nascent viral RNA molecules escape from these DMVs through a transmembrane pore[16] to reach sites of translation or virion assembly, which occurs at the ER–Golgi intermediate compartment (ERGIC)[17]. Here, newly synthesized viral genomes—coated with N protein—bud into the lumen of the ERGIC to form enveloped particles containing M, E and S proteins. Finally, progeny virions are trafficked to the cell surface for release. Although this process is poorly understood, a recent study showed that the *Betacoronavirus* mouse hepatitis virus (MHV) hijacks the lysosomal pathway for non-lytic egress of new infectious virions[18]. Each step of the viral life cycle depends on the interplay between viral components and cellular host factors, which is discussed below for SARS-CoV-2.

SARS-CoV-2 receptors

ACE2. The coronavirus S protein consists of two subunits, S1 and S2. S1 mediates receptor binding, usually through a receptor-binding domain (RBD) within S1, whereas S2 guides membrane fusion. As angiotensin-converting enzyme 2 (ACE2) was previously shown to be a crucial receptor for SARS-CoV infection in vivo[19], ACE2 was rapidly identified as a receptor for SARS-CoV-2. Structural studies revealed that the peptidase domain of ACE2 binds to the SARS-CoV-2 S RBD[20,21]. ACE2 was confirmed to be a functional receptor by showing that overexpression of human ACE2 enabled SARS-CoV-2 infection of poorly susceptible cell lines[22,23] and mice[24], which are naturally non-susceptible. ACE2 depletion inhibited SARS-CoV-2 infection of Vero E6 (ref. [25]), Huh7.5 (refs. [26,27]), Caco-2 (ref. [28]) and Calu-3 (refs. [29,30]) cells. By contrast, other studies reported that SARS-CoV-2 could infect ACE2-deficient cells[31], although this may be due to mutations in S[32]. ACE2 exists in a membrane-bound form and a soluble form, released after cleavage by ADAM17. A recent study suggested that soluble ACE2 can also promote infection by forming a complex with SARS-CoV-2 S and vasopressin[33].

Viral tropism is partly determined by the repertoire of receptors that a virus can engage. SARS-CoV-2 enters the body primarily through the respiratory tract[34] and is most abundantly detected in the airways, but also resides in the kidneys, liver, heart, brain, blood and intestines[35,36]. *ACE2* expression in specific airway cells is increased in patients with COVID-19 (ref. [37]), most likely because *ACE2* is an interferon-stimulated gene[38]. Although SARS-CoV-2 RNA was predominantly detected in airway cell types that also express *ACE2* (refs. [37,39]), a strict correlation at the single-cell level between *ACE2* expression and SARS-CoV-2 infection has not yet been demonstrated. As SARS-CoV-2 infects many organs, it is possible that other receptors contribute to viral dissemination in vivo. Recently identified SARS-CoV-2 candidate receptors that may cooperate with or act as an alternative to ACE2 are discussed below and summarized in Table 1.

Auxiliary SARS-CoV-2 receptors. Several SARS-CoV-2 receptors most likely function as cofactors that enhance entry through other receptors. It was shown that heparan sulfate (HS) binds to SARS-CoV-2 S[40–42] and that HS depletion decreases SARS-CoV-2 infection in vitro[42,43]. Thus, analogous to other viruses, SARS-CoV-2 may engage HS to facilitate initial cell attachment, increasing the likelihood of subsequent interactions with entry receptors[44]. As many viruses bind to HS as a consequence of adaptation to in vitro cultured cells, future studies should establish whether HS binding is a natural ability of SARS-CoV-2. Scavenger receptor class B member 1 (SRB1) is a cell-surface receptor that is involved in the uptake of lipids, including high-density lipoprotein (HDL). SARS-CoV-2 S1 binds to HDL, and the addition of HDL to cells enhances infection[45]. In the presence of HDL, overexpression of *SCARB1* (which encodes SRB1) stimulated infection, whereas knockdown of *SCARB1* reduced SARS-CoV-2 infection, suggesting that SRB1 mediates the cellular uptake of HDL-bound virus. A unique feature of SARS-CoV-2 that is absent in SARS-CoV is a polybasic motif (RRAR) at the S1/S2 boundary, which can be cleaved by furin[46], resulting in a C-terminally exposed RRAR peptide. Two independent studies showed that this peptide directly binds to neuropilin-1 (NRP1) and that NRP1 promotes SARS-CoV-2 infection[47,48] (Table 1). Although SRB1 and NRP1 may be able to independently support infection, the fact that these receptors enhance SARS-CoV-2 entry in the presence of *ACE2* overexpression[45,47,48] suggests that they serve as cofactors that potentiate infection through ACE2 or other receptors.

Alternatives to ACE2. Several candidate receptors were shown to enable SARS-CoV-2 infection in the absence of ACE2. The cell-surface proteins tyrosine-protein kinase receptor UFO (Axl)[31], low-density lipoprotein receptor class A domain–containing protein 3 (LDLRAD3) and C-type lectin domain family 4 member G (CLEC4G)[49] were all shown to bind to the N-terminal domain (NTD) of SARS-CoV-2 S. Moreover, their depletion in cell lines reduced SARS-CoV-2 infection and their overexpression in *ACE2*-knockout cells promoted infection, showing that these proteins are probably alternative receptors to ACE2. Basigin (also known as CD147/EMMPRIN), a broadly expressed protein that binds to various ligands, was shown to bind to the S RBD[50], although another study did not confirm this finding[51]. Notably, expression of human basigin enabled SARS-CoV-2 infection in mice. As SARS-CoV-2 cannot use mouse ACE2 (ref. [23]), these findings implicate basigin as an ACE2-independent host factor.

Other receptors. Several other candidate receptors were shown to bind to SARS-CoV-2 S and to facilitate SARS-CoV-2 infection when overexpressed, including asialoglycoprotein receptor 1 (ASGPR1), Kremen protein 1 (ref. [52]) and transferrin receptor[53]. The innate immune receptors CD209 (also known as DC-SIGN) and C-type lectin domain family 4 member M (CLEC4M; also known as L-SIGN or CD209L) bind to numerous viruses, including SARS-CoV and SARS-CoV-2 (refs. [54–57]). These receptors have been suggested to enable virus transport between target cells (*trans*-infection)[58]. Whether depletion of the above receptors in cells affects SARS-CoV-2 infection remains to be shown. Finally, several other SARS-CoV-2 receptor candidates were suggested on the basis of their direct interaction with S (Table 1).

In conclusion, several SARS-CoV-2 candidate receptors have been identified in addition to ACE2, although it remains to be established whether these receptor interactions are biologically relevant or have resulted from cell-culture-induced virus mutations. Future studies will need to evaluate whether their expression levels

FDA 26-3132 - Document 5

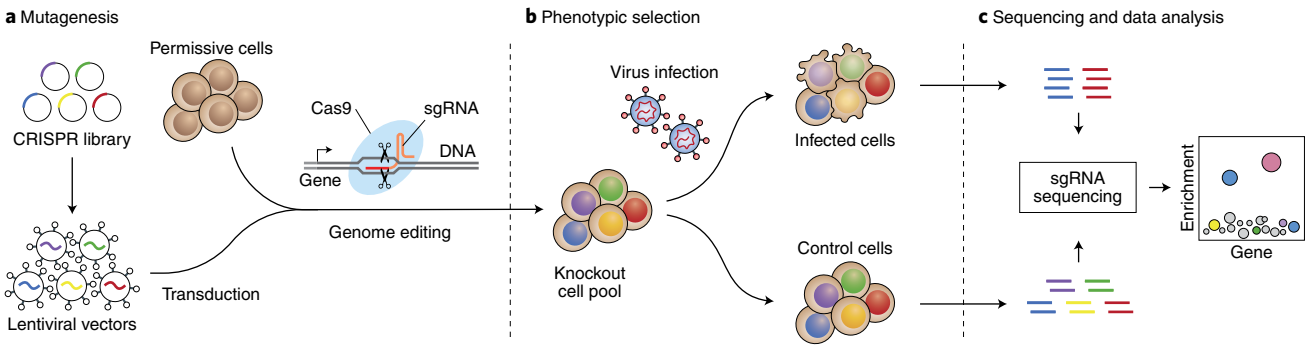
Table 1 | Overview of SARS-CoV-2 candidate receptors

Name	Physiological role	Evidence for its role as a SARS-CoV-2 receptor	Refs.	
			Preprint	Peer-reviewed
ACE2	Blood pressure regulation	Cryo-EM/crystal structures of ACE2 bound to the S RBD		20,21
		Enhanced infection after *ACE2* overexpression in cells		22,23
		Enhanced infection after human *ACE2* expression in mice		24,136
		Partial inhibition of infection after *ACE2* KO in cells		26
HS	Signalling, cell adhesion	Direct interaction between HS and S (EM, SPR, pull-down, glycan array, column chromatography)		40–42
		Partial inhibition of infection after enzymatic HS removal or KO of HS synthesis enzymes in cells		42,43
NRP1	Cardiovascular and nervous system development	Direct binding of NRP1 to the RRAR peptide in S (co-IP)		47
		Enhanced infection after *NRP1* overexpression in cells		48
		Partial inhibition of infection after *NRP1* KO/KD or treatment with NRP1-specific antibody in cells		47,48
SRB1	Lipid uptake receptor	Enhanced infection of cells after *SCARB1* overexpression and reduced infection after *SCARB1* KD in the presence of HDL.		45
Axl	Growth factor signalling	Direct interaction of Axl with the S NTD (pull-down, BLI) Enhanced infection after *AXL* overexpression in *ACE2*-KO cells Partial inhibition of infection after *AXL* KO in cells		31
Basigin	Spermatogenesis, vision, immune responses	Direct binding of basigin to S RBD (SPR, ELISA, co-IP, EM) Enhanced infection after human *BSG* expression in cells and mice Partial inhibition after human *BSG* KD in cells		50
LDLRAD3, TMEM30A and CLEC4G	Unknown, flippase, glycan binding	Direct interaction with the S NTD (Co-IP) Enhanced infection after overexpression in cells Partial inhibition of infection after KD in cells	49	
CD209 and CLEC4M	Cell adhesion and pathogen recognition	Direct interaction with S (pull-down, dot blot, SPR, EM)	54,55	56,57
		Enhanced infection after overexpression in cells	54	
ASGPR1 and Kremen protein 1	Glycoprotein homeostasis/apoptosis	Direct interaction with S (co-IP) Enhanced infection after overexpression in cells	52	
Transferrin receptor (TfR)	Iron transport	Direct interaction of TfR with S and ACE2 (ELISA, SPR) Enhanced infection after human *TF* expression in mice	53	
HAVcr-1 (also known as KIM1 and TIM1)	Immune system regulation	Direct interaction between HAVcr-1 and S RBD (co-IP, FRET, MST)	137	138
		Inhibition of virosome uptake by anti-HAVcr-1 antibodies or *HAVCR1* KO	137	
BiP (also known as GRP78)	Protein folding	Direct interaction of GRP78 with S (co-IP) Partial inhibition of infection by anti-GRP78 antibodies	139	
Sialic acid	Signalling/adhesion	Direct interaction with S protein (BLI)	140	

BiP, ER chaperone BiP; BLI, biolayer interferometry; co-IP, co-immunoprecipitation; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; FRET, Förster resonance energy transfer; HAVcr-1, hepatitis A virus cellular receptor 1; KD, knockdown; KO, knockout; SPR, surface plasmon resonance.

in SARS-CoV-2 target cells is sufficient to be relevant for infection. At present, none of the SARS-CoV-2 receptors identified, including ACE2, has been validated by genetic depletion in an animal model. Such studies will be required to establish the relevance of each receptor for SARS-CoV-2 in vivo.

Proteases required for SARS-CoV-2 entry



After receptor binding, the viral envelope fuses with the host cell membrane, a process guided by host protease–mediated cleavage of S. SARS-CoV-2 has remarkable flexibility in protease requirements, and the local protease availability and temperature[59] influence the viral entry route and cell tropism (reviewed in refs. [6,7]). Proteolytic activation of S occurs in two sequential steps.

The first cleavage (priming) occurs at the S1/S2 boundary for some, but not all, coronaviruses, typically during S biosynthesis at the *trans*-Golgi network of infected cells. After this cleavage, the two subunits remain bound together by non-covalent bonds and are incorporated together into assembled virions. Priming generally facilitates receptor binding and can expose hidden cleavage sites. The unique polybasic motif at the S1/S2 boundary in SARS-CoV-2 S forms a minimal furin-like cleavage site[60]. Indeed, it was shown that SARS-CoV-2 particles harbour cleaved S protein and that furin inhibition substantially reduces the amount of cleavage[46,60,61]. Furin is a ubiquitously expressed endoprotease that is mainly localized in the *trans*-Golgi. Thus, the polybasic furin cleavage site is believed to be a gain-of-function that enables systemic spread of SARS-CoV-2.

Box 1 | CRISPR-based functional genetic screens for proviral host factors

Large-scale loss-of-function genetic screens are a powerful tool in the study of proviral host factors, enabling comprehensive and systematic assessment of virus–host interactions (reviewed in ref. [157]). Advantages of CRISPR-based screens are that these screens can be pooled and can be applied in any cell model, have high specificity and are based on a complete block of gene function, in contrast to RNA interference screens. To mutagenize cells, a genome-wide CRISPR library, packaged into lentiviral vectors, is introduced into a large cell population at a low multiplicity of infection to prevent multiple gene perturbations per cell (**a**). A single-guide RNA (sgRNA) directs the endonuclease Cas9 to a specific gene, at which error-prone repair of Cas9-mediated double-stranded breaks generates loss-of-function mutations, resulting in a pool of different knockout cells. A genetic screen for proviral host factors requires a permissive cell line that can be infected by the virus of interest. Phenotypic selection is usually based on the ability of a virus to induce cell death, enabling the rapid clearance of susceptible cells and expansion of virus-resistant cells (**b**). Alternatively, a fluorescent reporter virus or antibody staining of viral proteins is used to separate infected from uninfected cells[158]. Genomic DNA is extracted from selected cells, as well as unselected control cells, followed by PCR amplification and sequencing of sgRNAs (**c**). sgRNAs that are enriched in the virus-infected population as compared with the control population represent genes of which knock out prevents virus infection and are therefore proviral host factors. As cell survival mostly requires inactive virus replication, such screens generally detect genes that are involved in viral entry, translation or genome replication, but not the later stages of assembly and egress. CRISPR knockout screens cannot identify genes that are essential for cell proliferation, as their knockout depletes cells from the population. A similar strategy can be used to uncover antiviral host factors (restriction factors) by performing CRISPR-based gain-of-function screens and selecting for genes that prevent virus infection after overexpression[159].

In support of this, loss of the furin cleavage site attenuates replication in respiratory cells and reduces pathogenesis in animal models, but does not completely abolish infection[61–64]. MERS-CoV S also harbours a multibasic site that can be primed by furin, in contrast to S in the more closely related SARS-CoV, which is not primed[60].

The second cleavage (activation) occurs at the S2′ site immediately downstream of the fusion peptide and is crucial for infection of all coronaviruses. It induces conformational changes that liberate the fusion peptide, which then penetrates the host cell membrane, leading directly to membrane fusion. SARS-CoV-2 S activation at S2′ can be accomplished by transmembrane protease serine 2 (TMPRSS2) on the plasma membrane, but also by endosomal cathepsin proteases, of which cathepsin L is probably the most important[22,65]. S1/S2 priming is a prerequisite for subsequent TMPRSS2-mediated activation at the S2′ site, but not for S2′ activation by cathepsin L in TMPRSS2-negative cells[60,62,66]. These observations are consistent with the concept of early and late entry routes for coronaviruses. For SARS-CoV-2, priming by furin and activation by TMPRSS2 enable the more efficient early route through fusion at the plasma membrane. The gain of an S1/S2 multibasic site may explain the expanded tropism of SARS-CoV-2 to epithelial cells of the aerodigestive tract, which highly express TMPRSS2 (refs. [67,68]). In cells lacking TMPRSS2, S1/S2 priming is redundant and SARS-CoV-2 is endocytosed, with fusion occurring late in acidified endo/lysosomal compartments after activation by cathepsins[66].

Other proteases, such as PC1, trypsin-like proteases and cathepsins, can cleave peptides mimicking the multibasic S1/S2 site of SARS-CoV-2 in vitro[69]. Moreover, studies using pseudoviruses and selective protease inhibitors suggest that alternative proteases can cleave at S1/S2 in cells[66]. However, the biological relevance of alternative proteases in the pathogenesis of SARS-CoV-2 needs to be determined. Finally, plasmin, which is commonly elevated in people with hypertension or diabetes, may cleave at the multibasic site[70]. Similarly, S2′ cleavage can be accomplished by alternative transmembrane serine proteases, as was demonstrated for transmembrane protease serine 4 (TMPRSS4) in small intestinal enterocytes[67].

Functional genetic screens for SARS-CoV-2 host factors

Several independent CRISPR-based functional genetic screens have been carried out (Box 1) to uncover SARS-CoV-2 proviral host factors. Most were performed on a genome-wide scale[25,26,29,30,43,64,71,72], but some of the screens probed a subset of genes derived from interactome analyses[27,73] (Fig. 2). All of the screens were based on cell survival, which has the limitation that genes that are essential for cell proliferation are unlikely to be detected. Moreover, such functional screens are biased towards genes that are required for early stages of the viral life cycle and fail to detect genes that are involved in virion assembly or release. Of the many experimental parameters that differed between screens (Supplementary Table 1), the choice of cell line seems to be crucial because gene overlap was mainly observed between screens carried out in the same cell type (Fig. 2). Although lung tissue is the primary site of SARS-CoV-2 infection, multiple cell lines from different origins have been used to define host factor dependencies, mainly due to lack of a virus-induced cytopathic effect in lung-derived cell lines. Vero E6 cells are non-human African green monkey kidney-derived cells

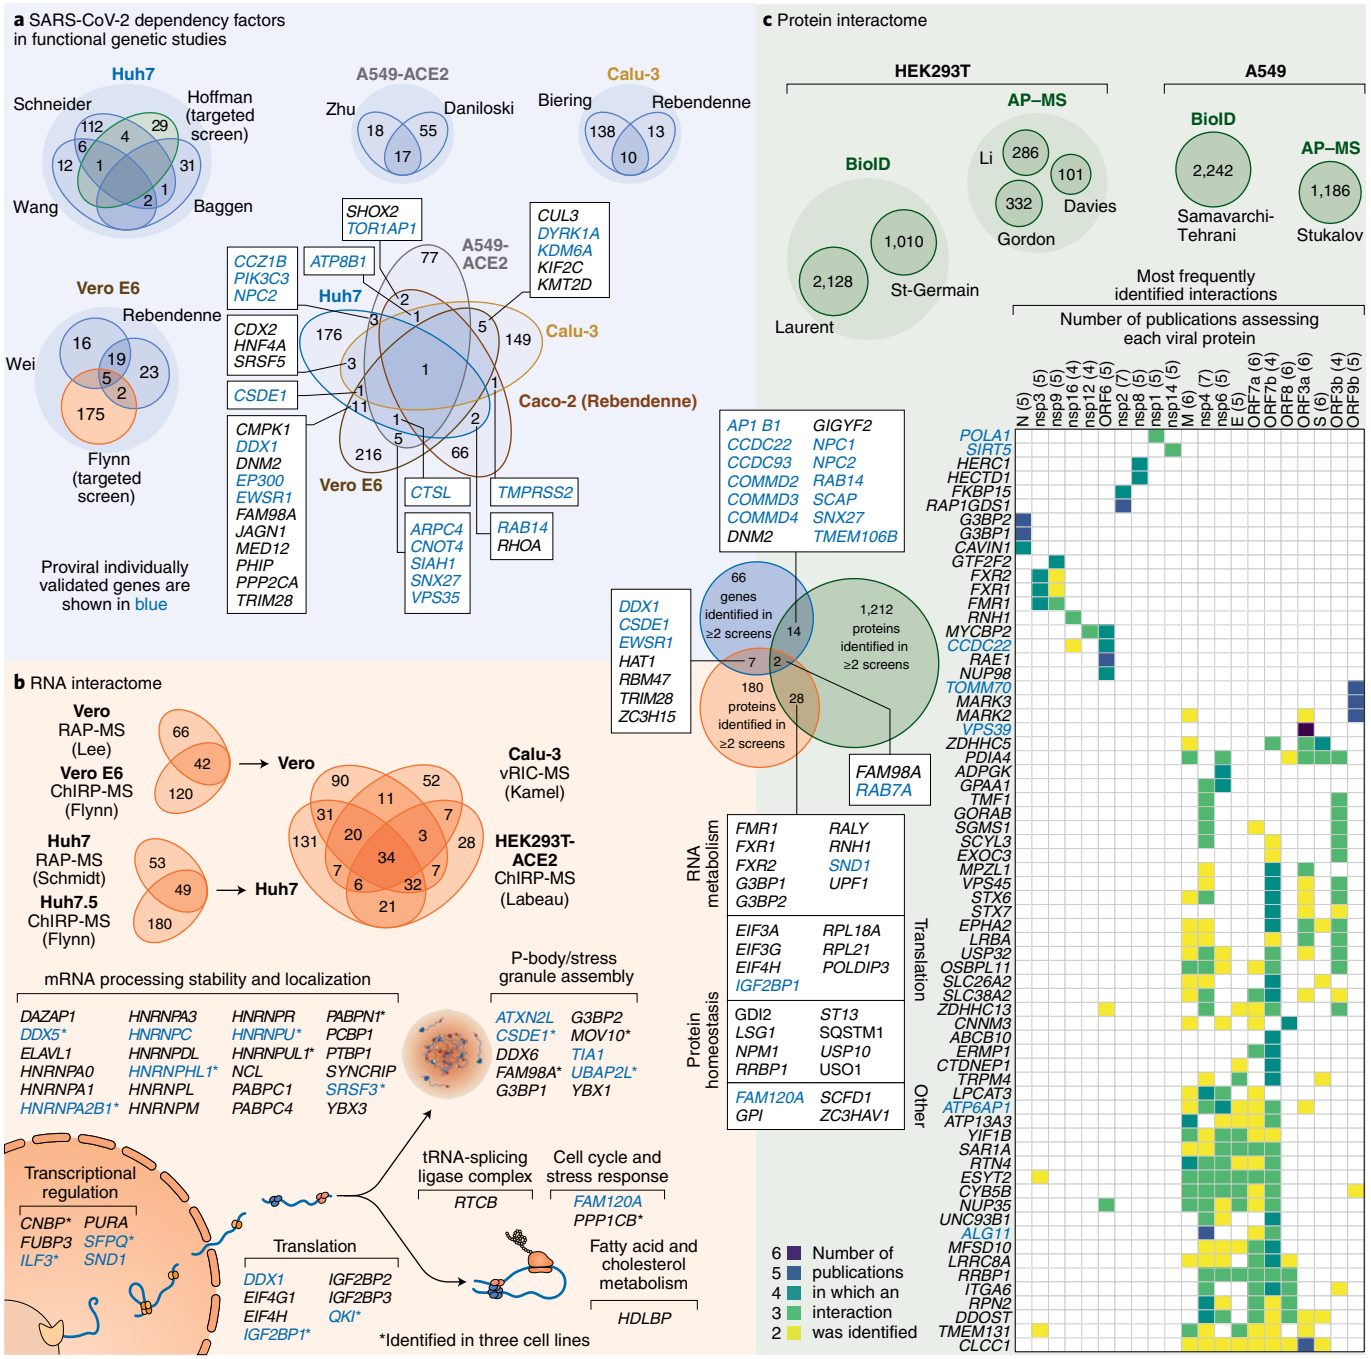

Fig. 2 | Overlapping host factors identified in functional genetic and interactome screens for SARS-CoV-2. a–**c**, Overview of human genes identified as SARS-CoV-2 proviral host factors in functional genetic screens (**a**) and genes encoding proteins identified in interactome screens as binding partners for viral RNA (**b**) or viral proteins (**c**). **a**, The number of top-ranked hits or validated proviral genes found in CRISPR-based loss-of-function studies (Zhu et al.[64], Daniloski et al.[71], Biering et al.[29], Rebendenne et al.[30], Hoffmann et al.[27], Schneider et al.[26], Baggen et al.[43], Wang et al.[72] and Wei et al.[25]). **b**, The number of proteins identified in viral RNA interactomes (Lee et al.[99], Flynn et al.[73], Schmidt et al.[100], Kamel et al.[101] and Labeau et al.[102]). Gene names are listed for proteins that meet one of the following three criteria: identified in five out of the six screens; identified in all four cell types; or identified in three cell types and functionally validated. Genes are clustered according to molecular function. **c**, The total number of cellular proteins identified in viral protein interactomes for each publication (Laurent et al.[108], St-Germain et al.[107], Li et al.[104], Gordon et al.[78], Davies et al.[103], Stukalov et al.[105] and Samavarchi-Tehrani et al.[106]) (top). Bottom, the number of publications in which a specific virus–host protein–protein interaction was detected. Genes encoding human proteins identified either in four or more publications or identified with the highest frequency for a specific SARS-CoV-2 protein (and in more than 50% of conducted screens) are shown. For viral proteins with >20 cellular interaction partners identified as such, only partners with a specificity index >2 are included (that is, the total detection number of the cellular protein divided by the number of unique viral proteins with which it was found to interact). Different isoforms were not taken into account. Genes and proteins detected in Vero cells were converted to their human orthologue. The complete gene lists are provided in Supplementary Table 2. The central Venn diagram represents the total number of genes or proteins identified in at least two screens by each approach. Genes identified by multiple orthogonal approaches are listed and clustered according to molecular function. Genes that have been individually validated as proviral factors by knockdown or knockout are shown in blue.

Table 2 | Validated SARS-CoV-2 proviral host factors that serve as host factors for various viruses

Gene	Virus	Family	Function as proviral host factor	Refs.
AP1B1, AP1G1 (clathrin-associated adaptor protein complex 1)	HCV HIV	*Flaviviridae* *Retroviridae*	Virion release and cell-to-cell spread Promotes virion release through an interaction between Gag and AP-1μ	141 142
RAB7A	HIV	*Retroviridae*	Virion assembly and release	143
RAB14	HIV	*Retroviridae*	Env incorporation into assembling virions	144
VPS39 (HOPS complex)	MHV EBOV	*Coronaviridae* *Filoviridae*	Transport of virus from early endosomes to lysosomes	75 76
ATP6AP1	IAV	*Orthomyxoviridae*	Endosomal acidification is required for fusion	80
VPS29, VPS35 (retromer complex)	HCV	*Flaviviridae*	Proposed to deliver cargoes to viral replication sites through retrograde transport	87
	HPV	*Papillomaviridae*	Trafficking virus from early endosomes to the TGN	86
SNX27	HTLV	*Retroviridae*	Recycling the virus receptor GLUT1 to the plasma membrane	85
ACTR2	RSV	*Pneumoviridae*	Cell-to-cell spread through filopodia	145
SREBP pathway (*SREBF2, SCAP, MBTPS2*)	ANDV MERS-CoV	*Hantaviridae* *Coronaviridae*	Supports virus internalization into cells Suggested to have a role in DMV formation	146 147
NPC1	EBOV	*Filoviridae*	Lysosomal entry receptor	76
NPC1, NPC2	CHIKV	*Togaviridae*	Required for endocytosis or fusion	148
SIGMAR1	HCV	*Flaviviridae*	Supports early RNA replication at the ER	149
TMEM41B	ZIKV, YFV	*Flaviviridae*	Remodels host cell membranes that are required for the formation of viral replication complexes	91
PIK3C3	HBV	*Hepadnaviridae*	Supports DNA replication by inducing autophagy after HBx binding	150
CNOT4	IAV	*Orthomyxoviridae*	Required for NP ubiquitination	151
SIAH1	DENV2	*Flaviviridae*	Prevents antiviral signalling by ubiquitinating MyD88	97
JMJD6	VSIV	*Rhabdoviridae*	Inhibits the antiviral type-I interferon response	98
EWSR1	HCV	*Flaviviridae*	Supports replication through binding to the CRE in the viral RNA	152
CSDE1	CV-B3	*Picornaviridae*	Required for IRES-mediated translation	153
EMC1	SV40	*Polyomaviridae*	Mediates ER-to-cytosol transport of virions during entry	154
TOR1AIP1	HSV-1 PrV	*Herpesviridae* *Herpesviridae*	Interacts with torsin-1a, which supports nuclear egress of HSV-1 and PRV virions	155 156

Genes with known functions for other viruses that are displayed in Fig. 1 are shown. The selection of genes was determined on the basis of a literature search and includes only genes that were demonstrated (by genetic depletion) to be required for infection of other viruses, and for which the role in infection is at least partially known. ANDV, Andes orthohantavirus; AP-1μ, adaptor protein complex 1, mu subunit; CHIKV, Chikungunya virus; CRE, *cis*-acting replication element; CV-B3, coxsackievirus B3; DENV2, dengue virus 2; EBOV, Ebola virus; HBV, hepatitis B virus; HCMV, human cytomegalovirus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV-1; herpes simplex virus; HTLV, human T-cell leukaemia–lymphoma virus; IAV, influenza A virus; IRES, internal ribosome entry site; NP, nucleoprotein; PrV, pseudorabies virus; RSV, respiratory syncytial virus; SREBP, sterol-regulatory-element-binding protein; SV40, *Macaca mulatta* polyomavirus 1; TGN, *trans*-Golgi network; VSV; vesicular stomatitis Indiana virus; YFV, Yellow fever virus; ZIKV, Zika virus.

that are permissive to a wide range of viruses in vitro. Whereas the human hepatocellular carcinoma Huh7 or colorectal adenocarcinoma Caco-2 cells are permissive to SARS-CoV-2 infection, the lung adenocarcinoma A549 cell line requires ectopic overexpression of the ACE2 receptor to support SARS-CoV-2 replication, while infection and cytopathic effect in the lung cell line Calu-3 is low. Here, we discuss genes that were consistently identified using functional genetic screens and were individually validated as proviral SARS-CoV-2 host factors (Fig. 1 and Supplementary Table 2). Although the precise role in the SARS-CoV-2 life cycle remains unknown for many of these genes, some have known functions in the life cycle of other viruses (Table 2).

The only gene identified by screens in all five cell lines tested is *ACE2* (Fig. 2). Of the other receptor candidates identified, transmembrane protein 30A (*TMEM30A*) was identified in one screen[43], whereas the HS biosynthesis gene *EXT1* was independently identified in three Huh7 screens[26,43,72]. Importantly, screens carried out in Huh7, A549 and Vero E6 cells identified *CTSL* (encoding cathepsin L), but not *TMPRSS2*, suggesting that viral entry occurred through the late endosomal route in these models. By contrast, screens in Calu-3 and Caco-2 cells[29,30] identified *TMPRSS2*, but not *CTSL*, implying that these screens probably identified factors that are involved in the early entry route.

Vesicle trafficking. Besides receptors and proteases, members of different complexes involved in vesicle biology were identified as essential for SARS-CoV-2 infection, including Rab GTPases (*RAB7A*, *RAB10* and *RAB14*). In particular, *RAB7A* was extensively validated and found in multiple screens, as were components of its dedicated Rab guanine nucleotide exchange factor, the Mon1–Ccz1 complex[74] (*CCZ1*, *CCZ1B* and *C18orf8*). *RAB7A* and *CCZ1B* were also found to support HCoV-229E and HCoV-OC43 infection[26,27,72]. Among other functions, Rab7 regulates endosomal maturation and interacts with the homotypic fusion and protein sorting (HOPS) complex, of which a subunit, the Vam6/Vps39-like protein (*VPS39*), was found to support SARS-CoV-2 infection. The HOPS complex mediates fusion of lysosomes with late endosomes or autophagosomes and, as shown for MHV[75] and Ebola virus[76] (Table 2), may cooperate with Rab7 to traffic incoming SARS-CoV-2 virions to lysosomal fusion sites. Rab7 was also found to promote cell-surface expression of ACE2 (ref. [71]). Moreover, SARS-CoV-2 ORF3A binds to the HOPS subunit Vam6/Vps39-like

protein to block autophagosome–lysosome fusion, preventing lysosomal destruction of viral components in the later stages of its life cycle[77]. Genetic screens also identified the S1 (*ATP6AP1*) and A (*ATP6V1A*) subunits of the vacuolar-ATPase proton pump[71], which were found to bind to SARS-CoV-2 nsp6 and M, respectively[78]. These factors are required for luminal acidification of vesicles and also facilitate influenza A virus entry[79,80]. *TMEM106B*, which encodes another endo-lysosomal protein, was shown in multiple studies to be required for SARS-CoV-2 but not HCoV-229E[26,43,72]. TMEM106B regulates lysosome function and interacts with the V-ATPase S1 subunit[81]. TMEM106B facilitates SARS-CoV-2 pseudovirus entry[43], further suggesting a role of the lysosomal compartment in SARS-CoV-2 entry. Furthermore, *TMEM106B* expression is elevated in SARS-CoV-2-infected airway cells from patients with COVID-19 (ref. [43]), but whether this is the cause or consequence of infection needs to be determined.

Many genes uncovered by genetic screens are involved in retrograde transport[82]. These include members of the retromer and retriever complexes (*VPS29*, *VPS35* and *VPS35L*), the retromer-associated protein sorting nexin-27 (*SNX27*) and components of the COMMD–CCDC22–CCDC93 (CCC) complex (Fig. 1). These complexes facilitate cargo enrichment and budding from the endosomal membrane to generate recycling vesicles. This budding process is driven by branched actin polymerization initiated by the Arp2/3 and WASH complexes[83], of which members were found in multiple SARS-CoV-2 screens[64,71] (*ACTR2*, *ACTR3*, *ARPC3*, *ARPC4* and *WASHC4*). Finally, multiple screens identified a member of the exocyst complex[26,72] (*EXOC2*), which interacts with the Arp2/3 complex[84] and mediates tethering of recycling and secretory vesicles to the plasma membrane. As knockout of retrograde transport genes inhibited SARS-CoV-2 pseudovirus entry and reduced cell-surface expression of ACE2 (ref. [64]), SARS-CoV-2 may require this process for receptor recycling, as shown for human T-cell leukaemia–lymphoma virus[85]. Alternatively, retrograde transport may facilitate virus trafficking to replication sites, as shown for human papillomavirus[86], or may serve to deliver cargoes to replication sites, as suggested for hepatitis C virus[87] (Table 2).

Notably, screens in Calu-3 cells did not identify any of the above-mentioned vesicle-trafficking genes, but revealed two subunits of clathrin-associated adaptor protein complex 1 (*AP1B1* and *AP1G1*)[29,30], which mediates transport between the *trans*-Golgi network and endosomes (Fig. 1). These genes were shown to support SARS-CoV-2 entry without affecting ACE2 expression on the cell surface[30] and may be required for the correct localization of other proviral factors that are involved in TMPRSS2-mediated entry.

PI3K signalling. Genetic screens also identified members of the phosphatidylinositol 3-kinase (PI3K) pathway (Fig. 1) as host factors for SARS-CoV-2, as well as for HCoV-229E and HCoV-OC43 (refs. [26,43,64,71,72]). These include PI3K type 3 (*PIK3C3*) and PI3K regulatory subunit 4 (*PIK3R4*), core subunits of a complex that produces phosphatidylinositol 3-phosphate (PI3P) and regulators of this complex (*WDR81* and *WDR91*)[64,71]. Screens also uncovered protein VAC14 homologue (*VAC14*)[26,72], which regulates the conversion of PI3P to phosphatidylinositol 3,5-bisphosphate. This signalling pathway is involved in a wide range of cellular functions, including endosomal maturation, retrograde transport and autophagy initiation (reviewed in ref. [88]). PI3K signalling may therefore facilitate SARS-CoV-2 infection by initiating the vesicle-trafficking processes discussed above, or by activating the autophagy machinery. Indeed, multiple studies showed that SARS-CoV-2 infection depends on transmembrane protein 41B (*TMEM41B*)[26,43,89], which is involved in the early stages of autophagosome formation[90]. *TMEM41B* is also required for HCoV-229E, HCoV-OC43 and HCoV-NL63 (refs. [26,43]); SARS-CoV; and MERS-CoV[89], and was recently shown to facilitate flavivirus replication complex formation[91] (Table 2). As genes required for later stages of autophagosome formation were not identified, it is possible that SARS-CoV-2 specifically hijacks early components of the autophagy machinery, including PI3K signalling, to support its life cycle.

Lipid homeostasis. Several genes identified in genetic screens with SARS-CoV-2 control cholesterol synthesis[26,72]. Sterol-regulatory-element-binding protein 1 and 2 (*SREBF1* and *SREBF2*) are transcription factors that upregulate enzymes required for fatty acid and cholesterol synthesis. Their activity is regulated by sterol-regulatory-element-binding protein cleavage-activating protein (*SCAP*) and endopeptidase S1P and S2P (*MBPTS1* and *MBPTS2*)[92], which were all identified in genetic screens. *SREBF2* was also found to support the replication of HCoV-229E, HCoV-OC43 and HCoV-NL63 (ref. [26]). Moreover, SARS-CoV-2 was found to require the late endosomal and lysosomal proteins Niemann–Pick C1 and C2 (*NPC1* and *NPC2*), which transport cholesterol from the lysosomal lumen into the lysosomal membrane[93]. Although these genes probably have indirect roles in infection, NPC1 can also directly function as a viral receptor, as shown for Ebola virus[76] (Table 2). Recently, 25-hydrocholesterol—which broadly inhibits the fusion of enveloped viruses by depleting cholesterol from the plasma membrane[94]—was shown to inhibit SARS-CoV-2 S-mediated fusion, suggesting a role of cholesterol in viral entry. Genetic screens also identified two components (*TMEM30A* and *ATP8B1*) of a P4-ATPase flippase complex that transports aminophospholipids from the outer to the inner leaflet of various membranes[29,30,43,64]. Moreover, the lipid transport protein sigma non-opioid intracellular receptor 1 (*SIGMAR1*) was found to bind to nsp6 in an interactomic screen[78]. As all steps of the viral life cycle are membrane-associated, cholesterol and other lipids could have various roles in SARS-CoV-2 infection, including innate immune system suppression, as shown for other viruses[95].

Other proviral host factors. Other identified SARS-CoV-2 host factors are involved in transcriptional regulation, including transcription factors, histone-modifying enzymes and members of the SWI/SNF complex[25,26,64,71] (Fig. 1). Moreover, screens identified several components of E3 ubiquitin ligases[25,71]. These genes may indirectly affect virus replication by regulating expression levels of other proviral or antiviral factors. For example, *EP300* and *HMGB1* enhance the expression of ACE2 on the cell surface[25,30,96]. E3 ubiquitin–protein ligase SIAH1 (*SIAH1*) and JmjC-domain-containing protein 6 (*JMJD6*) were previously shown to support infection of dengue virus[97] and vesicular stomatitis Indiana virus[98], respectively, by promoting the degradation of antiviral proteins (Table 2).

Together, functional genetic screens uncovered numerous proviral genes that are probably required for SARS-CoV-2 entry, translation or replication (Box 1). Notably, viruses used in two screens contained deletions near the polybasic cleavage site in S[43,64], whereas the sequences of the passaged viruses used in screens in the other studies were not specified[25,26,29,30,71,72]. Such deletions prevent TMPRSS2-mediated S activation and force virus entry through the endocytic route[64]. Thus, future studies with wild-type SARS-CoV-2 may be useful to extend the compendium of SARS-CoV-2 proviral host factors.

Viral RNA and protein interactomes

Interactome screens probe for cellular factors interacting with viral RNA and/or proteins and can therefore provide valuable insights into pathways that facilitate or inhibit the viral life cycle. These screens are complementary to functional genetic screens as they can also detect cell-essential factors. In brief, RNA interactome screens involve SARS-CoV-2 infection of cells, followed by RNA–protein cross-linking and identification of interacting proteins[73,99–102]. The SARS-CoV-2 RNA interactome was determined in multiple cell lines

FOL 26-3132 - Document 5

(Fig. 2) using different cross-linking techniques: formaldehyde and ultraviolet light. Ultraviolet light at 254 nm (RNA antisense purification coupled with mass spectrometry (RAP–MS))[99,100] is a more specific RNA–protein cross-linker than formaldehyde (comprehensive identification of RNA-binding proteins (chIRP-MS))[73,102], as it does not efficiently cross-link protein–protein interactions. An even more specific cross-linking technique (viral RNA interactome capture (vRIC)-MS)[101] applies 365 nm ultraviolet light after treatment with a transcription inhibitor and the photoactivatable nucleotide analogue 4-thiouridine to ensure exclusive cross-linking of 4-thiouridine-containing viral RNA. The SARS-CoV-2 protein interactome was mapped in HEK293T/17 and A549 cells using affinity-tag purification (affinity purification (AP)–MS)[78,103–105] or pull-down of tagged proteins using proximity biotinylation (BioID)[106–108]. In contrast to RNA interactomes, protein interactomes were determined by expressing individual viral proteins in uninfected cells. This approach requires prudence during interpretation, as well as validation, before making claims about virus–host interactions, as individually expressed viral proteins may localize differently and lack the context of true infection. Although these screens vary in the set of probed SARS-CoV-2 proteins, integrating the results of these studies generates a robust cellular interactome for 21 SARS-CoV-2 proteins (Fig. 2 and Supplementary Table 2).

Viral RNA interactome. When the viral RNA is released into the cytoplasm, it hijacks cellular RNA-binding proteins involved in all stages of the mRNA life cycle to achieve the arduous task of regulating translation and replication in the hostile environment of the host cell. A total of 95 proteins, representing a broad range of RNA-related functionalities, were found to bind to SARS-CoV-2 RNA in at least three different cell types, whereas 34 proteins were identified in all four cell types (Fig. 2). Flynn et al. reported a significant bias towards antiviral factors in their viral RNA interactome[73], which may explain the limited overlap between RNA interactomes and proviral factors identified in functional screens. Nevertheless, 17 of these 95 frequently detected interactors were functionally validated as proviral host factors for SARS-CoV-2 (Fig. 2).

A strong interplay was detected between SARS-CoV-2 RNA and ribonucleoprotein granules such as paraspeckles, P-bodies and stress granules. Similarly, protein families such as cold-shock domain proteins, eukaryotic translation initiation factors (*EIF3/4*) and heterogeneous nuclear ribonucleoproteins showed extensive viral RNA interaction. Several heterogeneous nuclear ribonucleoproteins have known functions in the life cycle of coronaviruses and other positive-strand RNA viruses, facilitating RNA synthesis and translation[109]. This overlapping SARS-CoV-2 RNA interactome further consisted of proteins that are involved in a plethora of cellular functions, such as transcriptional regulation, mRNA processing, stress response, fatty acid metabolism and the tRNA-splicing ligase complex[101] (Fig. 2).

SARS-CoV-2 relies completely on the host translation machinery to translate its capped and poly-adenylated genome. Thus, unsurprisingly, many RNA interactome studies contained factors that are involved in the recognition of the poly(A) tail (*PABPC1*, *PABPC4* and *PABPCN1*) and components of eukaryotic initiation factors (eIF) responsible for cap binding (eIF4F subunits) or subsequent connection to the ribosome (eIF3), as well as some 40S ribosome subunits. Remarkably, eIF4E was not retrieved in any screen, suggesting that SARS-CoV-2 translation is eIF4E-independent, similar to other capped positive-strand RNA viruses such as Sindbis virus[110]. In this regard, the identification of La-related protein 1 (*LARP1*) in the interactome of both SARS-CoV-2 RNA[73,99,100] and the N protein[78] is of special interest. LARP1 regulates the stability and translation of cellular mRNAs containing an oligopyrimidine (TOP) motif by binding to this motif and the adjacent cap, blocking the access of eIF4E. As LARP1 was validated as an antiviral factor binding to the 5′-leader of SARS-CoV-2, which contains a TOP-like motif, this may explain why eIF4E is absent from the viral RNA interactome.

Box 2 | Cellular antiviral factors that limit SARS-CoV-2 infection

As obligate intracellular parasites, viruses need to evade the host's antiviral responses to successfully establish infection. To trigger the innate immune response during infection, host cells rely on pattern recognition receptors (PRRs), such as Toll-like receptors and RIG-I-like receptors[160], to recognize specific pathogen-associated molecular patterns (PAMPs). For RNA viruses, the main intracellular PAMP is double-stranded RNA formed during viral replication, which can be recognized by cytosolic receptors, such as RIG-I, MDA-5 and PKR[161]. Although PKR activation mainly results in translational shut-off and stress granule formation, RIG-I and MDA-5 PAMP–PRR complexes bind to the mitochondrial antiviral-signalling protein (MAVS) to activate the transcription factors NFκB and interferon regulatory factors (IRFs), inducing the expression of type-I interferons (IFNs) as well as a range of other cytokines[162]. After binding to their cognate receptors, IFNs trigger the expression of several hundred IFN-stimulated genes performing various molecular functions in an effort to control viral dissemination. Like all viruses, SARS-CoV-2 has evolved several mechanisms to evade this antiviral signalling cascade.

The SARS-CoV-2 interactome captures this interplay between innate immune response and virus, encompassing both sides of the battle: the cellular effort to detect and eliminate the infection, as well as the molecular mechanisms evolved by the virus to escape and inhibit the immune response. As such, these interactomes exposed a strong interplay with stress granules (SGs), which have a pivotal role in establishing an antiviral state by limiting viral RNA translation and serving as an antiviral and apoptotic signalling hub. Viruses can inhibit their formation by sequestering or degrading stress granule components such as Ras GTPase-activating protein-binding protein (G3BP) 1 and 2 (ref. [163]), which were consistently detected in the SARS-CoV-2 RNA and N protein interactome, suggesting that SARS-CoV-2 also targets G3BP1 and G3BP2 to disrupt or deregulate SG formation[164]. Other SARS-CoV-2 proteins that have been shown to interfere with cellular antiviral responses are ORF9b and ORF6. ORF9b targets the mitochondrial import receptor subunit TOM70, which promotes MAVS activity by bridging MAVS to downstream proteins TBK1/IRF3 (ref. [165]). TOM70 was identified in several ORF9b interactome screens, and this interaction was shown to suppress MAVS-mediated type-I IFN signalling[166]. Finally, further downstream in the IFN signalling cascade, ORF6 was shown to bind to the nuclear pore complex component Nup98–Rae1 to disrupt the nuclear import of transcription factors STAT1 and STAT2 (ref. [167]), therefore impairing IFN-stimulated gene expression and further enabling SARS-CoV-2 infection.

Viral protein interactome. Of the cellular proteins found to interact with a specific SARS-CoV-2 protein (Fig. 2), a handful were identified in all of the screens conducted by at least five different research groups for a specific viral protein (G3BP1, G3BP2, TOMM70, RAE1, VPS39, MARK2 and MARK3). *G3BP1*, *G3BP2*, *TOMM70* and *RAE1* encode factors that are involved in host antiviral responses and are discussed in more detail in Box 2. The HOPS subunit Vam6/Vps39-like protein (VPS39) interacted consistently with ORF3a, as discussed above. ORF9b bound to

Table 3 | Druggable SARS-CoV-2 host factors

Protein	Gene	Therapeutic strategy	Clinical stage COVID-19
Angiotensin-converting enzyme 2	*ACE2*	Decoy receptor Pseudoligands; antibodies: TD-139, ensovibep Expression regulation: isotretinoin, RAAS inhibitors	I/II II/III III
Basigin	*BSG*	Antibody: meplazumab	II/III
HS		Lactoferrin	II/III
Transmembrane protease serine 2	*TMPRSS2*	Inhibitors: camostat mesylate, nafamostat, bromhexin, α1-antitrypsin, aprotinin	III
		Antiandrogens: bicalutamide, isotretinoin, enzulatamide	III
Cathepsin	*CTSL, CTSB, CTSD, CTSK*	Inhibitors: teicoplanin, MDL 28170, ONO 5334, VBY-825	Preclinical
Plasmin	*PLG*	Inhibitor: tranexamic acid	III
Furin	*FURIN*	shRNA: vigil	Preclinical
Anoctamin-6/transmembrane protein 16F (TMEM16F)	*ANO6*	Inhibitor: niclosamide	III
Elongation factor 1-alpha 1	*EEF1A1*	Inhibitor: plitidepsin	III
V-type proton ATPase catalytic subunit A	*ATP6V1A*	Inhibitor: biphosphonates (etidronic acid, alendronic acid)	Preclinical
Dual-specificity tyrosine-phosphorylation-regulated kinase 1A, phosphatidylinositol 4-kinase beta, activin receptor type-1B	*DYRK1A, PI4KB, ACRV1B*	Inhibitor: fostamatinib (not specific; anti-inflammatory)	III
Histone deacetylase 9	*HDAC9*	Inhibitors: romidepsin, belinostat, panobinostat, vorinostat	Preclinical
1-Phosphatidylinositol 3-phosphate 5-kinase	*PIKFYVE*	Inhibitor: apilimod	II
Sigma non-opioid intracellular receptor 1	*SIGMAR1*	Inhibitor: fluvoxamine, naltrexone (anti-inflammatory)	III
Calcium-transporting ATPase type 2C member 1	*ATP2C1*	Inhibitor: sevoflurane, isoflurane (anti-inflammatory)	III

Genetically validated SARS-CoV-2 host factors for which inhibitors are under clinical investigation for COVID-19 or approved/in advanced clinical stage for alternative indications and amenable for drug repurposing. For COVID-19 therapeutic strategies in which more than one agent is under investigation, the clinical stage of the most advanced agent is given. When the inhibitor is expected to merely have an anti-inflammatory effect rather than a direct antiviral effect, this is noted in the table. Inhibitors of which clinical investigations are halted were omitted. Sources: Clinicaltrials.gov (https://www.clinicaltrials.gov/ct2/home) and DGiDb (https://www.dgidb.org/). shRNA, short hairpin RNA.

microtubule affinity regulating kinase (MARK) 2 and 3, of which the latter was shown to affect the monocyte count in the blood of patients with COVID-19 (ref. [111]). Although MARK2 is upregulated in SARS-CoV- and MERS-CoV-infected cells[112], its kinase activity was found to be decreased in SARS-CoV-2-infected cells[113]. Interestingly, MARK2 is also hijacked by HIV-1 to facilitate microtubule-associated particle uncoating[114].

Several other interesting proteins identified with a high frequency are HERC1, CCDC22, ALG11 and ZDHHC5. Probable E3 ubiquitin–protein ligase HERC1 (encoded by *HERC1*) was picked up as a nsp8 binder and is a guanine nucleotide exchange factor that activates Rab proteins, several of which were functionally validated as proviral host factors. ORF6 showed robust interaction with the proviral coiled-coil-domain-containing protein 22 (*CCDC22*), a component of the CCC complex and regulator of NF-κB signalling. For glycolipid alpha-1,2-mannosyltransferase (ALG11), a direct link with coronavirus infection was lacking until now. However, the high-confidence interaction of ALG11 with nsp4 is an interesting topic for further research, as ALG11 is an ER-localized *N*-glycosylation protein, and *N*-glycosylation of MHV nsp4 has been shown to affect DMV morphology and RNA replication[115]. The most frequent interaction partner for SARS-CoV-2 S was the plasma-membrane-localized palmitoyltransferase ZDHHC5. Coronaviruses rely on post-translational palmitoylation of S for efficient virion production and S-mediated membrane fusion[116]. ZDHHC5 drives S palmitoylation and the consequent infectivity of HCoV-229E, and may be of equal importance for the palmitoylation of SARS-CoV-2 S[117].

Host factors as SARS-CoV-2 drug targets?

Agents that target proviral host factors may be attractive drug candidates because of a reduced chance of resistance development and the potential for broad action against viral variants. Several efforts to identify agents that inhibit SARS-CoV-2 by targeting a host protein have been undertaken[28,118–122]. Drug repurposing approaches that bypass costly and time-consuming drug discovery processes are of particular interest. Here, we summarize agents that are directed against rigorously validated host factors and that are currently in clinical trials for COVID-19 treatment, or that are approved drugs that are provisionally eligible for drug repurposing (Table 3).

SARS-CoV-2 receptors. Multiple strategies to hamper the interaction between SARS-CoV-2 and ACE2 are being pursued (Table 3; reviewed in ref. [123]). The use of excessive soluble ACE2 as a decoy to trap SARS-CoV-2 virus is under investigation. Other strategies aim to block the binding of the S RBD to ACE2 using pseudoligands or blocking antibodies, or to interfere with *ACE2* expression. As such, multiple clinical studies are evaluating the use of the anti-acne drug isotretinoin, which acts, at least partly, by downregulating *ACE2* (ref. [122]). Notably, ACE2 is a key enzyme of the

FOIA 20-3132 - Document 5

renin–angiotensin–aldosterone system (RAAS), which regulates blood pressure. RAAS inhibitors (angiotensin converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARBs)) are commonly prescribed hypertension drugs. Although ACEi do not directly block ACE2, studies suggested that they increase *ACE2* expression and may therefore worsen COVID-19 severity[124], raising concerns about the continuation of these drugs in patients with COVID-19 who are hypertensive. However, clinical investigations revealed no adverse effects[125,126], probably because ACEi/ARBs also fulfil anti-inflammatory and anti-oxidative functions. Thus, international recommendations are now against the discontinuation of these drugs in patients with COVID-19.

Blocking the accessibility of alternative receptors basigin (CD147) and HS is also under clinical investigation for COVID-19 treatment (Table 3).

Host proteases. TMPRSS2-mediated S activation at the plasma membrane is an attractive therapeutic intervention point. As *TMPRSS2* is not a cell-essential gene, inhibition is expected to cause negligible side effects. The inhibitor camostat mesylate, which has been approved for non-COVID-19 indications in Japan, is being investigated in multiple ongoing clinical trials, as well as alternative approved serine protease inhibitors (namostat, aprotinin). The protein α1-antitrypsin (α1AT) is a highly abundant circulating serine protease inhibitor that is part of the human innate immune system and has been shown to inhibit TMPRSS2 and SARS-CoV-2 entry[127]. Clinical trials with α1AT purified from donor blood, available as a pharmaceutical product (prolastin), are underway. As *TMPRSS2* expression is androgen regulated[128], several studies also investigated androgen-directed therapy (bicalutamide, enzulatamide, isotretinoin). Isotretinoin reduces dihydrotestosterone levels and, as such, downregulates *TMPRSS2*. As it also downregulates *ACE2*, isotretinoin may have a multifaceted impact on SARS-CoV-2 infectivity.

Inhibition of cathepsins, the main proteases required for pH-dependent endocytic entry, has also been examined as COVID-19 therapy[129]. However, the anti-malaria drugs chloroquine and hydroxychloroquine, which inhibit endosomal acidification required for cathepsin activity, were found to be unsuccessful in the clinic, possibly due to the existence of multiple entry routes, despite having proven antiviral activity in cell culture[130]. Similarly, studies on chlorpromazine, an anti-psychotic drug that inhibits clathrin-dependent endocytosis, and tamoxifen, an anti-cancer drug that inhibits endosomal acidification, were planned but put on hold. The glycopeptide antibiotic teicoplanin, a cathepsin L inhibitor that has been shown to inhibit the entry of SARS-CoV, MERS-CoV and Ebola virus in cell culture[131], was suggested as a complementary treatment option for COVID-19 (ref. [132]) but is not currently under clinical investigation.

The inexpensive, commonly used drug tranexamic acid, which may inhibit SARS-CoV-2 S priming by suppressing plasmin activation, is the subject of a planned clinical trial. Similarly, vigil, a plasmid delivery vehicle that contains a furin-specific short hairpin RNA that is in advanced clinical testing for cancer treatment, has been proposed as a COVID-19 therapy[133].

Other host factors. Only a few approved drugs against rigorously validated SARS-CoV-2 host factors involved in post-entry steps are currently available (Table 3). Histone deacetylase inhibitors are a relatively new class of anti-cancer agents that interfere with transcriptional regulation. For example, panobinostat was shown to downregulate ACE2 in cell culture[134]. However, the use of histone deacetylase inhibitors against SARS-CoV-2 remains unproven. The phosphatidylinositol 3-phosphate 5-kinase (PIKFYVE) inhibitor apilimod was shown to reduce viral replication in primary cells and ex vivo lung cultures and is currently being trialled against COVID-19 (ref. [121]). The same applies to niclosamide, an approved antiparasitic agent that targets TMEM16 proteins and inhibits S-mediated syncytium formation and viral replication[120], and plitidepsin, an anti-cancer agent (targeting elongation factor 1-alpha 1) with limited approval that shows in vitro and in vivo antiviral activity[135].

Outlook

The urgency imposed by the COVID-19 pandemic and the availability of functional genetic and interactomic technologies have led to the discovery of SARS-CoV-2 host factors at an unprecedented rate. Taken together, these studies have identified a large cadre of candidate receptors, genetic dependencies and cellular proteins that interact with SARS-CoV-2 RNA and proteins. Although the biological roles of some factors have been extensively investigated, other proviral host factors that were identified in multiple studies have not been characterized. Future studies should further unravel the roles of these cross-validated factors in SARS-CoV-2 infection. Moreover, studies in animal models will be required to assess the relevance of identified host factors in vivo. As SARS-CoV-2 will probably not be the last zoonotic coronavirus to emerge, it will be crucial to explore which druggable proviral host factors are also required by other pathogenic coronaviruses, to develop broad-spectrum antivirals in preparation for possible future epidemics.

ABSTRACT

The COVID-19 pandemic raised by SARS-CoV-2 is a public health emergency. However, lack of antiviral drugs and vaccine against human coronaviruses demands a concerted approach to challenge the SARS-CoV-2 infection. Under limited resource and urgency, combinatorial computational approaches to identify the potential inhibitor from known drugs could be applied against risen COVID-19 pandemic. Thereof, this study attempted to purpose the potent inhibitors from the approved drug pool against SARS-CoV-2 main protease (M^{pro}). To circumvent the issue of lead compound from available drugs as antivirals, antibiotics with broad spectrum of viral activity, i.e. doxycycline, tetracycline, demeclocycline, and minocycline were chosen for molecular simulation analysis against native ligand N3 inhibitor in SARS-CoV-2 M^{pro} crystal structure. Molecular docking simulation predicted the docking score > −7 kcal/mol with significant intermolecular interaction at the catalytic dyad (His41 and Cys145) and other essential substrate binding residues of SARS-CoV-2 M^{pro}. The best ligand conformations were further studied for complex stability and intermolecular interaction profiling with respect to time under 100 ns classical molecular dynamics simulation, established the significant stability and interactions of selected antibiotics by comparison to N3 inhibitor. Based on combinatorial molecular simulation analysis, doxycycline and minocycline were selected as potent inhibitor against SARS-CoV-2 M^{pro} which can used in combinational therapy against SARS-CoV-2 infection.

1. Introduction

Human coronaviruses (HCoVs), such as middle-east respiratory syndrome coronavirus (MERS-CoV), severe acute respiratory syndrome coronavirus (SARS-CoV), and 2019 novel coronavirus (2019-nCoV, also called as SARS-CoV-2) that emerged from animal reservoirs, have aggravate the pandemic with high mortality and morbidity. Coronaviruses (CoVs) are positive-sense, single-stranded RNA (ssRNA) virus which contain the largest RNA genome of 27–32 kb with six to ten open reading frames (ORFs) enclosed in an enveloped protein to form spherical particles of 100–160 nm size [1,2]. The genetic material of HCoVs is highly susceptible to frequent recombination process which has been suggested to direct the establishment of new HCoV strains with altered virulence [3]. As a result, a total of seven main HCoVs have been recorded, viz. HCoV-229E, HCoV-NL63, HCoV-OC43, HCoV-HKU1, MERS-CoV, SARS-CoV, and SARS-CoV-2; these viruses are held accountable for fatal infections in the respiratory system and other system symptoms, including diarrhea and nausea [4,5].

HCoVs belong to the Coronaviridae family of the order Nidovirales and classified into four genera (α, β, γ, and δ) [6]. Recently discovered SARS-CoV-2 belongs to the β genus which shares 79.5% sequence similarity to SARS-related coronavirus and is 96% identical at the whole-genome level to a bat coronavirus [7,8]. The genome analysis of coronaviruses, including SARS-CoV-2 genome (GenBank:MN908947.3), revealed four non-structural proteins, i.e. papain-like protease (PL^{pro}), 3-chymotrypsin-like ($3CL^{pro}$), helicase, and RNA polymerase; four structural proteins, viz. nucleocapsid (N) protein, membrane (M) protein, envelope (E) protein, Spike (S) protein, and accessory proteins [1,9–11]. Both $3CL^{pro}$ and PL^{pro} are reported in transcription and replication of the virus [6]. Remarkably, *in vitro* inhibition of these proteases by the selected inhibitors has shown antiviral activity against coronaviruses (CoVs) [12,13]. These observations concluded the $3CL^{pro}$ as the main coronavirus protease (M^{pro}) [14], which is essentially required to conduct the replication cycle of the virus [6,15]. Like in other HCoVs, SARS-CoV-2 M^{pro} digests the polyprotein at conserved sites; it starts with autolytic cleavage from pp1a and pp1ab site encoded by the

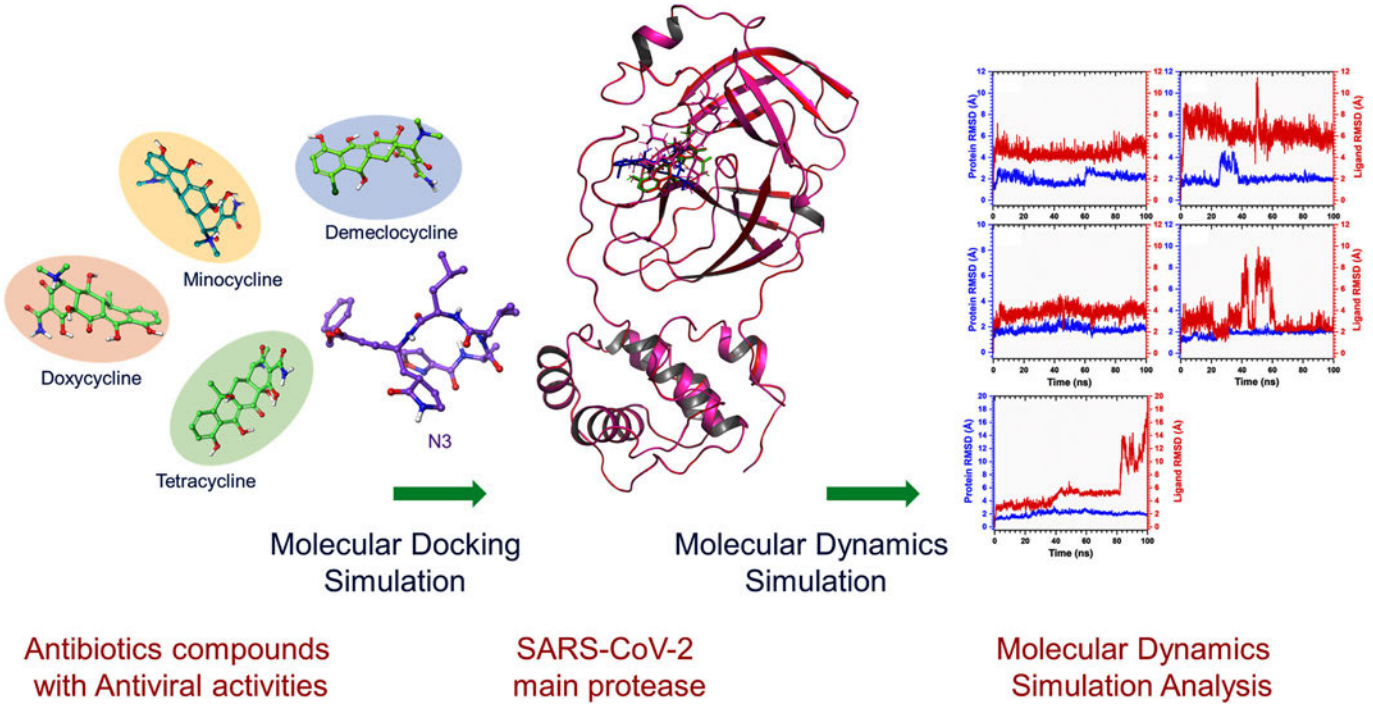

Fig. 1. Repurposing of antibiotics tetracyclines as potential inhibitors of SARS-CoV-2 main protease (M^{pro}) via combinatorial molecular simulation calculations.

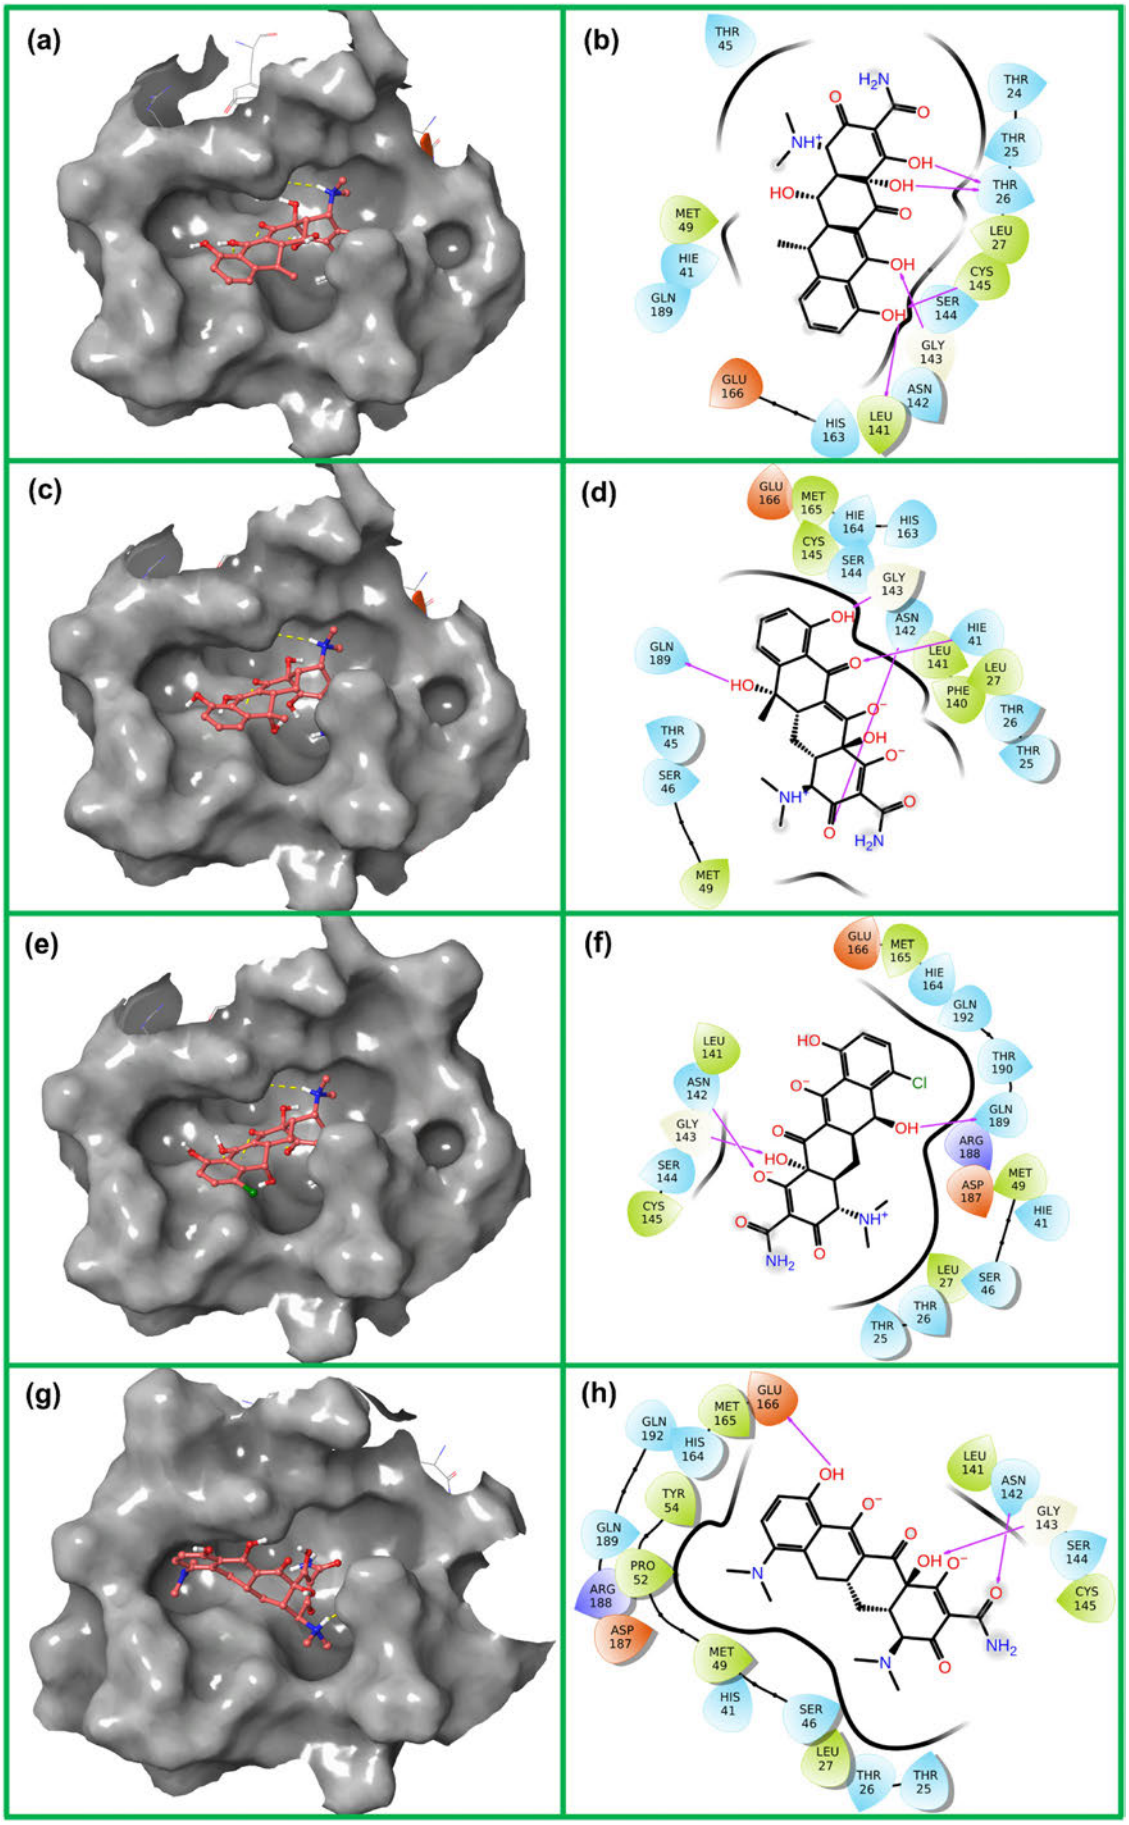
virus ORF1a/b which shares 96% sequence similarity with M^{pro} of SARS-CoV strain [16,17]. To conquer coronavirus infections, the inhibition of viral M^{pro}, which is functionally important in the viral life cycle and absence of its human homologues, has been approved as conventional antiviral therapeutic strategy [12].



In current scenario, despite numerous efforts, no drug or vaccine is yet approved against the HCoVs and expected to take further months to years for the new interventions [11]. Recently, various M^{pro} inhibitors were demonstrated for broad-spectrum *in vitro* activities against CoVs via interacting with conserved key residues required for the substrate recognition at respective M^{pro} enzymes [18,19]. Moreover, with the urgency of SARS-CoV-2 outbreak, drug repurposing is represented as an effective drug discovery approach from existing drugs to suggestively shorten the time and condense the cost by comparison to *de novo*drug discovery strategy and randomized clinical trials [20]. To facilitate the rapid drug discovery, computational drug repurposing approaches have been established as an effective method to reveal the new indications from already known drugs with the aid of computational algorithms such as molecular docking simulation and molecular dynamics simulation to predict the drug-target interactions and binding stability, respectively [21,22]. Previously, computational drug repurposing approaches were employed to identify the potential drug candidates against viral infections, including Ebola, ZIKA, dengue, and influenza infections [23], and for HCoVs such as SARS-CoV and MERS-CoV [24–26]. Also, nonpeptidic active-site-directed inhibition of SARS-CoV M^{pro} was discovered by a combination of screening and docking methods [27]. Likewise, bifunctional aryl boronic acid compounds were discovered to inhibit the SARS-CoV M^{pro} using combination of experimental and computational methods [28]. After SARS-CoV-2 outbreak, computational drug repurposing was also applied to find the potential drugs and some of the investigations are already reported [29–31]. In area of drug repurposing, antibiotics from tetracyclines and its derivatives have been repurposed against viral infections [32,33]. These antibiotics are well designated as broad-spectrum bacteriostatic inhibitors which selectively inhibit the microbial protein synthesis only, including naturally occurring polyketide compounds (chlortetracycline, oxytetracycline, and tetracycline) and their semisynthetic derivatives (minocycline, doxycycline, and methacycline) [32]. Notably, tetracycline derivatives, i.e. doxycycline, was reported to exert antiviral effects against antimurine retrovirus [34], Chikungunya infection [33], and blockage of dengue virus replication in infected cell lines [35,36]. Besides, demeclocycline is known to exert anti-viral activity on west Nile virus (WNV) [37] and included in the list of antiviral compounds [38]. Another, broad spectrum tetracycline derivative minocycline was initially reported against human immunodeficiency virus (HIV) type 1 infection [39], and later studied for other viruses such as WNV, Japanese encephalitis virus (JEV), Simian Immunodeficiency virus (SIV), Sindbis, human T-lymphocytic virus type-1 (HTLV-1), Rabies, and Reoviruses [40]. Moreover, tetracyclines (e.g. tetracycline, doxycycline, and minocycline) which are known as zinc chelating agents were postulated to inhibit COVID-19 infection by restricting viral replication in the host [41]. Additionally, synthetic halogenated tetracycline eravacycline was demonstrated with inhibitory effect against SARS-CoV, SARS-CoV-2, MERS-CoV, and hepatitis C virus (HCV) using computational studies [42].

Hence, under the impression of tetracyclines and their derivatives inhibits viral infections, we hypothesized that antibiotics reported for antiviral activities may be helpful in the SARS-CoV-2 inhibition by blockage of its main protease, viz. M^{pro}. Thereof, we employed structure based molecular docking for selected four tetracyclines, i.e. doxycycline, tetracycline, demeclocycline, and minocycline known for antiviral activities against other viruses, with M^{pro} from SARS-CoV-2. Similar virtual screening approach was recently applied to identify the tetracycline derivatives as Flavivirus inhibitors [36]. Following, docked protein-antibiotics complexes were evaluated for the complex stability via classical molecular dynamics simulation. The binding affinity and stability of selected viral protease-antibiotics complexes were also compared to the docked complexes of protease with native ligand N3 inhibitor to generate a comparative study as mentioned in Fig. 1.

2. Methodology

2.1. Receptor and ligand collection

Crystal structure of the novel SARS-CoV-2 main protease (SARS-CoV-2 M^{pro}) was downloaded from PDB database (https://www.rcsb.

(caption on next page)

Fig. 2. 3D and 2D interaction profiles for SARS-CoV-2 M^{pro}-antibiotics; (a–b) doxycycline, (c–d), tetracycline, (e–f) demeclocycline, and (g–h) minocycline, depicting active residues around the ligand at 4 Å area in the active pocket of SARS-CoV-2 M^{pro}. In 2D interaction maps, hydrogen bond formation (pink arrows), hydrophobic (green), polar (blue), red (negative), violet (positive) and glycine (grey) interaction are also logged between the docked SARS-CoV-2 M^{pro} and selected antibiotics. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

org/) with PDB ID:6lu7 [43]. The viral M^{pro} was elucidated at 2.16 Å resolution as dimer, where each monomer contained three domains; domain I (residues 8–101), domain II (residues 102–184), and domain III (residues 201–303) connected by long interconnecting loop (residues 185–200) between the domains II and III. The catalytic dyad (His41 and Cys145) and substrate binding sites were also defined between the domains I and II in the crystal structure with N3 inhibitor [43]. Besides, 3D structures of selected antibiotics, i.e. doxycycline (CID: 54671203), tetracycline (CID: 54675776), demeclocycline (CID: 54680690), and minocycline (CID: 54675783), were also downloaded from PubChem database (https://pubchem.ncbi.nlm.nih.gov/).

2.2. Molecular docking simulation

Molecular docking simulation between the SARS-CoV-2 M^{pro} and selected antibiotics was conducted in Chimera-AutoDock Vina plugin setup to determine the interacting residues of the protein with respective ligands. Briefly, protein and ligand structures were minimized using the default parameters in structure minimization tool in USCF Chimera-1.14 [44]. Following, receptor and ligands were prepared using Dock prep tool in Chimera under default parameters, where native ligand from the crystal structure was removed, polar hydrogen atoms and charges were added. Finally, molecular docking simulations were performed using AutoDock Vina [45] plugin with default setting at the native ligand binding pocket by adopting the docking grid size of 60 × 40 × 40 Å along both three (X, Y, and Z) axes, covering all the essential residues center at −8.918, 17.918, 62.905 Å region, to provide copious space for the ligand conformations. By docking, at least 10 conformers were generated and conformer with lowest binding energy and RMSD were chosen for further analysis in free academic Maestro v12.3 (Schrödinger Release 2020-1: Maestro, Schrödinger, LLC, New York, NY, 2020). Herein, noncovalent interactions, viz. hydrogen bonding, hydrophobic, π-π interaction, π-cation interaction, positive (basic or positive amino acids), negative (acidic or negative amino acids), polar (polar amino acids), glycine (non-polar interaction), and salt bridges interactions, were calculated at cutoff radius of 4 Å under default conditions, and both 3D and 2D interaction images were generated. Similar docking methodology was also employed for the crystal structure ligand, i.e. Michael acceptor inhibitor, known as N3 inhibitor [43], to validate the docking procedure and for comparative analysis with the selected antibiotics.

2.3. Molecular dynamics simulation

The best scored poses for receptor-ligand complexes were evaluated for complex stability by 100 ns molecular dynamics (MD) simulations using free academic Desmond v5.6 module of Schrödinger-Maestro v11.8 [46] under Linux environment on HP Z2 workstation. All the MD systems for protein-ligand complexes were fabricated as an orthorhombic grid box (10 Å × 10 Å × 10 Å buffer) followed by addition of TIP4P (transferable intermolecular potential 4 point) water molecules for system minimization using System Builder tools in Desmond-Maestro interface. Later, salt and ion placement were omitted at 20 Å from the ligand and whole system was neutralized by addition of counter ions. Besides, 0.002 ps time interval was set for the anisotropic diagonal position scaling to reserve the constant pressure during MD simulation. Additionally, temperature of the system was set at 300 K coupled with 20 ps NPT reassembly at 1 atm pressure. Furthermore, system density was preserved near 1 g/cm^3 and all the calculations were conducted under default parameters. Finally, MD simulation for each complex was conducted for 100 ns interval under similar conditions. Subsequently, the simulation trajectories were analyzed by simulation interaction diagram tool in Desmond v5.6 module of Schrödinger-Maestro v11.8 [46].

3. Results and discussion

3.1. Intermolecular interaction analysis

The molecular docking algorithms have been widely used to predict the bioactive compounds or drug repurposing against various drug targetable proteins in diseases and infections [36,47]. Likewise, this study also employed the molecular docking simulation approach for the selected antibiotic tetracyclines, i.e. doxycycline, tetracycline, demeclocycline, and minocycline, to predict their instinctively potential against SARS-CoV-2 infection by its M^{pro} inhibition. All the docked drugs and N3 inhibitor showed significant docking confirmation with binding affinity energies > −7 kcal/mol at least RMSD (0 value by default in AutoDock Vina under default parameters) in the active pocket of SARS-CoV-2 M^{pro} with respect to N3 inhibitor (Figs. 2, S1). The docked SARS-CoV-2 M^{pro}-doxycycline complex was recorded with significant −7.6 kcal/mol docking score and formed five hydrogen bonds with the viral protease by active residues Thr26 (2.8 Å and 2.33 Å), Leu141 (2.33 Å), Gly143 (2.86 Å), and Cys145 (3.23 Å); additional interactions, i.e. hydrophobic (Leu27, Met49, Leu141, Cys145, Met165), polar (Thr24, Thr25, Thr26, Hie41, Thr45, Asn142, Ser144, His163, and Gln189), negative (Glu166), and glycine (Gly143), were logged in SARS-CoV-2 M^{pro}-doxycycline complex (Fig. 2a–b). Whereas, SARS-CoV-2 M^{pro} docked complex with tetracycline was logged for docking energy of −7.5 kcal/mol and formation of four hydrogen bonds with the active residues His41 (2.84 Å), Asn142 (3.33 Å), Gly143 (2.84 Å), and Gln189 (3.86 Å) was also recorded. Moreover, hydrophobic interactions (Leu27, Met49, Phe140, Leu141, Cys145, and Met165), polar interactions (Thr25, Thr26, His41, Thr45, Ser46, Asn142, Ser144, His163, His164, and Gln189), negative interactions (Glu166), and glycine interactions (Gly143) were also observed between the residues of SARS-CoV-2 M^{pro} and atoms of tetracycline (Fig. 2c–d). Similarly, SARS-CoV-2 M^{pro}-demeclocycline complex exhibited significant docking score of −7.4 kcal/mol along with formation of three hydrogen bonds at essential residues Asn142 (3.03 Å), Gly143 (2.80 Å), and Gln189 (3.74 Å) of SARS-CoV-2 M^{pro}. Additionally, the respective complex was noted for hydrophobic interactions (Leu27, Met49, Leu141, Cys145, and Met165), polar interactions (Thr25, Thr26, Hie41, Ser46, Asn142, Ser144, His164, Gln192, Thr190, and Gln189), negative interactions (Glu166 and Asp187), positive interactions (Arg188), and glycine interactions (Gly143) (Fig. 2e–f). While, SARS-CoV-2 M^{pro}-minocycline complex showed substantial binding energy of −7.1 kcal/mol followed by formation of three hydrogen bonds with the residues Asn142 (2.64 Å), Gly143 (2.54 Å), and Glu166 (2.84 Å) in the active pocket of viral protease. Other intermolecular interactions, viz. hydrophobic interactions (Leu27, Met49, Pro52, Tyr54, Leu141, Cys145, and Met165), polar interactions (Thr25, Thr26, His41, Ser46, Asn142, Ser144, His164, and Gln189), negative interactions (Glu166 and Asp187), positive interactions (Arg188), and glycine interactions (Gly143), were also observed for SARS-CoV-2 M^{pro}-minocycline docked complex (Fig. 2g–h). The substantial docking energy and formation of strong hydrogen bonds between the atoms of respective antibiotics with active residues of SARS-CoV-2 M^{pro} indicate the substantial stability of docked protease-antibiotics complexes.

Furthermore, the docked poses of the antibiotics with SARS-CoV-2

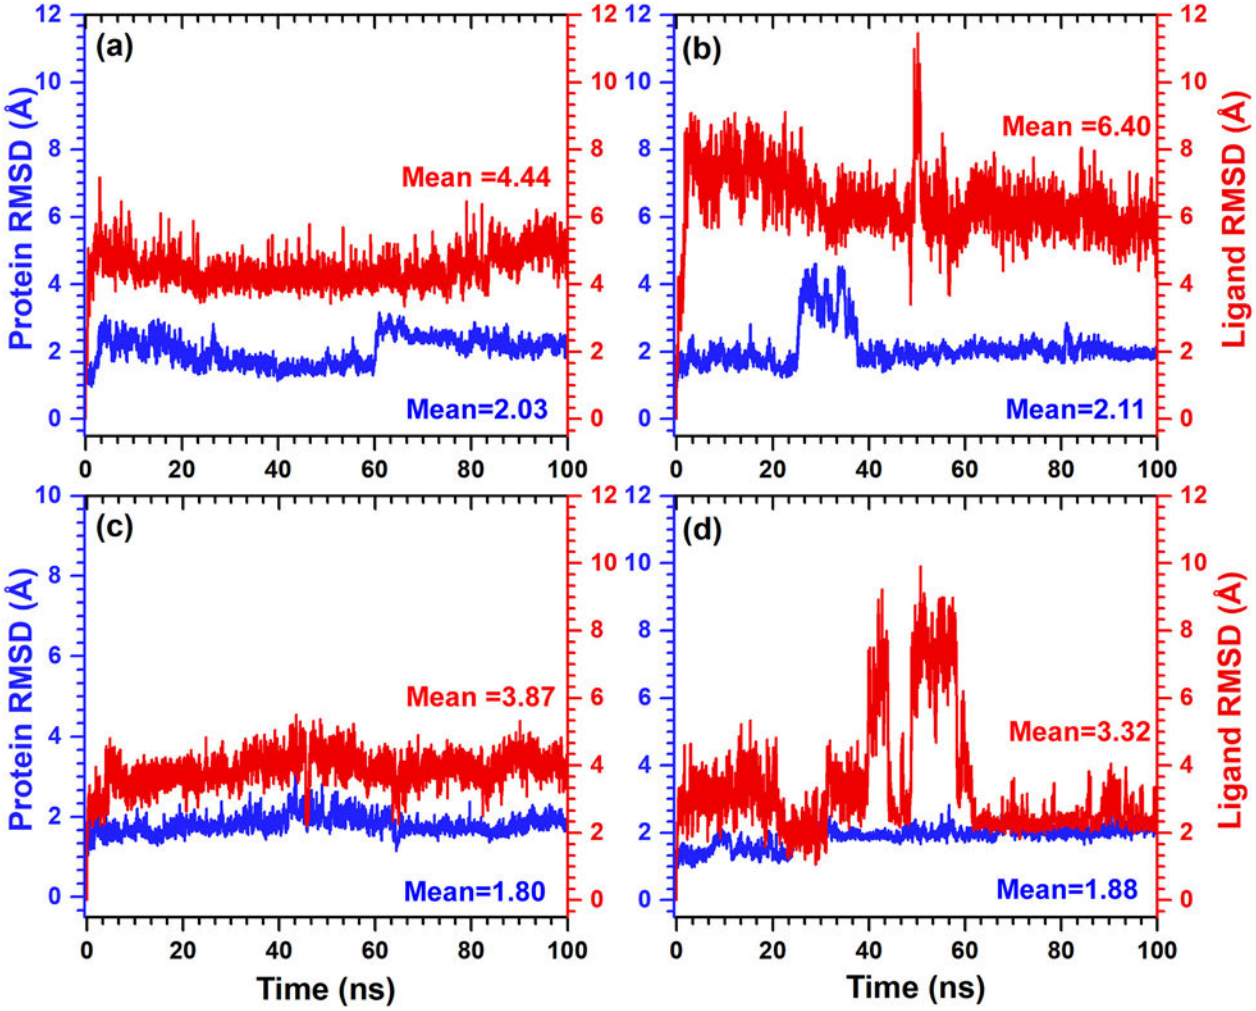


Fig. 3. Calculated RMSD values for α-carbon atoms (blue curves) of SARS-CoV-2 M^{pro} and selected ligands (red curves), viz. (a) doxycycline, (b), tetracycline, (c) demeclocycline, and (d) minocycline plotted with respect to 100 ns MD simulation time. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

M^{pro} were also compared to the SARS-CoV-2 M^{pro}-N3 inhibitor docked complex (Fig. S2). The comparative docking analysis includes docking energy and intermolecular interaction profiling between the selected complexes. From molecular docking simulation analysis, N3 inhibitor (−7.6 kcal/mol) showed relatively similar docking energy by comparison to selected antibiotics (maximum docking score −7.6 kcal/mol logged for SARS-CoV-2 M^{pro}-doxycycline complex). Moreover, SARS-CoV-2 M^{pro}-N3 inhibitor complex exhibited formation of four hydrogen bonds with residues Cys145 (2.01 Å), Glu166 (2.16 Å), and Gln189 (2.30 and 3.06 Å) along with other intermolecular interactions (Fig. S2). Interestingly, in SARS-CoV-2 M^{pro}-antibiotic complexes, doxycycline also generated five hydrogen bonds and minimum of three hydrogen bonds were noted for the minocycline docked at the active pocket of viral protease. Besides, both antibiotics and N3 inhibitor exhibited significant hydrophobic, polar, negative, positive, and glycine interactions with common residues of the SARS-CoV-2 M^{pro} (Figs. 2, S2). Interestingly, selected antibiotics docked with SARS-CoV-2 M^{pro} exhibited one or more than type of interaction with the catalytic dyad (Cys145 and His41), substrate binding residues (Phe140, Leu14, Gly143, Ser144, His163, Met165, and Glu166) and other essential residues required for the substrate binding pocket (Thr24, Thr25, Met49, Phe140, Asn142, His163, Met165, Asp187, and Gln189) (Figs. 2, S2) as reported in the viral protease crystal structure with N3 inhibitor [43]. Additionally, Gln189 residue, which is absolute requirement for S1 subsite at the P1 position was logged in the interaction profile with the selected antibiotics with SARS-CoV-2 M^{pro} inhibitors [43]. As, the antibiotics were logged for intermolecular interaction with residues of active site and substrate-binding pocket located between the clefts of domain I and domain II of vial main protease, suggested to inhibit the proteolytic function of SARS-CoV-2 M^{pro}, which is required for the viral replication and pathogenesis [43]. Moreover, interacted residues of SARS-CoV-2 M^{pro} in the antibiotics docked complexes are highly conserved as substrate-recognition pocket of the CoVs, suggested the selected screened antibiotics can be employed for the development of broad spectrum of antiviral drugs against HCoVs. Hence, molecular docking simulation analysis for the screened antibiotics with respect to N3 inhibitor suggested that the selected drug molecules have the potential to inhibit SARS-CoV-2 M^{pro} by interacting with its catalytic dyad and substrate binding residues.

3.2. Molecular dynamics simulation analysis

Molecular dynamics simulation can be employed to the docked complexes to study their stability and intermolecular interaction profiling with respect to time [47,48]. In this study, docked complexes of antibiotics and N3 inhibitor with viral protease were subjected to 100 ns molecular dynamics (MD) simulation to predict the respective complex confirmation change, stability, and intermolecular interactions between the active residues of the receptor and atoms of the ligand molecules. Initially, last pose from simulation trajectory was extracted

and studied for the intermolecular interaction for the respective complexes. A maximum of three hydrogen bonds were recorded for SARS-CoV-2 M^{pro}-demeclocycline, two hydrogen bonds for SARS-CoV-2 M^{pro}-tetracycline, only one hydrogen bond in each SARS-CoV-2 M^{pro}-doxycycline and SARS-CoV-2 M^{pro}-minocycline complex against SARS-CoV-2 M^{pro}-N3 inhibitor (no hydrogen bonding) (Figs. S3, S4). These observations predicted that selected antibiotics have substantial affinity with the active pocket of SARS-CoV-2 M^{pro} by comparison to N3 inhibitor. To further verified the selected receptor-ligand complex stabilities, four properties were calculated from respective simulation trajectories, i.e. (a) root mean square deviation (RMSD), (b) root mean square fluctuation (RMSF), (c) protein secondary structure element (SSE) changes to nullify abnormal structural changes and conformational modification of docked ligands with respect to simulation time, and (d) protein-ligand contacts mapping, was performed to analyze the type of interaction between the ligand atoms and residues of the protein during MD simulation.

3.2.1. RMSD and RMSF

To quantify the degree of conformational changes in protein and ligand of the docked complexes, initially RMSD for protein (Cα, backbone, side-chain, and heavy) and fit ligand on protein were calculated from 100 ns simulation trajectories for each complex. The Cα atoms of SARS-CoV-2 M^{pro} docked with selected antibiotics and N3 inhibitor showed acceptable fluctuations (mean = 1.80 to 2.11 Å) with equilibration till end of simulation (Figs. 3, S5). Likewise, backbone, side-chain, and heavy atoms of SARS-CoV-2 M^{pro} from respective complexes were noted for stable deviations (< 3 Å), except for receptor complex with tetracycline (< 4.5 Å) showed fluctuation around 20–40 ns followed by state of equilibrium till end of 100 ns simulation (Fig. S6). Besides, RMSD of the four antibiotics fit on protein exhibited acceptable deviations (Fig. 3). Notably, tetracycline and minocycline showed maximum variation (< 10.5 Å) between 40 and 60 ns interval followed by equilibrium at 5.8 Å and 2.2 Å, respectively at the end of 100 ns simulation (Fig. 3). While RMSD for the N3 inhibitor fit on protein showed variations (~6 Å) between 40 and 60 ns and then higher deviations (~9-18 Å) after 80 ns till end of 100 ns interval (Fig. S5). These results indicate that antibiotics docked protease complexes have attained the equilibrium during 100 ns simulation while N3 inhibitor docked complex required longer simulation interval to achieve the complex stability. Thereof, based on mean of the RMSD trajectories, the selected antibiotics were concluded with significant complex stability by comparison to N3 inhibitor docked with SARS-CoV-2 M^{pro}.

Furthermore, flexibility of SARS-CoV-2 M^{pro} docked with selected compounds was analyzed to monitor the deviations in the protein residues and ligand atoms during simulation (Fig. S7). In all the complexes, acceptable RMSF values for the protein residues were recorded with respect to time where residues on the N-terminal (< 2 Å) exhibited low fluctuation compared to the C-terminal (last 10 residues with variation of > 4.5 Å). Besides, ligands were also monitored to have significant contacts with the residues in β-strands (containing active pocket of the protein), supports the integration of the docked ligands with residues on the active region of SARS-CoV-2 M^{pro} (Fig. S7). Moreover, intermolecular interactions of the ligands with secondary structure elements (α-helices and β-strands) of the protein indicate induction of slight rigidity in the protein structure. Hence, these acceptable RMSF values for protein structure and residue-ligand contact mapping suggested the structural stability of SARS-CoV-2 M^{pro} complexes with antibiotics by comparison to native ligand N3 inhibitor of crystal structure during 100 ns simulation.

Likewise, RMSF calculated for the selected antibiotics fit on SARS-CoV-2 M^{pro} with respect to simulation time suggested the acceptable deviations (< 3.5 Å) in mean structure of the ligand, expect for tetracycline (atoms at position 19 to 28) and minocycline (atoms at position 19 to 28) (Fig. S8). These variations in heteroatoms of the ligands were also concluded to contribute in relatively higher ligand fit on protein RMSD against other antibiotics during simulation. Furthermore, RMSF calculated for the N3 inhibitor fit on SARS-CoV-2 M^{pro} exhibited higher deviations (5–10 Å) (Fig. S8), which were suggested to contribute higher RMSD in the fit ligand on protein during MD simulation (Fig. S5). In conclusion, RMSD and RMSF indicate the acceptable changes in the antibiotics docked SARS-CoV-2 M^{pro} complexes by comparison to SARS-CoV-2 M^{pro}-N3 inhibitor during 100 ns MD simulations.

3.2.2. Protein secondary structure elements (SSE)

The protein SSE (α-helices and β-strands) were monitored for SSE distribution and SSE composition analysis for the respective residue index during the simulation to observed changes in the domains of SARS-CoV-2 M^{pro} docked with respective ligands (Fig. S9). The selected complexes of SARS-CoV-2 M^{pro} with antibiotics and N3 inhibitor exhibited only α-helix structures in the C-terminal region (201–303) which formed the domain III of the viral protease. While, N-terminal region showed both α-helices and β-strands (1–200) which constitute the domain I and domain III for the viral protease, defined in the crystal structure for the formation of active pocket [43]. These observations concluded the secondary structure of SARS-CoV-2 M^{pro} complexed with all the selected ligands (%total SSE = 45 ± 1.2). Interestingly, β-strand (%total 25 ± 1.1) secondary structures in the active pocket of SARS-CoV-2 M^{pro} were monitored to be significantly occupied by selected antibiotics and N3 inhibitor (Fig. S9). Furthermore, torsion angle potential plot was also studied for all the selected ligands which exhibits the relation between the torsion angle of the respective ligands to their respective potential energy [49]. The torsion angle provides the necessary information for the number of rotatable bonds in the ligand molecule (Fig. S10). Here, doxycycline, tetracycline, demeclocycline, minocycline, and N3 inhibitor were predicted with 6, 6, 7, 6, and 22 rotatable bonds in their structures. The torsion potential and histogram relationships provide a standard method to get an insight into the conformational strain introduced in the ligands during simulation, which assisted to understand the protein-bound ligand conformation. These results indicate that ligand with a smaller number of rotatable bonds showed stronger rigidity and vice-versa may contribute to generate optimum geometry for the ligand in the active pocket to attained higher stability. This can be correlated with the docking score and number for intermolecular interactions in the respective docked complexes (Figs. 2, S2). Moreover, modifications introduced in the fit ligand on protein during MD simulation were also calculated in terms of ligand RMSD, radius of gyration, intra-molecular hydrogen bonds, molecular surface area (MolSA), solvent accessible surface area (SASA), and polar surface area (PSA) (Fig. S11). These results suggested the stability of selected antibiotics at the active pocket of SARS-CoV-2 M^{pro} by comparison to N3 inhibitor.

3.2.3. Protein-ligand interaction mapping

The binding mode of ligand with the active pocket of SARS-CoV-2 M^{pro} can be further analyzed for the atomic level interactions which includes hydrogen bond formation, hydrophobic contact, ionic interaction, and salt bridge formation during MD simulation. Hence, these protein-ligand interactions were extracted from 100 ns simulation trajectories to support the respective complex stability during MD simulation. All the antibiotics by comparison to N3 inhibitor showed significant interactions with the essential catalytic residues, i.e. His41 and Cys145, in addition to other substrate binding residues in the active pocket of SARS-CoV-2 M^{pro} (Figs. 4, S12); these residues were also recorded for the intermolecular interaction with the ligands during molecular docking simulation (Figs. 2. S2). Interestingly, all the antibiotics were observed for higher number of interactions with residues in protein-ligand mapping and formation of hydrogen bond with active residues of the protein for 30% of the simulation interval with an exception in SARS-CoV-2 M^{pro}-tetracycline complex (Fig. 4). However, only Asn142 and Glu166 were predicted with substantial hydrogen boning and water bridges formation in SARS-CoV-2 M^{pro}-N3 inhibitor

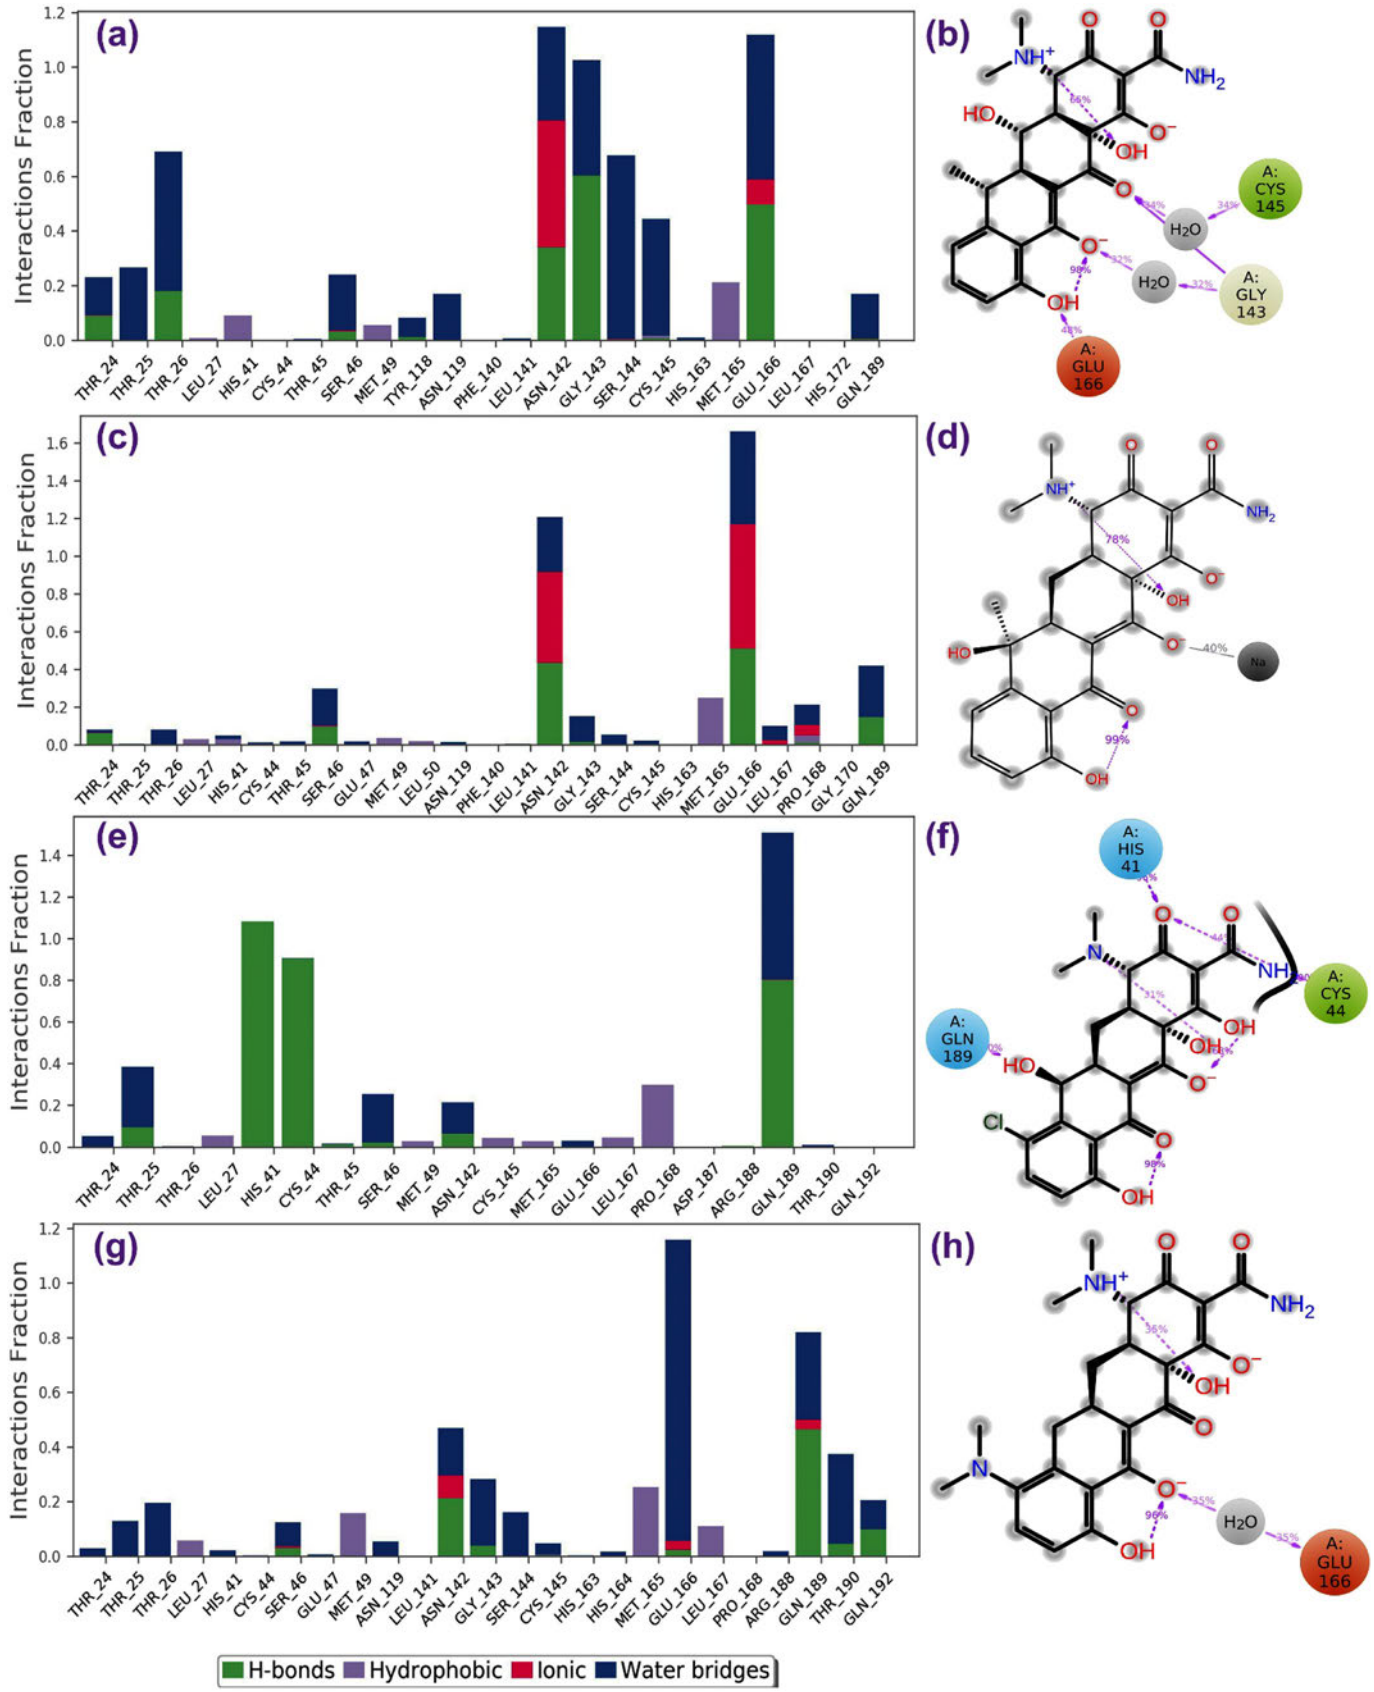

Fig. 4. Protein-ligand interactions mapping for SARS-CoV-2 M^{pro} with selected antibiotics, i.e. (a–b) doxycycline, (c–d) tetracycline, (e–f) demeclocycline, and (g–h) minocycline, extracted from 100 ns MD simulations. In 2D interaction diagram, the residues cystine (green), glutamic acid (red), histidine and glutamine (blue), and glycine (grey) exhibit the hydrophobic, negative, polar and non-polar interactions, respectively along with hydrogen bonding (pink arrow) and ionic interaction with sodium ion (black line) with the receptor are extracted at 30% of the total MD simulation interaction interval. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

complex from protein-ligand interaction mapping data analysis (Fig. S12). Furthermore, total number of contacts and their density with respect to time were also calculated (Fig. S13). Again, these plots suggested the multiple interactions of the selected antibiotics by comparison to N3 inhibitor with the essential residues (His41, Asn142, Gly143, Cys145, Glu166, and Gln189) in the active pocket of SARS-CoV-2 M^{pro}. These observations suggested the substantial protein-ligand intermolecular interactions and stability of four antibiotics by comparison to N3 inhibitor throughout the 100 ns MD simulations.

Hence, based on docking score and simulation trajectory analysis, selected four antibiotics are predicted as potential SARS-CoV-2 M^{pro} inhibitor in the order, viz. doxycycline, minocycline, demeclocycline, and tetracycline, to challenge the SARS-CoV-2 infection by comparison to N3 inhibitor. Recently combinational therapy of lopinavir with the other potent compounds against SARS-CoV-2 virus has been suggested to increase synergy and decrease the effective concentration of lopinavir [50]. For instance, triple antiviral therapy composed of interferon β-1b, lopinavir–ritonavir, and ribavirin against SARS-CoV-2 M^{pro} was reported as superior and safe against lopinavir–ritonavir alone to reduce the virus shedding, lessening symptoms, and facilitating discharge of infected patients with mild to moderate degree of SARS-CoV-2 infection [51]. In this regard, based on our computational studies, the selected antibiotics, i.e. doxycycline, minocycline, demeclocycline, and tetracycline, may be helpful as combinational therapy with lopinavir-ritonavir and ribavirin against SARS-CoV-2 infection.

4. Conclusion

This study was aimed to repurpose the antibiotics with known antiviral activity as potential inhibitor against SARS-CoV-2 M^{pro} with the aid of molecular simulation approaches. A total of four potent antibiotics, viz. doxycycline, tetracycline, demeclocycline, and minocycline were evaluated as SARS-CoV-2 M^{pro} inhibitor by comparison to native ligand of SARS-CoV-2 M^{pro} crystal structure (N3 inhibitor). Molecular docking simulation for the selected antibiotics showed docking score > -7 kcal/mol and interaction with catalytic dyad of SARS-CoV-2 M^{pro}, i.e. His41 and Cys145. These complexes were further analyzed for structural stability by 100 ns classical molecular dynamics simulation, suggested the considerable stability of SARS-CoV-2 M^{pro} docked complexes with antibiotics by comparison to N3 inhibitor of SARS-CoV-2 M^{pro} via strong multiple intermolecular interactions. From the binding mode analysis, before and after molecular dynamics simulation analysis followed by interaction profiles collected during the simulation interval supported the selected antibiotics for substantial stability on the active pocket of SARS-CoV-2 M^{pro}. In conclusion, based on docking score and molecular dynamics simulation trajectory analysis, selected four antibiotics can be used as potential SARS-CoV-2 M^{pro} inhibitor in the order, viz. doxycycline, minocycline, demeclocycline, and tetracycline to challenge the SARS-CoV-2 infection. Hence, the screened and computationally validated antibiotics can be further evaluated for *in vitro* SARS-CoV-2 M^{pro} inhibition and viral infection as single dose or in synergistic concentrations for the drug development and combinational therapy against SARS-CoV-2 infection.

Abstract

Background: Ivermectin, an anti-parasitic agent, also has anti-viral properties. Our aim was to assess whether ivermectin can shorten the viral shedding in patients at an early-stage of COVID-19 infection.

Methods: The double-blinded trial compared patients receiving ivermectin 0·2 mg/kg for 3 days vs. placebo in non-hospitalized COVID-19 patients. RT-PCR from a nasopharyngeal swab was obtained at recruitment and then every two days. Primary endpoint was reduction of viral-load on the 6th day (third day after termination of treatment) as reflected by Ct level>30 (non-infectious level). The primary outcome was supported by determination of viral culture viability.

Results: Eighty-nine patients were eligible (47 in ivermectin and 42 in placebo arm). Their median age was 35 years. Females accounted for 21·6%, and 16·8% were asymptomatic at recruitment. Median time from symptom onset was 4 days. There were no statistical differences in these parameters between the two groups.

On day 6, 34 out of 47 (72%) patients in the ivermectin arm reached the endpoint, compared to 21/ 42 (50%) in the placebo arm (OR 2·62; 95% CI: 1·09-6·31). In a multivariable logistic-regression model, the odds of a negative test at day 6 was 2.62 time higher in the ivermectin group (95% CI: 1·06–6·45). Cultures at days 2 to 6 were positive in 3/23 (13·0%) of ivermectin samples vs. 14/29 (48·2%) in the placebo group (p=0·008).

Conclusions: There were significantly lower viral loads and viable cultures in the ivermectin group, which could lead to shortening isolation time in these patients.

The study is registered at ClinicalTrials.gov: NCT 044297411.

Background

Ivermectin is an FDA-approved broad spectrum anti-parasitic agent, which was initially approved in humans in 1987 to treat onchocerciasis, awarding the discoverers the Nobel prize of Medicine in 2015. Its main activity was known for therapy against infections caused by roundworm parasites. Over the years, the spectrum was extended and included also parasitic skin infections such as scabies among others. [1]

In the last decade, several in-vitro studies have shown its anti-viral activity against a broad range of viruses, mainly RNA viruses including HIV, influenza and several flaviviruses such as Dengue virus (DENV), Zika, and West Nile Virus.[2-6] Recently ivermectin was tested in vitro against SARS-CoV-2 and showed ~5000-fold reduction (99.8%) in viral RNA after 48 hours.[7] However, it was criticized that the dosing used in the study cannot be achieved with the current approved dose.[8]

In addition, ivermectin has anti-inflammatory properties.[9] Since the excessive inflammatory response to SARS-CoV-2 is thought to be a major cause of disease severity and death in patients with COVID-19, [10] ivermectin may have further value in addition to its anti-viral properties.

With its high safety profile, ivermectin is a potential treatment against COVID-19 in its different stages. Some clinical studies have shown beneficial results regarding clinical outcomes and the length of viral shedding, however most of them are lacking a high standard of rigorous methodology.[11]

Here we conducted a double blinded randomized control trial to assess whether Ivermectin can shorten viral shedding, in non-hospitalized patients at the early stage of COVID-19 infection.

Methods

Study design

A randomized controlled, double blinded trial to evaluate the effectiveness of ivermectin in reduction of viral shedding among mild to moderate COVID-19 patients. The study was conducted in hotels located in (Tel-Aviv, Jerusalem and Ashkelon) Israel, that have been designated as isolation facilities for mild to moderate COVID-19 patients, not requiring oxygen.

Institutional Review Board (IRB) approval was given by the Sheba Medical Center's IRB (7156/20**)**. Written informed consent was received from each participating individual before recruitment.

Study population

Patients were eligible for enrollment in the study if they were 18 years of age or older; not pregnant; with molecular confirmation of COVID-19 by RT-PCR; and with the intention to receive results within the first three days from symptoms onset. However due to the delay (three to four days) in getting results in the community, we extended the time up to seven days from symptoms onset. Since our main outcome was the change in viral shedding (as reflected by Ct value), asymptomatic cases were also included within 5 days from molecular diagnosis.

Patients were excluded if they weighed below 40kg, were with known allergy to the drugs, unable to take oral medication, participating in another RCT for treatment of COVID-19. In addition, patients who had RT-PCR results with Ct (cycle threshold) value >35 in first two consecutive were excluded. Patients with comorbidities of cardiovascular disease, diabetes, chronic respiratory disease (excluding mild intermittent asthma), hypertension, and or cancer were defined as high-risk patients.

Randomization

Randomization in a 1:1 ratio was done by computer-generated program using randomization.com (http://www.jerrydallal.com/random/randomize.htm) by Clinical Research Coordinator (CRC), blinded to the rest of

medRxiv preprint doi: https://doi.org/10.1101/2021.05.31.21258081; this version posted May 31, 2021. The copyright holder for this preprint

the study team. This CRC was not requiting patients and the numbered pills bottles were available only for the physician who were requiting.

Patients assigned to the intervention arm received ivermectin in a dosage regimen according to body weight; patients weighing between 40-69 kg received four tablets (=12mg) daily and patients weighing ≥70kg received five tablets (=15mg) daily, all for three days. Patients assigned to the placebo arm received the same number and same appearance of pills per weight daily, for three days. They were guided to take the pills one hour before a meal. The investigators and patients were blinded to the assignment.

Intervention

On the day of randomization and treatment initiation, patients were tested for SARS-CoV-2 by reverse transcriptase polymerase chain reaction (RT-PCR) from nasopharyngeal (NP) swabs (day zero). Tests were then administered every two days from day six up to day 14, unless patients were discharged earlier from the isolation facilities. The protocol was amended at the beginning of September when the Ministry of Health changed the policy of isolation and allowed infected patients to leave the facility 10 days from symptom onset without further testing. At this point testing at day two and four were added to the protocol.

Sinc results of the test could have been influenced by the examiner who performed the swab and with differences between labs,[12, 13] a small number of trained practitioners were allocated to obtain the swab during the entire rial and instructed to use a uniform technique. In addition, all RT-PCR tests, including verification that patients were positive on day zero, were conducted by the same lab, at the Israel Central Virology Laboratory of the Ministry Of Health (located at Sheba Medical Center).

Patients were followed up daily by telephone until their discharge. Patients were asked whether they took the pills as guided, if they noticed any adverse effect following treatment and whether there were any follow up of symptoms.

Unexpectedly some patients who were isolated in the hotels as verified positive patients were found to be borderline or negative upon our RT-PCR test (Figure 1). Therefore,

Patients with missing data along the follow up were carried over from the last data available

medRxiv preprint doi: https://doi.org/10.1101/2021.05.31.21258081; this version posted May 31, 2021. Outcomes

The primary clinical endpoint was viral clearance following a diagnostic swab taken on the sixth day (third day after termination of treatment), in the intervention group compared to placebo. Although negative PCR is defined in Israel with Ct>40, reaching this level may take a few weeks, and there is significant evidence that a non-infectious state is usually achieved at Ct level>30.[14-16] Therefore we defined a negative test at a non-infectious level as measured by RT-PCR of Ct values >30 (less than $3{\cdot}4X10^4$ viral copies)

Post-Hoc analysis: Toward the end of our study (January 2021) the central virology lab. established a Biosafety Level 3 (BSL-3) unit, allowing us the ability to culture the virus. Since positive medium of participating patients were kept in -80c, we were enabled to culture them. Thus, an end point of culture viability at days 2-6 post-intervention was added.

PCR testing

The presence of the SARS-COV-2 RNA was detected using the Seegene Allplex CoV19 detection kit, according to the manufacturer's instructions (See supplement). The test detects three viral genes: envelop (E), nucleocapsid (N) and RNA-dependent RNA polymerase (RdRp). For each sample, Ct level was defined as the Ct level of the highest viral load (low Ct).

Viral copies Determination

Determination of the copies number in the examined samples was performed by generating standard curves for each reaction, thereby enabling the conversion of the Cq values to viral genome copies, as detailed in the Supplementary methods.

In-Vitro cultures

Positive samples were stored at -80°C and were thawed for culturing on Vero E6 cells at 37°C for seven days, as detailed in the Supplementary methods.

Statistical methods

Sample size: Based on published data from the Ministry of Health at the time of study initiation, we expected less than 10% of patients at day six show a negative RT-PCR test. With the interventional drug we expected a reduction of at least 25% in the proportion of positive cases. Hence, considering a potential decrease from 90% to 67·5% (25% decrease), with a power (1-β) of 80% at a significance level of 5% ($\alpha = 0{\cdot}05$), a minimal sample size of 96 participants in total, was required to detect a statistically significant difference. Therefore, 48 patients were needed in each study arm. To account for a loss to follow-up of 10% after 14 day, we aimed to recruit a total of 105 participants.

Statistical analysis: Statistical analysis was done by the Biostatistics and Biomathematics Unit, Gertner Institute, Sheba Medical Center, Tel-Hashomer, Israel.

Continuous variables are presented as mean ± standard deviation or as median and interquartile range. Categorical variables are presented as N (%). Differences between ivermectin and placebo groups were assessed using a Chi-square test and t-test, for categorical and continuous data respectively. Where cross tabulation frequencies were less than 5, the Fisher exact test was used. A multivariate logistic regression model was used to determine the impact of ivermectin while controlling for age, sex, weight, and being symptomatic or not on reduction of viral load on day 6^{th} as reflected by Ct level>30. Results include adjusted odds ratios (OR), and 95% confidence intervals (CI). Kaplan-Meier curves were drawn, and survival analysis conducted with log-rank test using for time to negative RT-PCR (Ct level>30) result.

Boxplots were produced in R version 4·0·2. For figure readability, viral load values were log-transformed.

For all analyses, significance was set at $p < 0{\cdot}05$. All data analyses were performed with the SAS 9·4 software (Cary, NC, USA).

FOI 26-3132 - Document 5

Results

From May 15th, 2020 through end of January 2021, a total of 116 patients underwent randomization, and 89 were eligible for analysis (Figure 1).

The baseline study population characteristics are detailed in Table 1. The median age of the patients was 35 years (range, 20 to 71), 22·4% equal or older than 50 years and 7·8% equal or older than 60 years. A majority of the patients were males (78·4%). Twelve (13·5%) patients had comorbidities associated with risk for severe disease [17]; 17% and 9·5% among the ivermectin and placebo groups respectively, p=0·53.

Clinical Presentation

Among the study population 83% were symptomatic. The most common symptoms, fatigue, fever, cough, headache, and myalgia were prevalent in approximately half of the study population. (symptoms detailed in Table S1-supplement). None of these variables were statistically different between the two study arms.

Study Outcome

Viral load during the study period is depicted in Figure 2. Viral load of the ivermectin group decreased faster in comparison to the placebo group at the early stage of the intervention, during days two to six. As spontaneous recovery takes place also in the placebo group the viral load is decreasing, having similar viral load since day eight.

As mentioned above, our calculations were based on negative results reflected in Ct >30. The rate of negative RT-PCR for SARS-CoV-2 at day four (one day after termination of treatment) through day ten was higher in patients receiving ivermectin but was statistically significant on days six to eight (Table 2).

In the multivariable logistic regression model, the adjusted odds ratio of negative SARS-CoV-2 RT-PCR negative test (Ct>30) at day six and eight for the ivermectin group were 2·62 (95% CI: 1·06–6·45, P=0·04) and 3·87 group (95% CI: 1·36–11·04, P=0·01) fold higher than for the placebo group, respectively. (Table 3)

FOI 26-3132 - Document 5

Kaplan-Meier analysis (Figure 3) adjusted to symptom onset showed the significant difference between the ivermectin and placebo arms during the course of treatment.

Clinical outcome

During the study period four patients were referred to hospitals, with three of them being in the placebo arm. The first placebo-treated patient was hospitalized for 11 days with prolonged respiratory symptoms and needed oxygen even after his discharge from hospital. The second was hospitalized for one day due to respiratory complaints. The third one was referred to hospital due to headache and dizziness and was diagnosed with sinusitis after evaluation (brain CT and MRI). In addition, one asymptomatic patient became symptomatic, which occurred in the placebo group. In the ivermectin arm, one patient was referred to hospital due to shortness of breath at the day of recruitment. He continued the ivermectin and a day later was sent back to the hotel in good condition.

Culture Positivity rate

A convenient sample of 16 samples on day of recruitment (day zero) was cultured. Ct levels ranged from 14-28 (mean 21·5±4·1), and among them 13/16 (81·2%) turned to be positive. Culture viability was tested further by available samples on days two, four and six after intervention (see details Table S2–supplement). Altogether 52 samples were cultured; viable culture in the placebo group were positive in 14 out of 29 cultures (48·2%) while among the ivermectin group, only 3/23 (13·0%) were found positive (P=0·008).

In a composite calculation, taking into account Ct values >30 together with non-viable culture, the negative results of the ivermectin group reached significance even at day four (one day after ending the treatment) with 86% negative patients compared to 59% in the placebo group (P=0·04) (see Table 2b).

Adverse events

Among the 116 intention to treat participants, 3 patients reported having diarrhea following the treatment, two (3·5%) in the ivermectin group and one (1·7%) in the placebo group. In all cases the diarrhea resolved in two days. Two patients in the placebo arm reported rash during the treatment course which subsided within one to two days.

FOI 26-3132 - Document 5

No other adverse effects were reported. All of the eligible 89 patients for analysis reported to be adherent to the treatment as guided.

Discussion

In this double-blind, randomized trial with mild COVID-19 patients, ivermectin significantly reduced time of viral shedding and affected viral viability when initiated at the first week after evidence of infection. Our primary endpoint was to show the benefit of ivermectin on day six (three days after ending treatment) which was achieved with 72% of samples being non-infectious (Ct>30) in comparison to 50% among the placebo group (OR 2·6). Even at day 4 (1 day after treatment end) the ivermectin group showed an OR of 2·4, although this did not reach significance, possibly due to a small sample size on that day.

The anti-viral activity was also reflected in the Kaplan-Meier curve where the effect of the drug was seen after the second day of treatment (Figure 3).

To further explore the anti-viral activity, we observed the culture viability in both placebo and ivermectin groups. This post-hoc analysis became available in our institution at the end of the study only, when the BSL-3 lab was established (January 2021). The results show the advantage of ivermectin where only 13% of samples stayed positive on days 2two to six, while 48% stayed positive in the placebo group (P=0·008).

The broad-spectrum antiviral activity of ivermectin is related to its ability to target the host importin (IMP) α/β1 nuclear transport proteins responsible for nuclear entry of cargoes of viral proteins, which in turns block the host anti-viral activity. In some viruses the viral protein (such as integrase and NS5) has been identified while in SARS-CoV-2 the protein was not identified.[18, 19] The anti-viral properties of ivermectin against SARS-CoV-2 was shown in an in-vitro model.[7] A major criticism regarding this in-vitro model was that the ivermectin concentration used was more than 35 times higher than the maximum plasma concentration after oral administration of the approved dose.[8] But higher doses may not be necessary as some models predict that the lungs achieve higher

FOI 26-3132 - Document 5

concentrations, up to 10-fold higher than in the serum.[20] In addition, ivermectin concentrations in blood may not reflect the activity of its other metabolites which might be the active agents.[21, 22]

In humans, several randomized control trials have been recently published. A double-blind randomized control trial conducted in Colombia by López-Medina et al., included 476 mild patients randomly assigned to receive either oral ivermectin 300 mcg/kg for five days vs. placebo.[23] The study was initially aimed to examine ivermectin as an agent which could prevent clinical deterioration when given during the early stage of COVID-19. However, the endpoint of this study was altered to be time to resolution of symptoms within 3 weeks, as the original endpoint of clinical deterioration could not be achieved due to the low number of hospitalizations in their cohort. As the authors mentioned in their limitations, reduction in the viral load or viral shedding better reflects the anti-viral activity of the drug rather than longevity of symptoms[23]. Peer reviewed randomized control trials from Bangladesh support our finding of faster viral clearance in the ivermectin group, and in a small RCT from Spain, treatment with ivermectin showed a tendency toward faster viral clearance.[24, 25]

One may wonder about the public health benefit of treating mild patients since shortening the period of relatively mild symptoms may not merit a mass drug administration of ivermectin to the large population of non-hospitalized patients. However, inducing faster viral clearance and therefore reducing the time until the patient reaches a state of being non-infectious have an extremely important public health impact. Taking the two composites; Ct values above 30 and negative cultures, leads to almost 90% non-infectious status at day four (one day after ending treatment) among ivermectin users [] . From the public health point of view, it may shorten isolation time, which can serve as a major relief of the economic and social burden.

Our study has several limitations. First, the sample size was relatively small, and was designed to look for differences in viral load, but not for clinical deterioration and prevention of hospitalization. The second limitation was that drug therapy was not physically observed by investigators. Finally, our study was conducted among mild-non-hospitalized patients and therefore the results cannot be applied to a more severe or immune-suppressed populations.

The strength of our study was its double-blind structure with more substantial outcomes such as Ct values and culture viability where the laboratory personnel did not have any information concerning the patients' assignment.

FOI 26-3132 - Document 5

In conclusion, our study strongly supports the notion that ivermectin has anti-SARS-CoV-2 activity. If used at the early stage of disease onset, it may shorten the isolation time and reduce transmission. Further studies are needed to test its ability to prevent clinical deterioration for high-risk groups and to examine its potential as a prophylactic drug. Vaccines are now starting to become available, but it will take years before they are distributed worldwide. As this drug may also reduce mortality, urgent intervention with further well-designed studies are needed.

ABSTRACT

The inflammatory response to pathogen-associated molecular patterns such as lipopolysaccharide (LPS) in sepsis is mediated *via* Toll-like receptors (TLRs). Since TLRs also trigger various immune functions, including phagocytosis, their modulation is a promising strategy in the treatment of sepsis. As antibiotics have immunomodulatory properties, this study examined the effect of commonly used classes of antibiotics on i) the expression of TLRs and cytokines and ii) the phagocytic activity under sepsis-like conditions *in vitro*. This was achieved by incubating THP-1 monocytes and peripheral blood mononuclear cells (PBMCs) obtained from patients after open-heart surgery with the addition of LPS and six key antibiotics (piperacillin, doxycycline, erythromycin, moxifloxacin or gentamicin). After 24 h, mRNA levels of both cytokines (IL-1β, IL-6) and TLRs (1, 2, 4, and 6) were monitored and phagocytosis was determined following coincubation with *Escherichia coli*. Each antibiotic differentially regulated the gene expression of the investigated TLRs and cytokines in monocytes. Erythromycin, moxifloxacin and doxycyclin displayed the strongest effects and changed mRNA-levels of the investigated genes up to 5.6-fold. Consistent with this, antibiotics and, in particular, moxifloxacin, regulated the TLR-and cytokine expression in activated PBMCs obtained from patients after open-heart surgery. Furthermore, piperacillin, doxycyclin and moxifloxacin inhibited the phagocytic activity of monocytes. Our results suggest that antibiotics regulate the immune response by modulating TLR- and cytokine expression as well as phagocytosis under septic conditions. Moxifloxacin, doxycycline and erythromycin were shown to possess the strongest immunomodulatory effects and these antibiotic classes should be considered for future immunomodulatory studies in sepsis.

1. Introduction

Sepsis is one of the leading causes of death in critically ill patients and is associated with a hospital mortality of approximately 30% [1]. The clinical manifestation of sepsis is characterized by the cardinal signs of inflammation including tachycardia, leukocytosis, tachypnea, and pyrexia, which are collectively defined as systemic inflammatory response syndrome (SIRS). This systemic inflammatory response results from excessive stimulation of innate immune cells by exposure to different evolutionarily conserved molecular structures on infectious microorganisms, known as "pathogen-associated molecular patterns" (PAMPs)[2].

The recognition of PAMPs is mediated by pattern recognition receptors (PRR) including the Toll-like receptors (TLRs), the Nod-like receptors (NLRs), the C-type lectin receptors (CLRs) and the RIG-like receptors (RLRs) [3]. TLRs are the most widely studied PRRs and are considered to be the primary sensors of pathogens [4]. Lipopolysaccharide (LPS) released from gram-negative bacteria is recognized by TLR4 and comprise a major class of PAMP that causes sepsis through the induction of pro-inflammatory cytokines such as IL-1β and IL-6 [4,5]. Beside their role in the recognition of invading microbes, TLR-signaling further triggers the clearance of pathogens by phagocytosis, which plays a key role in the immune response during sepsis [6]. Due to the pivotal contribution of TLRs in sepsis, their modulation and signaling pathways became a research focus and it has been suggested that TLRs could be potential target molecules for the treatment of sepsis [7–9].

FOI 26-3132 - Document 5

Although significant resources have been invested during the last decade in new treatments for sepsis, almost all have failed to improve outcomes and intervention with antibiotics remains one of the most effective strategies. Antibiotics have widely appreciated bacteriostatic or bactericidal properties and are used in the therapy of numerous infections, including those associated with sepsis. Interestingly, some antibiotics also directly modulate the immune system in addition to exerting their antimicrobial properties. Thereby, antibiotics interact with host immune cells and regulate their immune function, which has beneficial effects in various inflammatory conditions [10,11]. Previous studies have shown that antibiotics improve survival in animals challenged with LPS or multidrug-resistant pathogens, suggesting an immunomodulatory and non-antimicrobial effect of antibiotics under septic conditions [12–15]. Furthermore, clinical data showed for the first time that the immunomodulatory properties of macrolide antibiotics improve the outcome of septic patients [16].

Yet, little is known about the molecular and cellular mechanisms by which antibiotics modulate the immune system during sepsis. Thus, the aim of this study was to examine the effect of antibiotics on the expression of TLRs and sepsis-related cytokines under inflammatory conditions that mimic sepsis. We focused on classes of antibiotics that are commonly used in the treatment of sepsis and investigated their effects on LPS-activated human immune cells, including leukocytes isolated from patients with a systemic inflammatory response after open-heart surgery. These research findings clearly indicate that the classes of chinolones (moxifloxacin), tetracyclines (doxycycline) and macrolides (erythromycin) regulate the expression of TLRs and cytokines in septic conditions. Thus, use of these antibiotics can be one useful clinical treatment for septic patients.

2. Material and methods

2.1. Reagents and THP-1 cells

LPS from *Escherichia coli* (serotype 055:B5) was purchased from Sigma-Aldrich (Taufkirchen, Germany) and antibiotics were obtained from the manufacturer: gentamicin (GMC), piperacillin (PIP) and doxycycline (DXC) from Ratiopharm (Ulm, Germany); erythromycin (ERY) from Amdipharm (Dublin, Ireland) and moxifloxacin (MXF) from Bayer (Leverkusen, Germany). Human monocytic THP-1 cells (ATCC TIB-202) [17] were grown in suspension in RPMI1640 (PAA, Coelbe, Germany) containing 10% FCS (Biochrom, Berlin, Germany), 0.05 mM 2-mercaptoethanol (Sigma-Aldrich, Taufkirchen, Germany), 100 mg/mL penicillin, 100 mg/mL streptomycin (both from Invitrogen, Frankfurt, Germany) and were maintained at 37 °C in a humidified incubator containing 5% CO_2. The cells were cultured in antibiotic- and FCS-free suspension for 48 h before experimental use to avoid any confounding stimulation that might result from antibiotics or endotoxins present in the cell culture medium. The viability of monocytes was determined by the tryptan blue staining method. Cells with viability greater than 90% were used for the experiments.

2.2. Patients and healthy volunteers

With the approval of the Ethics Committee of the Rheinische Friedrich-Wilhelms-University Medical School in Bonn (number of approval: 125/08), and following written informed consent, we recruited six healthy, non-smoking male volunteers and eight patients scheduled to undergo cardiopulmonary bypass (CPB) for routine elective coronary artery grafting. We excluded patients with acute or chronic infection, immunocompromised patients, patients with autoimmune disorders, or those taking immunosuppressive or anti-infective drugs in the preceding five days. All patients underwent a routine procedure with median sternotomy and use of CPB. Anesthesia was induced with etomidate, sufentanil and cisatracurium and was maintained using isoflurane and sufentanil. Thereafter, the patients received 1.5 g cefuroxime as perioperative antibiotic prophylaxis. The CPB technique included non-pulsatile flow with moderate hypothermia (32 °C–34 °C) and the CPB pump was primed with a standard electrolyte solution containing 10,000 IU heparin. Additional heparin was given if the activated clotting time failed to reach at least 480 s. Cardioplegia was induced by application of Calafiore warm blood-cardioplegic solution. Weaning from CPB was achieved after rewarming and inotropic support with epinephrine (0.025–0.15 μg/kg/min) in all patients and additional norepinephrine (0.025–0.15 μg/kg/min) as necessary. After CPB, heparin was neutralized with protamine sulfate until the preoperative activated clotting time was achieved. Postoperative fluid management consisted of isotonic-balanced electrolyte solution (30–40 ml/kg/day) for basic replacement and gelatin, fresh frozen plasma, or packed red cells according to hemodynamic status and laboratory parameters. Postoperative antibiotic prophylaxis was performed with 3 × 1.5 g cefuroxime every 8 h after admission on ICU.

2.3. Blood collection and preparation of peripheral blood mononuclear cells

Blood samples obtained from healthy volunteers were collected by peripheral vein puncture. Patient blood samples were taken through an indwelling central venous catheter before induction of anesthesia, 30 min and 24 h after end of surgery. In general, blood collection was performed before routinely planned administration of antibiotic prophylaxis. Monovette blood collecting system (Sarstedt, Nuembrecht, Germany), containing EDTA as anticoagulant, was used. Peripheral blood mononuclear cells (PBMCs) were immediately isolated from blood samples by sucrose gradient (PANcoll, PAN-biotech, Aidenbach, Germany) as described elsewhere [18]. After washing, PBMCs were cultured as described above.

2.4. In vitro stimulation experiments

THP-1 cells and PBMCs at a concentration of 1×10^6 cells/mL in 6-well plates (Cellstar, Greiner bio-one, Frickenhausen, Germany) were separately incubated in the presence of either LPS (10 μg/ml), GMC (5 μg/ml), ERY (2 μg/ml), MXF (20 μg/ml), DXC (8 μg/ml), PIP (100 μg/ml) or a combination of LPS with each antibiotic. The cells were incubated at 37 °C and were removed from culture plates after 24 h for isolation of RNA.

2.5. Isolation of RNA and Real-time PCR

Total RNA was isolated from the THP-1 cells and PBMCs using RNeasy mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. cDNA was generated from total RNA using the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Darmstadt, Germany) as recommended by the manufacturer. Cycling conditions were 25 °C for 10 min, 37 °C for 120 min, and 85 °C for 5 s. Real-time PCR was carried out on the 7900HT Fast Real-Time PCR system from Applied Biosystems using TaqMan Gene Expression Assays primer/probe sets (Applied Biosystems) and the standard thermal-cycling conditions for relative quantification designed by the manufacturer. Quantification of the PCR signals for each sample was performed by comparing the cycle threshold values in duplicate for the gene of interest with the cycle threshold values for the GAPDH housekeeping gene. The mean relative mRNA expression was determined by using the SDS software V2.2 and the $2^{-\Delta\Delta CT}$ method [19].

2.6. Phagocytosis assay

The phagocytic activity of THP-1 cells was examined by measuring the uptake of pHrodo *E. coli* BioParticles (Invitrogen) as described by Wan et al. [20]. To prepare BioParticles, 2 ml of PBS were used for reconstitution of the BioParticles. THP-1 cells (1×10^6 cells/ml) were incubated with antibiotics in the presence or absence of LPS as

FOI 26-3132 - Document 5

described above for 24 h, followed by an additional incubation with pHrodo *E. coli* BioParticles for 2 h. DNA staining for viability measurement was performed just prior to flow cytometry analysis with 2 μg/ml Hoechst 33342 (Invitrogen). Flow cytometry was conducted using a Canto III Flow Cytometer System (BD Biosciences, Heidelberg, Germany) and FlowJo Analysis Software (Treestar, Ashland, OR, USA). Phagocytic activity was expressed as the percentage of cells that performed phagocytosis compared to the total number of viable monocytes.

2.7. Statistical analysis

Statistical analysis was performed using GraphPad Prism 5 (GraphPad Software, La Jolla, CA, USA). Mann–Whitney *U* test was used to examine differences in phagocytic assay and in gene expression of both THP-1 cells and PBMCs from healthy volunteers. Data obtained from CPB surgery patients were analyzed by paired *t*-test. Values of $p < 0.05$ were considered significant. All data are expressed as mean ± SEM unless otherwise noted.

3. Results

3.1. Antibiotics differentially modulate the gene expression of TLRs and cytokines in monocytes

To determine a putative immunomodulatory effect of antibiotics in sepsis, we initially incubated human THP-1 monocytes with clinically relevant concentrations of commonly used classes of antibiotics, namely PIP (beta-lactam), DXC (tetracycline), ERY (macrolide), MXF (quinolone), and GMC (aminoglycoside) in the presence or absence of LPS. The expression of genes encoding IL-1β, IL-6, TLR1, TLR2, TLR4, and TLR6 was monitored by RT-PCR after 24 h. Tested antibiotics showed differential regulatory effects on gene expression of the investigated cytokines and TLR-subtypes (Fig. 1). The magnitude of this regulation differed between the various classes of antibiotics. Whereas ERY displayed strong immunomodulatory properties in terms of increasing the gene expression up to 5.6-fold (TLR4; Fig. 1E; $p < 0.05$) in LPS-stimulated cells, PIP only altered the mRNA levels up to 2.3-fold (TLR1; Fig. 1C; $p < 0.05$) compared to LPS-activated controls. In detail, PIP increased the expression of TLR1, TLR2, TLR4 and TLR6 by ≈2-fold when compared to unstimulated controls (Fig. 1C–F; $p < 0.05$). In co-stimulation with LPS, the number of genes regulated by the presence of PIP also included IL-1β and IL-6 (Fig. 1A,B; $p < 0.05$). In contrast, cells incubated with either DXC or GMC alone exhibited significantly reduced mRNA levels of IL-1β (DXC and GMC; Fig. 1A; $p < 0.05$), TLR1 (DXC, Fig. 1C; $p < 0.05$), TLR4 (GMC, Fig. 1E, $p < 0.05$) and TLR6 (DXC and GMC, Fig. 1F; $p < 0.05$). Furthermore, co-incubation of monocytes with LPS led to a significant down-regulation of IL-6 by both DXC and GMC compared to their LPS-stimulated controls (Fig. 1B; $p < 0.05$). The incubation of monocytes with either ERY or MXF resulted in differential regulation of several genes: THP-1 cells cultured in the presence of ERY alone showed significantly higher mRNA levels of IL-1β ($p < 0.05$), whereas ERY in combination with LPS reduced mRNA levels of IL-1β when compared to their respective controls (Fig. 1B; $p < 0.05$). THP-1 monocytes stimulated with ERY ± LPS exhibited significantly increased mRNA levels of TLR1, TLR2, TLR4 and TLR6 (Fig. 1C–F; $p < 0.05$). The activation status of monocytes also influenced the regulation of TLR4 gene expression by MXF. In LPS-activated cells, MXF significantly increased the TLR4 expression 2-fold, while MXF reduced the TLR4 mRNA level by more than 50% in the absence of endotoxin (Fig. 1E; $p < 0.05$). Furthermore, MXF significantly reduced IL-6 and TLR6 expression when cultured in the absence of LPS (Fig. 1B,F; $p < 0.05$) and reduced both IL-1β and IL-6 mRNA levels in LPS-activated cells (Fig. 1A,B; $p < 0.05$).

3.2. Antibiotics differentially modulate the gene expression of TLRs and cytokines in PBMCs

The immunomodulatory effects of antibiotics on a mixed immune cell population were studied in PBMCs obtained from healthy human donors and were stimulated under the same conditions as described above. Consistent with the results from THP-1 monocytes, PIP increased

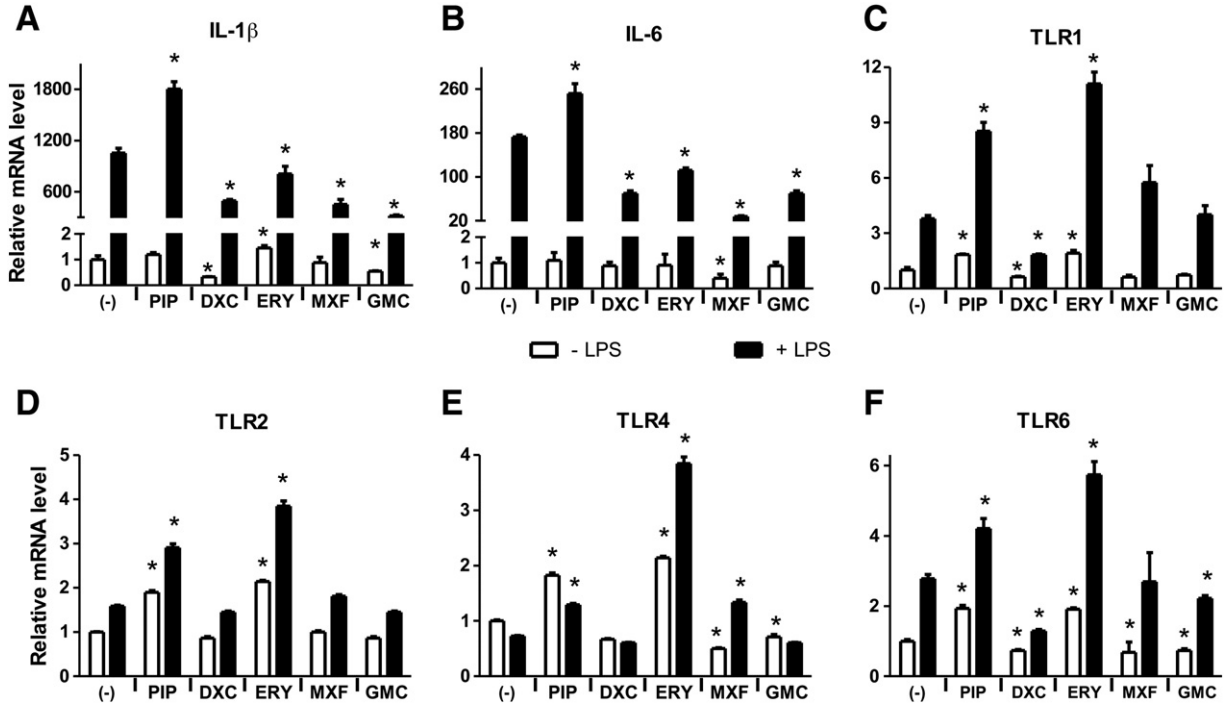

Fig. 1. Effect of antibiotics on cytokines and TLR expression in endotoxin-activated THP-1 monocytes. THP-1 monocytes were incubated with piperacillin (PIP), doxycycline (DXC), erythromycin (ERY), moxifloxacin (MXF) or gentamicin (GMC) in the presence or absence of LPS for 24 h. Quantitative Real-Time-PCR (qRT-PCR) analysis was performed to determine the expression levels of genes encoding IL-1β (A), IL-6 (B), TLR1 (C), TLR2 (D), TLR4 (E) and TLR6 (F) after normalization to GAPDH. Each bar represents the fold-change in mRNA expression comparing unstimulated control with antibiotic-incubated cells or LPS-stimulated control with LPS plus antibiotic-stimulated cells, respectively. Data are expressed as mean ± SEM; *, $p < 0.05$.

FOI 26-3132 - Document 5

the TLR2 expression, whereas DXC, MXF and GMC reduced the mRNA levels of TLR4 and/or TLR6 in PBMCs compared to their unstimulated controls (Fig. 2D–E; $p < 0.05$). Furthermore, down-regulation of TLR6 mRNA expression by both DXC and GMC was also found in LPS-activated PBMCs (Fig. 2F; $p < 0.05$). In contrast to the observed immunosuppressive effects of antibiotics on cytokine expression in the THP-1 cell line, PBMC cultured with DXC, MXF or GMC alone and GMC in combination with LPS exhibited significantly higher mRNA levels of IL-1β as compared to the respective controls (Fig. 2A, $p < 0.05$). Furthermore, PBMCs cultured with MXF alone revealed significantly increased mRNA level of IL-6 compared to unstimulated cells (Fig. 2B; $p < 0.05$).

3.3. Antibiotics differentially modulate the gene expression of TLRs and cytokines in PBMCs from patients with a systemic inflammatory response

We next studied the immunomodulatory effects of antibiotics on immune cells from patients with a systemic inflammatory response after open-heart surgery to mimic conditions found in sepsis. Therefore, PBMCs were isolated from 8 patients undergoing CPB-surgery before induction of anesthesia as well as 30 min and 24 h after surgery, followed by incubation with antibiotics and LPS as described above. The operation was uncomplicated in all of the patients and their demographic data as well as clinical profile are presented in Table 1. All patients were broadly immunostimulated, which was represented by a significant increase in the number of leukocytes after surgery (Table 2; $p < 0.05$). Yet, further parameters to diagnose a SIRS after surgery could not be evaluated as these were manipulated by routinely performed treatments such as cardiac pacing and mechanical ventilation. Blood from two patients could not be collected at 24 h after surgery due to their unstable condition. The PBMCs responded to the surgery by down-regulating mRNA levels of TLR2 after 30 min and both IL-1β and IL-6 after 24 h compared to preoperative collected cells (Figs. 3 and 4B; $p < 0.05$). In LPS-activated PBMCs, this effect was extended by up-regulation of IL-1β, IL-6, TLR1, TLR4 and TLR6 in cells obtained after 30 min and down-regulation of TLR2 in cells isolated 24 h after surgery compared to preoperative controls (Figs. 3 and 4; $p < 0.05$). Those effects were partially modulated by antibiotics, suggesting an immunomodulatory effect of antibiotics on either one or both studied time points (Figs. 3 and 4).

Therefore, we analyzed the effect of antibiotics on gene expression within each time point and found that in pre-operatively isolated PBMCs DXC increased the expression both IL-1β and IL-6, while PIP, DXC and MXF significantly increased the mRNA levels of TLR2 and reduced the TLR1 gene expression compared to unstimulated cells (Figs. 3 and 4A,B; $p < 0.05$). Furthermore, PIP significantly increased the

Table 1
Demographic data and perioperative characteristics of patients undergoing CPB surgery.

Patient characteristics (n = 8)	
Age (Years)	72.5 ± 8.3
Weight (kg)	83.0 ± 12.8
Height (cm)	171.9 ± 8.5
Pre-operative ejection fraction (%)	61.0 ± 13.2
Perioperative Data	
Duration of surgery (min)	258.6 ± 75.2
CPB time (min)	66.3 ± 12.4
ACC (min)	16.3 ± 23.5
Intubation time (h)	27.5 ± 9.5
Postoperative blood loss (ml)	1247.5 ± 466.4
Length of stay on ICU (h)	47.1 ± 26.7
Intraoperative red blood cell transfusion (n)	5/8
Postoperative red blood cell transfusion (n)	7/8

Values are presented as mean ± SD except for the number of transfused red blood cells. CPB indicates cardiopulmonary bypass; ACC, aortic cross-clamping; ICU, intensive care unit.

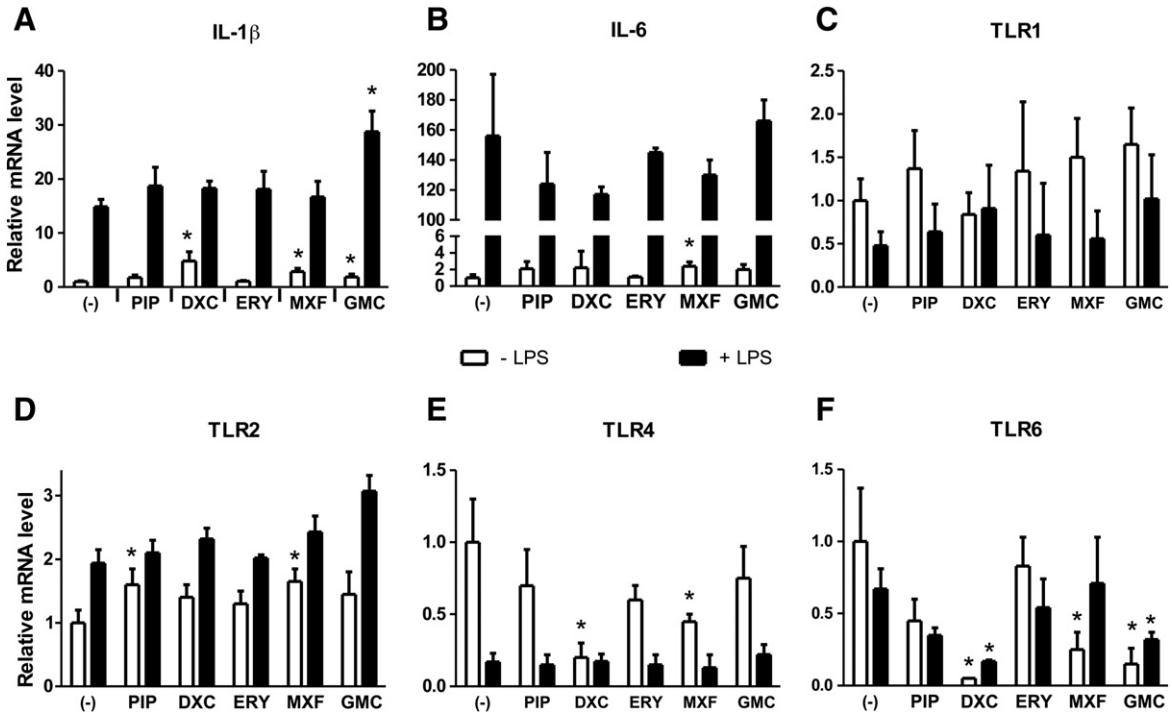

Fig. 2. Effect of antibiotics on cytokine and TLR-expression in endotoxin-activated PBMCs from healthy human donors *ex vivo*. Freshly isolated PBMC from healthy human donors were cultured with piperacillin (PIP), doxycycline (DXC), erythromycin (ERY), moxifloxacin (MXF) or gentamicin (GMC) in the presence or absence of LPS for 24 h and mRNA expression of IL-1β (A), IL-6 (B), TLR1 (C), TLR2 (D), TLR4 (E) and TLR6 (F) was measured by quantitative Real-Time PCR. Data represent the fold-change in mRNA expression comparing unstimulated control to antibiotic-incubated cells or LPS-stimulated control to LPS plus antibiotic-stimulated cells, respectively. Data are expressed as mean ± SEM of 6 individual donors in each group; *, $p < 0.05$.

expression of the gene encoding TLR6 compared to unstimulated pre-operatively collected PBMCs (Fig. 4D; $p < 0.05$). In LPS-activated PBMCs, only ERY reduced the mRNA-level of TLR1 whereas GMC increased IL-1β expression (Figs. 3A and 4A; $p < 0.05$). When PBMCs were stimulated *in vivo* by surgery and collected 30 min after surgery, PIP in co-stimulation with LPS significantly reduced their mRNA expression of TLR1 and TLR4 while TLR2 expression was increased compared to LPS-activated controls (Fig. 4; $p < 0.05$). The down-regulation of IL-1β and TLR2 by ERY also required the presence of LPS, whereas MXF increased both IL-1β and TLR2 expression and decreased TLR4 and TLR6 expression in the absence of LPS. The presence of LPS was also important for the regulatory activity of DXC: DXC alone significantly reduced TLR1 while DXC in combination with LPS increased TLR1 expression significantly compared to their respective controls (Fig. 4A; $p < 0.05$). When PBMCs were obtained from patients 24 h after CPB surgery, only MXF significantly reduced the mRNA level of TLR4 while no effect by other antibiotics was observed (Fig. 4C; $p < 0.05$).

3.4. Effect of antibiotics on bacterial phagocytosis

After monitoring an effect of antibiotics on the expression of TLRs, which play a critical role in regulating the phagocytosis of bacteria [6], we examined whether antibiotics may affect the phagocytosis of immune cells. Therefore, THP-1 monocytes were stimulated with antibiotics and LPS as described above, followed by incubation with heat-killed *E. coli*. As determined by flow cytometry, the inclusion of PIP, DXC, or MXF in combination with LPS during culturing decreased the percentage of phagocytizing cells (Fig. 5; $p < 0.05$ and $p < 0.01$, respectively). This effect was LPS-dependent as incubation with antibiotics alone had no effect on the phagocytic activity (data not shown).

4. Discussion

The excessive inflammatory response to microbial pathogens in sepsis is mediated *via* TLRs and their modulation might improve the outcome of septic patients by limiting the pathological inflammation [21]. Increasing evidence suggests that the immunomodulatory properties of antibiotics may have beneficial effects in sepsis [12–15]. Yet, the underlying molecular and cellular mechanisms including the effect of antibiotics on TLR expression remains unclear. The current study showed immunomodulatory properties of various classes of antibiotics on the expression of TLRs and sepsis-associated cytokines. Those effects were particularly found in immune cells that were activated by the sepsis mediator LPS and during a systemic inflammatory response after surgical trauma.

Innate immune cells, such as monocytes, play a central role in the pathogenesis of sepsis and are rapidly stimulated by various PAMPs, in particular LPS, originating from invading pathogens [2]. LPS triggers a

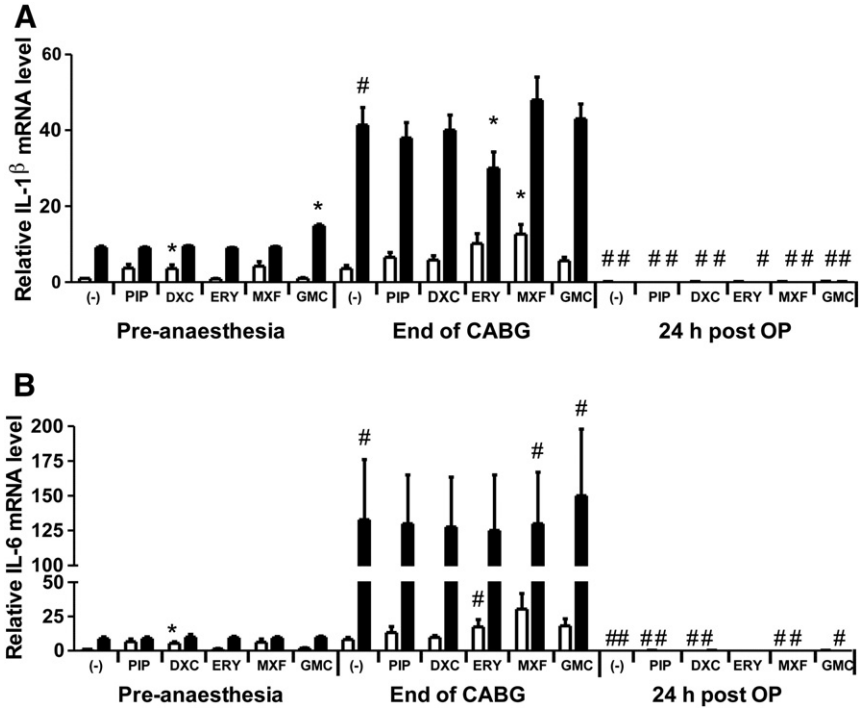

Fig. 3. Effect of antibiotics on cytokine expression in endotoxin-activated PBMCs before, 30 min and 24 h after CPB surgery. PBMCs from 8 patients undergoing CPB surgery were obtained before anesthesia, 30 min (End of CPB) and 24 h after operation (post op). Cells were cultured with piperacillin (PIP), doxycycline (DXC), erythromycin (ERY), moxifloxacin (MXF) or gentamicin (GMC) in the presence (solid bar) or absence (open bar) of LPS for 24 h and mRNA expression of IL-1β (A) and IL-6 (B) was measured by quantitative Real-Time PCR. Data are expressed as mean ± SEM and normalized unstimulated cells, which were collected at pre-operative time point. # indicates $p < 0.05$ compared to pre-anesthesia; in intergroup comparisons at the various time points * indicated $p < 0.05$.

pro-inflammatory response, which is characterized by a production of inflammatory cytokines such as IL-1β and IL-6, *via* TLR4 [4]. Furthermore, LPS-activation changes the expression of TLRs in immune cells and leads to a differential response to subsequent PAMP exposure, which can result in an excessive pro-inflammatory response or immunocompromised status of a septic patient [22]. Consistent with previous reports, we found that tetracyclines (DXC), macrolides (ERY) and fluoroquinolones (MXF) had anti-inflammatory properties, which manifest by inhibiting the expression of inflammatory cytokines in response to LPS [13,23–25]. At the same time, beta-lactams (PIP) showed pro-inflammatory effects by increasing mRNA levels of IL-1β and IL-6 [26]. Furthermore, the aminoglycoside GMC also reduced the mRNA levels of IL-1β and IL-6 in monocytes which is in agreement with the effects of GMC on renal tubule cells [27]. We demonstrated regulatory properties for all tested classes of antibiotics on TLR expression to a various extent. These effects ranged from modest effects found in GMC-

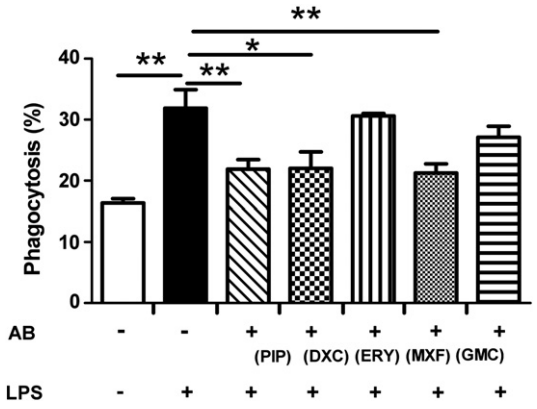

Fig. 5. Effect of antibiotics on phagocytosis of heat-inactivated *E. coli* by THP-1 cells. THP-1 cells were incubated with piperacillin (PIP), doxycycline (DXC), erythromycin (ERY), moxifloxacin (MXF) or gentamicin (GMC) in the presence of LPS for 24 h and were incubated thereafter for 2 h with heat-killed rhodamine-conjugated *E. coli*. DNA staining for viability measurement was performed just prior to flow cytometry analysis with Hoechst 33342. Data show percentage of monocytes positive for phagocytosis determined by flow cytometry and are expressed as mean ± SEM; *, $p < 0.05$; **, $p < 0.01$.

incubated cells to a very significant modulation of all investigated TLR-subtypes by ERY. Interestingly, the observed effects of antibiotics on monocytes did not correspond to the results observed in PBMCs. For example, MXF increased the expression of IL-1β and IL-6 in PBMCs whereas the same genes were down-regulated by MXF in monocytes. This observation that antibiotics have different immunomodulatory effects on monocytes and heterogeneous leukocyte populations such as PBMCs, which consist of lymphocytes (T cells, B cells, and NK cells), monocytes, and dendritic cells, has been previously described. Bailly et al. demonstrated that the quinolone ciprofloxacin suppressed the pro-inflammatory cytokine response to endotoxin in monocytes while the treatment of a mixed cell population with ciprofloxacin increased their expression [28,29]. These results suggest that cellular interactions could modify monocytic TLR- and cytokine expression to a modulation by antibiotics.

Although the current data do not provide evidence for the immunomodulation by antibiotics at protein levels, several studies showed that the regulation of the investigated mRNA for TLRs and cytokines is correlated with the change in protein expression [30–32]. Thus, those findings suggest that antibiotics modulate the responsiveness of immune cells to LPS, which might help to understand why antibiotics such as the macrolide clarithromycin have beneficial immunomodulatory effects during sepsis [16].

The molecular mechanisms that underlie the immunomodulatory effects of antibiotics are so far poorly understood. To the authors' knowledge, no previous study has revealed the mechanisms causing the observed effects of PIP and GMC on the immune response. Yet, DXC has been identified to inhibit LPS-induced NO production by immune cells *in vitro* [23]. DXC may also be responsible for the reduction of IL-1β and IL-6 expression. In addition, tetracyclines such as DXC possess strong chelating abilities, which have been associated with immunomodulatory effects by inhibiting protein kinase C (PKC) [33,34]. Since it has been shown that PKC inhibitors reduce LPS-stimulated cytokine secretion [35], the chelating abilities of DXC might also reduce the IL-1β and IL-6 expression through PKC inhibition. The macrolid ERY was found to block the activation of transcription factors NF-κB and IRF3 [24,36], thereby reducing the production of both pro- and anti-inflammatory cytokines. The inhibition of signaling pathways by ERY depends on which PAMP the immune cell is activated by. While IRF3 is inhibited by ERY after LPS stimulation, no effect of ERY on NF-κB, which is critical for the expression of IL1-β and IL-6, has been detected [24]. Thus, the observed effect in the current study might be due to an unknown molecular mechanism. In contrast to ERY, MXF also inhibits the activation of NF-κB by inhibition of I-κB degradation after LPS stimulation [37]. Furthermore, MXF also blocks the activation of mitogen-activated protein kinases, which leads to a suppression of pro-inflammatory cytokines. These inhibitory effects of MXF on the TLR4/LPS-signaling pathway could explain its anti-inflammatory properties including the reduction of the pro-inflammatory cytokines IL-1β and IL-6.

For the first time, we found that the phagocytic activity of LPS-stimulated THP-1 cells toward *E. coli* was inhibited by PIP, DXC and MXF regardless of their effects on TLR expression. The inhibiting properties of MXF on the phagocytic activity have been previously described for the internalization of the gram-positive bacterium *Staphylococcus aureus* [38]. In contrast, another report showed that PIP enhances the phagocytic activity of *E. coli* by murine macrophages [39]. However, the comparison of studies on the phagocytic activity, which focus on murine cells is limited as murine and human immune cells differentially express phagocytic receptors after LPS stimulation [40]. A TLR-independent modulation of these receptors, such as scavenger receptors (SR) or CLRs, might explain inhibitory effects of PIP, DXC and MXF. This constellation was previously described for the effect of the immunomodulatory agent resveratrol on the phagocytosis of bacteria by monocytes [41]. There, resveratrol inhibited phagocytic activity of THP-1 cells by reducing SR and CTRs expression regardless of TLR-signaling. Furthermore, it has been demonstrated that different patterns of cytokines can also modulate the activity of human phagocytes [42]. Since the effect of antibiotics on cytokine production is presumably not limited to IL-1β and IL-6, the generation of a distinct pattern of cytokines by PIP, DXC and MXF could be another reason for the observed effects of antibiotics on phagocytosis.

The examination of direct immunomodulatory effects of antibiotics on immune cells from septic patients is limited due to preexisting combined antibiotic treatment. Given that sepsis is considered a systemic inflammatory response to a suspected or confirmed infection, we examined the effect of antibiotics on immune cells from patients after open-heart surgery. This population exhibits a frequent and robust inflammatory response, which is caused by surgical trauma, CPB, reperfusion injury and endotoxemia [43,44].

As previously reported, the peak of the pro-inflammatory cytokine expression occurred immediately after surgery [45,46]. Furthermore, we observed increased cytokine production after LPS stimulation in immune cells isolated at the end of the operation, whereas no cytokine response to LPS was detectable in cells collected 24 h post-operation. This indicates an early increase in endotoxin sensitivity and late endotoxin tolerance of the collected immune cells. Consistent with this, PBMCs obtained directly after surgery showed an up-regulation of TLR4 expression that is also observed in septic patients [30]. The immunomodulatory effect of antibiotics on PBMCs collected from patients before surgery was in accordance with the effects observed in PBMCs from healthy donors. We further found that all antibiotics (with the exception of GMC) showed to a various extent effects on the expression of cytokines and/or TLRs in immune cells that were *in vivo* activated though CPB surgery. Here, MXF showed the most immunomodulatory effects. Furthermore, the up-regulation of TLR2 expression and the reduction of TLR4 mRNA levels by MXF were also observed in all investigated cell populations including THP-1 monocytes.

The modulation of the immune system *via* TLRs is a promising strategy in the treatment of sepsis [7–9]. Current findings suggest that several classes of antibiotics, which are commonly used in the treatment of sepsis, regulate the immune system in sepsis-like conditions through modulation of the expression of TLRs and pro-inflammatory cytokines as well as the phagocytotic activity. We found that these effects varied in the antibiotics belonging to different classes and thus identified quinolones, tetracycline and macrolides as classes with the highest potential to modulate the TLR expression in septic conditions. Thus, these antibiotics should be considered for future immunomodulatory studies in sepsis.

Keywords: COVID-19, doxycycline, coronavirus (CoV), SARS – CoV, anosmia

INTRODUCTION

Coronavirus Disease 19 (COVID-19) caused by Severe Acute Respiratory Syndrome-Coronavirus-2 (SARS-CoV-2) it usually manifests with respiratory symptoms (1).

Similarly, to other human respiratory Coronaviruses (HCoV), it seems to have a neuroinvasive and neurotropic activity (1, 2). In the retrospective case series study conducted by Mao et al. three categories of neurological symptoms COVID19-related included central nervous system (CNS) manifestations, peripheral nervous system (PNS) symptoms and musculoskeletal disorders (2).

Hyposmia has been reported as a possible peripheral nervous system (PNS) symptom caused by COVID-19 infection (2).

In our experience, the smell alteration (hyposmia, anosmia) seems to be one of the first manifestations of COVID-19 disease, with or without the loss of taste (dysgeusia). Sometimes it remains the only symptom; more often, it comes with fatigue, fever, and cough.

We provide a commentary on how COVID-19 could affect the sense of smell and the reason why doxycycline (Dox) could play a role in its recover.

ANOSMIA

The three leading causes of loss of smell reported in the literature are head trauma, chronic sinonasal inflammation and upper respiratory tract viral infections (3, 4). Anosmia is one between numerous olfactory disorders, but its mechanism is not clearly defined (3).

Post viral temporary chemosensory dysfunction after a common cold is widely reported (3, 5, 6).

The swelling of the mucosa in the olfactory cleft it seems to be cause of the transient olfactory and taste loss typically reported during the common cold. It usually leads to a conductive post-viral loss of smell, and it usually appears 3 months after the upper respiratory tract infection (3).

The olfactory neuroepithelium represents an important immunological barrier within the nasal cavity exposed to the external environment, and thus it is subject to both exogenous insults and endogenous host defense responses (7).

In the pathogenesis of chronic rhinosinusitis (CRS)-associated olfactory loss, interferon (IFN)γ-signaling pathways may play a pivotal role in orchestrating immune system function. They are able to modulate inflammatory response and pattern-recognition receptors expressed by the innate immune system during infection (7). Therefore, they support an inflammatory process underlying the olfactory impairment CRS-linked (8). As evidence of this (CRS)-associated olfactory dysfunction is relatively rapidly reversed with systemic corticosteroids (9).

On the other side, some post-viral sense of smell impairment may be partly independent of nasal congestion, thus explaining oxymetazoline failure in improving olfaction (10).

Therefore, it has been suggested that HCoV, thanks to their neuroinvasive, neurotropic, and neurovirulent properties may be able to induce neuronal impairment (11).

"Speed and Simplicity" of SARS-CoV-2

Entering into the respiratory tract, all HCoV invade and infect intra-luminal macrophages and epithelial cells. HCoV belong to Coronaviridae, enveloped non-segmented, single-stranded, positive-sense RNA viruses (+)ssRNA. Viral spike (S) proteins manage their cell entry program. They act by binding cell-surface receptors and facilitating the fusion of the virus-cell membrane (12). The spike protein is the key of coronaviruses tropism (12). These S proteins are organized in trimers that end up on the virion in a "corona" way giving it the characteristic crown-like look which seems to play a significative role in viral infection and pathogenesis (12). Similarly to SARS-coronavirus, SARS-CoV-2 seems able to enter in the respiratory epithelium (RE) by binding the human ACE2 receptor. Recombinant S protein has been shown to interact with recombinant ACE2 protein (13). S proteins are the major antigenic determinant managing host immune networks, inhibiting antibodies and the immunity response against the virus by inactivating IFN-α and IFN-ß (12, 14). It is well-established the pivotal role of IFN to protect most tissues from viral pathogenicity. The speed and simplicity of SARS-CoV-2 are typical. Host survival in the presence of the viral infection depends on the efficacy of its IFN system; as a matter of fact, virus survival is linked to its capacity to replicate and spread in the host, by carrying out mechanisms of evasion or subversion of the host IFN response (15).

New Insights Into the Doxycycline Activity

IFNα/β signaling plays a protective role in reducing the virus spread and modulating T cell non-cytolytic antiviral response in limiting viral load. Moreover, some RNA-viruses have developed mechanisms to counteract innate host defense to establish productive infections in their hosts. This is the case of an RNA virus, the vesicular stomatitis virus (VSV) (16).

Retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated gene-5 (Mda-5), seem to have an important role in the recognition of RNA viruses. In particular, it has been shown that immune signaling by RIG-I is involved in the generation of IFN-α/β following VSV infection. Under Dox treatment, cells released high levels of RIG-I proteins eliciting autonomous IFN response, thereby inhibiting viral infection *in vitro* (17).

In another RNA virus, the Respiratory Syncytial Virus (SRV), viral proteins inhibit IFN-α and IFN-β to establish infection (18), and it has been reported a higher expression of interferon-induced protein only after minocycline administration. This suggests an increasing innate immune response supported by tetracycline and the following RSV inhibition (19).

The second-generation tetracycline Dox has an anti-inflammatory and broad spectrum antimicrobial activity (20, 21).

In 1967, Dox was first approved by the FDA (20). It has minimal side effects and it is routinely prescribed for acne and rosacea. Dox is characterized by a ∼100% oral absorption and a prolonged serum half-life (18–22 h) (22).

In ophthalmology, Dox is usually administered in patients affected by ocular rosacea and posterior blepharitis (23). The Dox recommended dose is 40 mg modified release once daily, which could be replaced by minocycline 100 mg, based on patient tolerance or particular requirements (24).

The rationale in its administration is proteolysis inhibition promoted by matrix metalloproteinases (MMPs) (23, 25). MMPs are involved in the regulation of chemical and biological process likes vascular remodeling and angiogenesis (26), so Dox also has anti-angiogenic properties. (27) It regulates cytokines and diminishes neutrophil chemotaxis too (28).

Besides its well-known use in treating bacterial infections, some studies in the literature report that Dox possesses a broad activity against viral infection too (29–31).

The first who described the Dox antiviral effect was Sturtz in 1998 (29), and this suggestion has been confirmed in several followed-up studies. (16, 32, 33)

Topno et al. demonstrated that Dox could interfere with the virion's replication, affecting its structure and causing inhibition of Japanese encephalitis virus-induced pathogenesis *in vitro* (32). The same observation is also reported in a study regarding VSV infection (16) and against the chikungunya virus (CHIKV) (33), suggesting that Dox might interfere with viral replication by aiming proteins essential for these viruses for a successful infection. As proof of that, computational literature reports the Dox ability to bind CHIKV cysteine protease (33), and to exert a significant inhibitory effect on DNV NS2B-NS3 serine protease *in vitro* (30); both these proteases proved to be able to catalyze viral polyproteins cleavage during infection. Moreover, some studies with (+)ssRNA, Dengue virus (DNV), have demonstrated that Dox inhibits virus plaque assembly by interfering with the viral envelope conformational changes needed for virus entry (30). In both CHIKV and DNV, Dox seems to have the ability to bind virus envelop inhibiting viral entry into the cultured cells (30, 33).

Dox proved to be able to markedly decreased the virus-induced cytopathic effect (CPE) and significantly affect viral replication in a dose-dependent manner when used against Porcine Reproductive And Respiratory Syndrome virus (PRRSV) infection in cultured cells (31). Virus mRNA levels were strikingly reduced also in VSV-infected cells in response to Dox; both virus titers and the CPE of VSV infection were significantly influenced by Dox administration in a dose dependent manner (16).

DISCUSSION

Being the olfactory neural system able to regenerate throughout life, it can explain why the recovery of olfaction is common (34).

From our observation, anosmia affected mostly young adults rather than elderly patients, confirming existing findings in the literature (35, 36). It shows up more or less 6 days after fever, cough and muscle aches, but it can be the first and only symptom in many patients, with no mucosal swelling of the olfactory cleft, and that's why we hypothesize that it could be a possible PNS symptom as suggested (2). Among patients affected by PNS symptoms linked to COVID-19, the most common referred were hyposmia, hypogeusia, followed by neuralgia (2). Respiratory viruses such as rhinovirus and parainfluenza Epstein–Barr virus commonly could cause olfactory dysfunction (OD) by leading an inflammation in the olfactory mucosa resulting in rhinorrhea.

FOI 26-3132 - Document 5

Instead, COVID-19 seems to cause an atypical OD as it develops without rhinorrhea or nasal congestion (36).

In 2007, Suzuki et al. identified that coronavirus could be associated with anosmia, and he already speculated that nasal inflammation and related obstruction were not the only etiological factors underlying the OD in viral infection (37). As well-reported in the literature, HCoV could infect peripheral nerve terminals, using the trans-synaptic transfer to access the CNS (36, 38, 39)

In our preliminary observation, the administration of Dox 200 mg once daily seems to improve respiratory symptoms and anosmia under Dox treatment in six patients completely recover after only 2 days of treatment. From our experience, it seems reasonable to continue the treatment at least 8 days. The mean patients' age was 35.8 ± 6.8 years, and 4 (66.7%) were females. One patient reported anosmia as the only COVID-19 manifestation; instead of the other five patients who complained about the loss of smell, in which it appeared 5–7 days after mild fever, dry cough, and malaise. The average time of the recovery COVID-19-linked anosmia after the administration of Dox in these patients was 2.5 ± 0.5 days. We noticed a sudden improvement in all symptoms after the administration of Dox, but our most exciting insight is about the rapid recovery of the smell.

Unlike olfactory sensory neurons (OSNs), nasal epithelium, which includes the respiratory and olfactory epithelium (OE) expresses high levels of ACE2 (40). SARS-CoV-2 seems to target non-neural cell types in the peripheral olfactory system rather than directly enter OSNs, and it seems to be enough to generate cascading damage that could lead to the impairment of OSNs function altering the odor transduction which takes place on their cilia (40). The short-term COVID-19-linked anosmia reported in our experience supports the hypothesis that SARS-CoV2 affects the OE, which can quickly renew and recover following viral clearance (41). The average time to restore the sense of smell, most commonly reported in the literature, lasts from 1–8 days (36), if SARS-COV-2 could directly damage OSNs, recovery should take longer (42). Besides ACE2, Brann et al. also revealed that a cell-surface receptor, CD147, could play a role mediating SARS-CoV-2 cell entry (40). The expression of CD147 is detected in ciliated and goblet cells in the human nasal mucosa (43). Previous reports have shown that Dox has a significant inhibitory effect on CD147 expression (44, 45). Further studies are needed at present to define better if Dox has the ability to inhibiting viral entry by reduced CD147 expression levels. Moreover, thanks to its immunomodulatory and anti-inflammatory properties, Dox could limit the pro-inflammatory state induced by the glial cells activated by the neurotropic virus, ensuring proper epithelial reconstitution in the OE (46, 47). Given the possibility that COVID-19 occurs with the loss of smell and the evidence that corticosteroid may worsen the infection (48), Prof. Claire Hopkins, the British Rhinological Society president, recently suggested avoiding the use of these drugs in the therapeutic approach to the new-onset anosmia during the COVID-19 pandemic, especially if unrelated to previous head trauma or nasal pathology (48).

We are perfectly aware that there is a need for stronger evidence, but our article would intend to underline the importance of considering smell loss as a common symptom of COVID-19, supporting the rationale to treat such patients with Dox based on its interesting antiviral properties.

Background

The immediacy of "real-world" data in the pre-hospital treatment of Covid-19 using re-purposed drugs has been the keystone to the development of effective therapy in a pandemic situation. The sense of a "common-message database" for the therapeutic use of ivermectin (IVM) collated by clinicians over a time frame of little more than 12 months, involving patients and research workers across geographic and social lines, is extraordinary. From over 20 countries there are 63 controlled studies accepted for meta-analysis, that have included 47,500 subjects with 625 authors.

While this compelling database on the effectiveness of IVM would not be possible without "real-life" studies, at an individual level, these trials give additional value such as information on dosage and combination therapies. They also give confidence to local doctors and regulators as they seek optimal management strategies.

Here, we report successful pre-hospital treatment of Covid-19 patients in Sydney and Melbourne, Australia, using an ivermectin-doxycycline-zinc combination with an important set of observations on symptom resolution and oximetry.

The Study

Six hundred Australian residents with positive PCR symptomatic Covid-19 were treated with a combination of ivermectin (24 mg per day), doxycycline (100 mg bd), and zinc (50mg per day), for 10 days within 48 hrs of obtaining a positive PCR test for Covid-19. The treatment period was from June to September 2021. Seven percent (7%) were given additional vitamins and nutritional supplements. Only 7% identified adverse events from the therapy, mainly minor gut symptoms of nausea, diarrhoea and heartburn. No patient stopped therapy due to adverse drug events.

A subgroup in hotel and home quarantine was available for a more detailed assessment of symptoms and oxygenation status. This cohort of 126 was assessed for 10 symptoms according to a visual analogue scale (ranging from "0" for no symptoms, to "10" for most severe symptoms). Descriptive statistics are summarised in Table 1. P-Values were calculated using Wilcoxon matched-pairs signed-rank t-tests. Chi Squared analysis was used to analyse rates of hospitalization in the 600-patient cohort.

The Outcome

A total of 600 patients with positive PCR tests were treated with the ten-day course of "Ivermectin Triple Therapy" (ITT), which was fully completed in over 90% of those treated. None discontinued therapy as a result of drug side effects. Two visited the hospital for less than 24 hours following a transient arrhythmia and then went home, while five were admitted to hospital (0.83%). There were no deaths. In an equivalent control group of 600, not treated with triple therapy, 70 were admitted to hospital (11.5%), with 6 deaths (1%). Chi-squared analysis of hospitalisation rate shows a significant decrease ($P<0.001$) in the presence of

ivermectin triple therapy intervention. The control data was from contemporary infected subjects in Australia obtained from published Covid Tracking Data.
The subgroup of 126 in quarantine had more detailed documentation. They had an average age of 42 (range: 17-94). The results of symptom analysis are in Table 1. For the 10 symptoms analysed, 98% had a total symptom score severity reduction by the end of the treatment period (P< 0.0001). Symptoms that were most persistent were loss of taste and smell, cough, and fatigue. Oximetry readings in 71 subjects were consistent with mild disease in most (Table 1), though the range extended to the low 70's indicating severe disease in some individuals. At the completion of the 10 -day treatment programme, all subjects had normal oximetry readings.

Comment

This successful study of 600 consecutive subjects treated within 2 days of testing positive on PCR for Covid-19 infection, emphasises the value of early treatment. The results are consistent with the study by Hazan et al, further supporting the value of ITT therapy (ivermectin, doxycycline and zinc).[1] The current study differs from that of Hazan et al who successfully used lower doses of IVM and a shorter treatment duration. The current study also confirms the value of oximetry in monitoring response to therapy, with all hypoxic patients having normal oximetry levels following the treatment protocol. Few become hypoxic in the first 48 hours of symptoms. The rapid increase in oximetry values following IVM, noted by Hazan[1], confirms significant hypoxia was likely avoided in this treated group. Combining oximetry with visual analogue scales to monitor symptoms, is suggested as a valuable tool for future studies.

Visual analogue scale monitoring of symptoms of Covid-19 infection showed a fall from a median total symptom severity score of 37 (range: 0-100) at the onset of treatment to 3 (range: 0-62) at the conclusion of treatment (P<0.0001). The main persistent symptoms were loss of smell/taste, cough and fatigue, recognised to persist for longer periods, however, all displayed significant severity score reductions during the treatment period (P<0.0001). The impact of early treatment with ITT on subsequent "long Covid" will be an important question to pursue. Symptom resolution with untreated Covid-19 is generally 2-4 weeks, emphasising the value of visual analogue scale assessment.

The major differences in admission to hospital and death following ITT therapy compared to contemporary controls is consistent with the large and increasing body of data measuring the impact of ivermectin-combination therapy.[1–3] The results from this study invites comparison with recently announced data by Merck from a study of their re-cycled antiviral polymerase inhibitor, Molnupiravir. The Merck study with 385 treated patients involved a similar group to that treated in the current Australian study judged by near-identical hospital admission and mortality rates in both control groups. In the Merck study, the hospital admission rate was halved (7.3% of treated patients) with no deaths, similar to data for the "first cousin" of Molnupiravir, Favipiravir, which is used extensively in Russia. The important point is that the admission rate in the Merck study is 8-fold greater than the 90% reduction in hospital admissions recorded in the current ITT study (P<0.0001). The public health impact of these findings with a cheap, safe and available therapy, in terms of reduction of load on a health system that will be further stressed as country borders are re-opened, cannot be ignored.
The current study included "real-life" data on consecutive patients thus avoiding selection bias. Therapy was given in two states of Australia, involving over 30 front-line doctors. This compelling data reinforces the value of information from a range of sources and trial methodologies in assessing treatment options, especially in a pandemic situation. The number of patients in this report was capped at 600, as the Australian regulatory body (the TGA)

intervened in the middle of Australia's third Covid wave, to prohibit further prescription of ivermectin for Covid-19 by General Practitioners.

Table 1: Pre and Post Treatment Symptom Severity and Pulse Oximetry Data from Quarantined Individuals (N=126)

	Pre-Treatment			Post-Treatment			
Fever	114	4.2 (4.1)	3 (0-10)	114	0.1 (0.7)	0 (0-5)	<0.0001
Headache	116	5.8 (3.3)	6 (0-10)	116	0.5 (1.1)	0 (0-5)	<0.0001
Cough	120	5.2 (3.3)	5 (0-10)	120	1.1 (1.9)	0 (0-9)	<0.0001
Loss of Taste	111	4.1 (4.5)	2 (0-10)	111	1.8 (3.2)	0 (0-10)	<0.0001
Loss of Smell	112	4.4 (4.5)	2.5 (0-10)	112	2.0 (3.5)	0 (0-10)	<0.0001
Diarrhoea	115	2.3 (3.3)	0 (0-10)	115	0.2 (0.7)	0 (0-5)	<0.0001
Vomiting	114	1.0 (2.7)	0 (0-10)	114	0.03 (0.3)	0 (0-3)	<0.0001
Fatigue	118	6.6 (3.4)	8 (0-10)	118	1.4 (2.0)	0 (0-10)	<0.0001
Muscle Pains	118	5.4 (3.7)	5 (0-10)	118	0.6 (1.4)	0 (0-7)	<0.0001
Joint Pains	114	4.7 (3.9)	5 (0-10)	114	0.4 (1.2)	0 (0-7)	<0.0001
Total Symptom Severity	124	40.9 (26.1)	37 (0-100)	124	7.5 (10.3)	3 (0-62)	<0.0001
Oximetry Reading (%)	71	93.3 (5.0)	95 (71-99)	71	98.1 (1.1)	98 (95-100)	<0.0001

Symptoms were scored on a 0-10 scale with 0 being the absence of associated symptom and 10 being the most severe presentation as reported by the patient. Total Symptom Severity Score was a combined sum of all symptoms assessed and was scored out of 100. Oximetry Readings were scored out of 100%. N = the number of respondents and SD = Standard Deviation. *Non-parametric paired t-tests were performed.

Conclusion

In 'Real Life' this 10-day Ivermectin Triple Therapy reported here, appears to be a very safe, effective and inexpensive early antiviral treatment for Covid-19. Further detail from the more than 30 doctors involved in treating this patient group, will be used for a formal peer-reviewed publication.

P-glycoprotein ABCB1: a major player in drug handling by mammals

Piet Borst, Alfred H. Schinkel

J Clin Invest. 2013;123(10):4131-4133. https://doi.org/10.1172/JCI70430.

Hindsight

Mammalian P-glycoproteins are active drug efflux transporters located in the plasma membrane. In the early nineties, we generated knockouts of the three P-glycoprotein genes of mice, the *Mdr1a*, *Mdr1b*, and *Mdr2* P-glycoproteins, now known as *Abcb1a*, *Abcb1b*, and *Abcb4*, respectively. In the *JCI* papers that are the subject of this Hindsight, we showed that loss of *Mdr1a* (*Abcb1a*) had a profound effect on the tissue distribution and especially the brain accumulation of a range of drugs frequently used in humans, including dexamethasone, digoxin, cyclosporin A, ondansetron, domperidone, and loperamide. All drugs were shown to be excellent substrates of the murine ABCB1A P-glycoprotein and its human counterpart, the MDR1 P-glycoprotein, ABCB1. We found that the ability of ABCB1 to prevent accumulation of some drugs in the brain is a prerequisite for their clinical use, as absence of the transporter led to severe toxicity or undesired CNS pharmacodynamic effects. Subsequent work has fully confirmed the profound effect of the drug-transporting ABCB1 P-glycoprotein on the pharmacokinetics of drugs in humans. In fact, every new drug is now screened for transport by ABCB1, as this limits oral availability and penetration into sanctuaries protected by ABCB1, such as the brain.

P-glycoprotein ABCB1: a major player in drug handling by mammals

Piet Borst and Alfred H. Schinkel

Division of Molecular Oncology, The Netherlands Cancer Institute, Amsterdam, The Netherlands.

Mammalian P-glycoproteins are active drug efflux transporters located in the plasma membrane. In the early nineties, we generated knockouts of the three P-glycoprotein genes of mice, the *Mdr1a*, *Mdr1b*, and *Mdr2* P-glycoproteins, now known as *Abcb1a*, *Abcb1b*, and *Abcb4*, respectively. In the *JCI* papers that are the subject of this Hindsight, we showed that loss of *Mdr1a* (*Abcb1a*) had a profound effect on the tissue distribution and especially the brain accumulation of a range of drugs frequently used in humans, including dexamethasone, digoxin, cyclosporin A, ondansetron, domperidone, and loperamide. All drugs were shown to be excellent substrates of the murine ABCB1A P-glycoprotein and its human counterpart, the MDR1 P-glycoprotein, ABCB1. We found that the ability of ABCB1 to prevent accumulation of some drugs in the brain is a prerequisite for their clinical use, as absence of the transporter led to severe toxicity or undesired CNS pharmacodynamic effects. Subsequent work has fully confirmed the profound effect of the drug-transporting ABCB1 P-glycoprotein on the pharmacokinetics of drugs in humans. In fact, every new drug is now screened for transport by ABCB1, as this limits oral availability and penetration into sanctuaries protected by ABCB1, such as the brain.

Generating knockout mice

Generating knockout mice in the early 1990s was quite an adventure. The technology had just been developed, and the homologous recombination required to disrupt genes in mouse embryonic stem cells was still extremely inefficient. We were lucky, however, to work in The Netherlands Cancer Institute, where Hein te Riele and Anton Berns discovered in 1992 that gene targeting in embryonic stem cells could be made much more efficient by using isogenic DNA for transfection rather than DNA from a different mouse strain (1). Nevertheless, generating knockout mice remained a risky undertaking.

After protracted lab discussions, Alfred Schinkel, then a senior postdoc in the Borst lab, took the jump. With hindsight, this was the right decision. Although there were indications that drug-transporting P-glycoproteins could be important in drug pharmacokinetics, it was hard to get conclusive data, as the available inhibitors of P-glycoproteins were still toxic and not very specific. The knockout mice would fill that gap. We reduced the risk of getting scooped by generously explaining to our colleagues elsewhere that we had an edge and would get there first with the expert help of Anton Berns and his knockout crew. Apparently, the competition lost heart, and, in the end, we were the only lab to produce P-glycoprotein knockout mice.

A dead mouse with an unguarded blood-brain barrier

Before we were able to properly analyze the *Mdr1a* (*Abcb1a*) knockout mice, Schinkel received a message from our animal facility that his knockout mice were suddenly dying. When the animal caretakers were asked what they had done, their answer was predictably, "Nothing, we did nothing." It soon emerged, however, that the mice had been sprayed with the pesticide ivermectin to counteract a mite infestation. A toxicity analysis demonstrated that the homozygous *Mdr1a*$^{-/-}$ mice were 100-fold more sensitive to ivermectin than their *Mdr1a*$^{+/+}$ littermates (2). Ivermectin is a strong neurotoxin, but normally it is kept out of the brains of mammals by ABCB1. In the *Mdr1a*$^{-/-}$ mice, about 100-fold more ivermectin accumulated in the brain, leading to lethal neurotoxicity.

This and subsequent work (3–7) established that a drug-transporting P-glycoprotein is an integral part of the blood-brain barrier (BBB) and essential in keeping large, hydrophobic drugs out of the brain. This conclusion was not directly accepted by scientists working on the BBB. Soon after the ivermectin mishap, Piet Borst was invited to address the European BBB Society as a late-breaking speaker. Before the talk, an established BBB researcher explained why large, amphipathic drugs were unable to pass the BBB, using purely chemical arguments, hydrogen bonds, etc. Borst then came with his disappointing message: it is not the subtle chemistry, but a pump that drives the drug from the apical membrane of the cerebral endothelium back into the circulation. This message was not well received. One discussant shouted in desperation, "Did you verify that every single capillary in the brain contains P-glycoprotein?" Of course we had not, but Borst explained that mice without MDR1A P-glycoprotein were "stone dead" after ivermectin administration, indicating that P-glycoprotein should be an essential component of the entire BBB.

The ABCB1 P-glycoprotein also limits uptake of some drugs from the gut

The presence of ABCB1 in the apical membrane of the intestine made it likely that this protein would also impede the uptake of the substrate drugs. It took time before this was proven and even longer before it became accepted that P-glycoprotein is a major factor in the oral availability of some substrate drugs. In fact, when we showed that the MDR1A P-glycoprotein impedes the uptake of digoxin from the gut (5), it was hard to get this ground-breaking result published. Acceptance improved when we obtained the same result for the anticancer drug paclitaxel. In that case, uptake of the drug is nearly completely prevented by P-glycoprotein, making it necessary to administer the drug intravenously (6). The demonstration that P-glycoprotein limits the oral availability of some drugs as well as their penetration into the brain has led to

Conflict of interest: The research groups of the authors receive revenue from commercial distribution of some of the mouse strains mentioned in this paper.

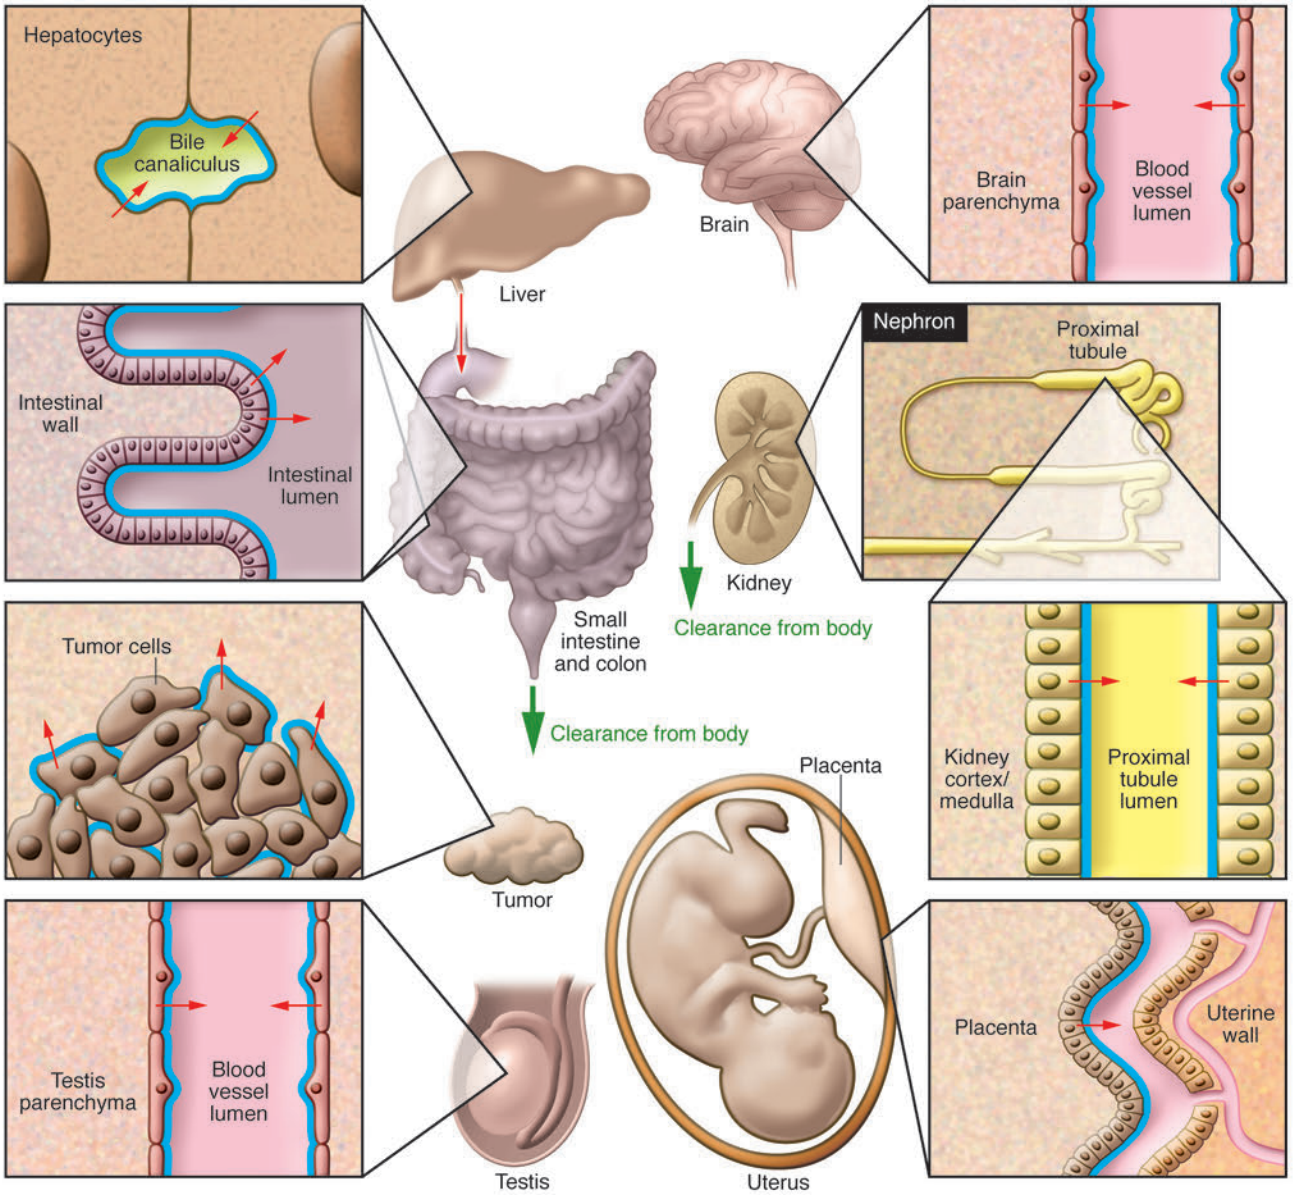

Figure 1
Overview of ABCB1 functional expression throughout the body. Blue lines indicate the location of ABCB1. Small arrows indicate the direction of ABCB1-mediated transport. Bold green arrows indicate net body excretion of ABCB1 substrates. ABCB1 in the BBB and blood-testis and placental fetal-maternal barrier protects brain, testis, and fetus, respectively, from accumulation of ABCB1 substrates. ABCB1 in small and large intestine reduces intestinal uptake (oral availability) and mediates direct intestinal excretion of substrates. ABCB1 in liver and kidney mediates hepatobiliary and renal excretion of substrates. ABCB1 expression in tumor cells can contribute to multidrug resistance.

numerous attempts to eliminate this barrier by using increasingly specific P-glycoprotein inhibitors. P-glycoprotein has also become a buzzword in the pharma industry, as everybody prefers orally available drugs.

Drug-transporting P-glycoprotein today

As the ABCB1 P-glycoprotein is a highly versatile, if not promiscuous, drug transporter, the number of drugs affected by P-glycoprotein has exploded. The number of tissues specifically protected by P-glycoprotein has also increased, as illustrated in Figure 1. Whereas the role of P-glycoprotein in pharmacokinetics is large and undisputed, its role in drug resistance of human tumors has turned out to be much smaller than initially anticipated. There is no doubt that modest amounts of P-glycoprotein can completely protect mouse tumors from substrate drugs, such as taxanes or anthracyclines, but human tumors seem to use this effective defense mechanism only rarely (8).

The knockout approach has been fruitful in pharmacology

After our initial success, we made knockouts of many other transporter protein genes and combined some of these in double knockouts and triple knockouts. Schinkel concentrated on P-glycoprotein and *Abcg2* and, more recently, on drug importers and P450

FOI 26-3132 - Document 5

drug-metabolizing enzymes. Borst knocked out MRPs (ABCCs) (9). Disrupting these genes has generated fundamental insight into the roles of these proteins in physiology and pharmacology. Obviously, eliminating the function of a gene in the germline can lead to secondary adjustments. Indeed, in 1994, we observed some upregulation of the second drug-transporting mouse P-glycoprotein gene, *Abcb1b* (*Mdr1b*), in the *Mdr1a* knockout (2). Thus far, however, these compensatory alterations have not affected the results of our knockout mice in a major way. We have never had reason to regret our entry into the transporter knockout field in 1990, and there is more to come.

Acknowledgments

We are grateful to the Dutch Cancer Society for their continued financial support of most of the work reviewed here. We also thank all our collaborators for their contributions and, especially, Els Wagenaar for her unrelenting dedication and success in generating the early knockout strains.

Ivermectin for Prevention and Treatment of COVID-19 Infection: A Systematic Review, Meta-analysis, and Trial Sequential Analysis to Inform Clinical Guidelines

Andrew Bryant, MSc,[1]* Theresa A. Lawrie, MBBCh, PhD,[2] Therese Dowswell, PhD,[2] Edmund J. Fordham, PhD,[2] Scott Mitchell, MBChB, MRCS,[3] Sarah R. Hill, PhD,[1] and Tony C. Tham, MD, FRCP[4]

Background: Repurposed medicines may have a role against the SARS-CoV-2 virus. The antiparasitic ivermectin, with antiviral and anti-inflammatory properties, has now been tested in numerous clinical trials.

Areas of uncertainty: We assessed the efficacy of ivermectin treatment in reducing mortality, in secondary outcomes, and in chemoprophylaxis, among people with, or at high risk of, COVID-19 infection.

Data sources: We searched bibliographic databases up to April 25, 2021. Two review authors sifted for studies, extracted data, and assessed risk of bias. Meta-analyses were conducted and certainty of the evidence was assessed using the GRADE approach and additionally in trial sequential analyses for mortality. Twenty-four randomized controlled trials involving 3406 participants met review inclusion.

Therapeutic Advances: Meta-analysis of 15 trials found that ivermectin reduced risk of death compared with no ivermectin (average risk ratio 0.38, 95% confidence interval 0.19–0.73; n = 2438; I^2 = 49%; moderate-certainty evidence). This result was confirmed in a trial sequential analysis using the same DerSimonian–Laird method that underpinned the unadjusted analysis. This was also robust against a trial sequential analysis using the Biggerstaff–Tweedie method. Low-certainty evidence found that ivermectin prophylaxis reduced COVID-19 infection by an average 86% (95% confidence interval 79%–91%). Secondary outcomes provided less certain evidence. Low-certainty evidence suggested that there may be no benefit with ivermectin for "need for mechanical ventilation,"

The authors have no conflicts of interest to declare.

T. A. Lawrie and A. Bryant cowrote the review; they also sifted the search and classified studies for inclusion and entered and checked the data in RevMan and performed analyses. Data extraction was divided among T. A. Lawrie, A. Bryant, and T. Dowswell. T. Dowswell and A. Bryant graded the evidence. E. J. Fordham prepared the text on ivermectin mechanisms, use in pregnancy, and among the elderly. S. R. Hill prepared the brief economic commentary. Clinicians S. Mitchell and T. C. Tham contributed to the interpretation of the evidence in the discussion and conclusions. All authors reviewed and approved the final version of the manuscript.

This article discusses off-label use of the FDA-approved medication ivermectin against COVID-19.

whereas effect estimates for "improvement" and "deterioration" clearly favored ivermectin use. Severe adverse events were rare among treatment trials and evidence of no difference was assessed as low certainty. Evidence on other secondary outcomes was very low certainty.

Conclusions: Moderate-certainty evidence finds that large reductions in COVID-19 deaths are possible using ivermectin. Using ivermectin early in the clinical course may reduce numbers progressing to severe disease. The apparent safety and low cost suggest that ivermectin is likely to have a significant impact on the SARS-CoV-2 pandemic globally.

Keywords: ivermectin, prophylaxis, treatment, COVID-19, SARS-CoV-2

INTRODUCTION

To date, very few treatments have been demonstrated to reduce the burden of morbidity and mortality from COVID-19. Although corticosteroids have been proven to reduce mortality in severe disease,[1] there has been little convincing evidence on interventions that may prevent disease, reduce hospitalizations, and reduce the numbers of people progressing to critical disease and death.

Ivermectin is a well-known medicine that is approved as an antiparasitic by the World Health Organization and the US Food and Drug Administration. It is widely used in low- and middle-income countries (LMICs) to treat worm infections.[2,3] Also used for the treatment of scabies and lice, it is one of the World Health Organization's Essential Medicines.[4] With total doses of ivermectin distributed apparently equaling one-third of the present world population,[5] ivermectin at the usual doses (0.2–0.4 mg/kg) is considered extremely safe for use in humans.[6,7] In addition to its antiparasitic activity, it has been noted to have antiviral and anti-inflammatory properties, leading to an increasing list of therapeutic indications.[8]

Since the start of the SARS-CoV-2 pandemic, both observational and randomized studies have evaluated ivermectin as a treatment for, and as prophylaxis against, COVID-19 infection. A review by the Front Line COVID-19 Critical Care Alliance summarized findings from 27 studies on the effects of ivermectin for the prevention and treatment of COVID-19 infection, concluding that ivermectin "demonstrates a strong signal of therapeutic efficacy" against COVID-19.[9] Another recent review found that ivermectin reduced deaths by 75%.[10] Despite these findings, the National Institutes of Health in the United States recently stated that "there are insufficient data to recommend either for or against the use of ivermectin for the treatment of COVID-19,"[11] and the World Health Organization recommends against its use outside of clinical trials.[12]

Ivermectin has exhibited antiviral activity against a wide range of RNA and some DNA viruses, for example, Zika, dengue, yellow fever, and others.[13] Caly et al[14] demonstrated specific action against SARS-CoV-2 in vitro with a suggested host-directed mechanism of action being the blocking of the nuclear import of viral proteins[14,15] that suppress normal immune responses. However, the necessary cell culture EC_{50} may not be achievable in vivo.[16] Other conjectured mechanisms include inhibition of SARS-CoV-2 3CLPro activity[17,18] (a protease essential for viral replication), a variety of anti-inflammatory effects,[19] and competitive *binding* of ivermectin with the viral S protein as shown in multiple *in silico* studies.[20] The latter would inhibit viral binding to ACE-2 receptors suppressing infection. Hemagglutination via viral binding to sialic acid receptors on erythrocytes is a recently proposed pathologic mechanism[21] that would be similarly disrupted. Both host-directed and virus-directed mechanisms have thus been proposed, the clinical mechanism may be multimodal, possibly dependent on disease stage, and a comprehensive review of mechanisms of action is warranted.

Developing new medications can take years; therefore, identifying existing drugs that can be repurposed against COVID-19 that already have an established safety profile through decades of use could play a critical role in suppressing or even ending the SARS-CoV-2 pandemic. Using repurposed medications may be especially important because it could take months, possibly years, for much of the world's population to get vaccinated, particularly among LMIC populations.

Currently, ivermectin is commercially available and affordable in many countries globally.[6] A 2018 application for ivermectin use for scabies gives a direct cost of $2.90 for 100 12-mg tablets.[22] A recent estimate from Bangladesh[23] reports a cost of US$0.60—US$1.80 for a 5-day course of ivermectin. For these reasons, the exploration of ivermectin's potential effectiveness against SARS-CoV-2 may be of particular importance

FOI 26-3132 - Document 5

for settings with limited resources.[24] If demonstrated to be effective as a treatment for COVID-19, the cost-effectiveness of ivermectin should be considered against existing treatments and prophylaxes.

The aim of this review was to assess the efficacy of ivermectin treatment among people with COVID-19 infection and as a prophylaxis among people at higher risk of COVID-19 infection. In addition, we aimed to prepare a brief economic commentary (BEC) of ivermectin as treatment and as prophylaxis for COVID-19.[25]

METHODS

The conduct of this review was guided by a protocol that was initially written using Cochrane's rapid review template and subsequently expanded to a full protocol for a comprehensive review.[26]

Search strategy and selection criteria

Two reviewers independently searched the electronic databases of Medline, Embase, CENTRAL, Cochrane COVID-19 Study Register, and Chinese databases for randomized controlled trials (RCTs) up to April 25, 2021 (see **Appendix 1–3**, **Supplemental digital content 1**, http://links.lww.com/AJT/A95); current guidance[25] for the BEC was followed for a supplementary search of economic evaluations. There were no language restrictions, and translations were planned to be performed when necessary.

We searched the reference list of included studies, and of two other 2021 literature reviews on ivermectin,[9] as well as the recent WHO report, which included analyses of ivermectin.[12] We contacted experts in the field (Drs. Andrew Hill, Pierre Kory, and Paul Marik) for information on new and emerging trial data. In addition, all trials registered on clinical trial registries were checked, and trialists of 39 ongoing trials or unclassified studies were contacted to request information on trial status and data where available. Many preprint publications and unpublished articles were identified from the preprint servers MedRχiv and *Research Square*, and the International Clinical Trials Registry Platform. This is a rapidly expanding evidence base, so the number of trials are increasing quickly. Reasons for exclusion were recorded for all studies excluded after full-text review.

Data analysis

We extracted information or data on study design (including methods, location, sites, funding, study author declaration of interests, and inclusion/exclusion criteria), setting, participant characteristics (disease severity, age, gender, comorbidities, smoking, and occupational risk), and intervention and comparator characteristics (dose and frequency of ivermectin/comparator). The primary outcome for the intervention component of the review included death from any cause and presence of COVID-19 infection (as defined by investigators) for ivermectin prophylaxis. Secondary outcomes included time to polymerase chain reaction (PCR) negativity, clinical recovery, length of hospital stay, admission to hospital (for outpatient treatment), admission to ICU or requiring mechanical ventilation, duration of mechanical ventilation, and severe or serious adverse events, as well as post hoc assessments of improvement and deterioration. All of these data were extracted as measured and reported by investigators. Numerical data for outcomes of interest were extracted according to intention to treat.

If there was a conflict between data reported across multiple sources for a single study (eg, between a published article and a trial registry record), we contacted the authors for clarification. Assessments were conducted by 2 reviewers (T.L., T.D., A.B., or G.G.) using the Cochrane RCT risk-of-bias tool.[27] Discrepancies were resolved by discussion.

Continuous outcomes were measured as the mean difference and 95% confidence intervalss (CI), and dichotomous outcomes as risk ratio (RR) and 95% CI.

We did not impute missing data for any of the outcomes. Authors were contacted for missing outcome data and for clarification on study methods, where possible, and for trial status for ongoing trials.

We assessed heterogeneity between studies by visual inspection of forest plots, by estimation of the I^2 statistic ($I^2 \geq 60\%$ was considered substantial heterogeneity),[28] by a formal statistical test to indicate statistically significant heterogeneity,[29] and, where possible, by subgroup analyses (see below). If there was evidence of substantial heterogeneity, the possible reasons for this were investigated and reported. We assessed reporting biases using funnel plots if more than 10 studies contributed to a meta-analysis.

We meta-analyzed data using the random effects model (DerSimonian and Laird method)[30] using RevMan 5.4.1 software.[27,31] The results used the inverse variance method for weighting.[27] Some sensitivity analyses used other methods that are outlined below and some calculations were performed in *R*[32] through an interface[33] to the *netmeta* package.[34] Where possible, we performed subgroup analyses grouping trials by disease severity, inpatients versus outpatients, and single dose versus multiple doses. We performed sensitivity analyses by excluding studies at high risk of bias. We conducted further post hoc sensitivity analyses using alternative methods to test the robustness of results in the presence of zero events in both arms in a number of trials[35] and estimated odds ratios [and additionally RR for the Mantel–Haenszel

FOI 26-3132 - Document 5

(MH) method] using a fixed effects model. The models incorporate evidence from single-zero studies without having to resort to continuity corrections. However, double-zero studies are excluded from the analysis; so, the risk difference was also assessed using the MH method as this approach can adequately incorporate trials with double-zero events. This method can also use a random-effects component. A "treatment-arm" continuity correction was used, where the values 0.01, 0.1, and 0.25 were added where trials reported zero events in both arms. It has been shown that a nonfixed continuity correction is preferable to the usual 0.5.[35] Other methods are available but were not considered due to difficulty in interpretation, sensitivity of assumptions, or the fact they are rarely used in practice.[36–40]

Trial sequential analysis

When a meta-analysis is subjected to repeated statistical evaluation, there is an exaggerated risk that "naive" point estimates and confidence intervals will yield spurious inferences. In a meta-analysis, it is important to minimize the risk of making a false-positive or false-negative conclusion. There is a trade-off between the risk of observing a false-positive result (type I error) and the risk of observing a false-negative result (type II error). Conventional meta-analysis methods (eg, in RevMan) also do not take into account the amount of available evidence. Therefore, we examined the reliability and conclusiveness of the available evidence using trial sequential analyses (TSA).[41–43] The DerSimonian–Laird (DL) method was used because this is most often used in meta-analytic practice and was also used in the primary meta-analysis.[30]

The TSA was used to calculate the required information size (IS) to demonstrate or reject a relative reduction in the risk (RRR) of death in the ivermectin group, as found in the primary meta-analysis. We assumed the estimated event proportion in the control group from the meta-analysis because this is the best and most representative available estimate. Recommended type I and II error rates of 5% and 10% were used, respectively (power of 90%),[43] powering the result on the effect observed in the primary meta-analyses. We did not identify any large COVID-19 trials powered on all-cause mortality, so powering on some external meaningful difference was not possible. Any small RRR is meaningful in this context, given the scale of the pandemic, but the required IS would be unfeasibly high for this analysis if powered on a small difference. The only reliable data on ivermectin in its repurposed role for treatment against COVID-19 will be from the primary meta-analysis. Therefore, assuming it does not widely deviate from other published systematic reviews, a pragmatic decision was therefore made to power on the pooled meta-analysis effect estimate for all-cause mortality a priori. This is more reflective of a true meaningful difference. We used a model variance-based estimate to correct for heterogeneity. A continuity correction of 0.01 was used in trials that reported zero events in one or both arms. The required IS is the sample size required for a reliable and conclusive meta-analysis and is at least as large as that needed in a single powered RCT. The heterogeneity corrected required IS was used to construct sequential monitoring boundaries based on the O'Brien–Fleming type alpha-spending function for the cumulative z-scores (corresponding to the cumulative meta-analysis),[43] analogous to interim monitoring in an RCT, to determine when sufficient evidence had been accrued. These monitoring boundaries are relatively insensitive to the number of repeated significance tests. They can be used to further contextualize the original meta-analysis and enhance our certainty around its conclusions. We used a two-sided test, so also considered futility boundaries (to test for no statistically significant difference) and the possibility that ivermectin could harm. Sensitivity analyses were performed excluding the trial of Fonseca,[44] which was a cause of substantial heterogeneity (but retained in the core analysis because it was at low risk of bias). Its removal dramatically reduced I^2 and D^2 (diversity) estimates, thus reducing the model variance-based estimate to correct for heterogeneity. Two further sensitivity analyses were performed using 2 alternative random effect models, namely the Biggerstaff–Tweedie (BT) and Sidik–Jonkman (SJ) methods.[43]

All outcomes have been assessed independently by 2 review authors (T.D. and A.B.) using the GRADE approach,[45] which ranks the quality and certainty of the evidence. The results of the TSAs will also form part of the judgment for the primary all-cause mortality outcome. The results are presented in a summary of findings table. Any differences in judgments were resolved by discussion with the wider group. We used Cochrane Effective Practice and Organisation of Care guidance to interpret the evidence.[46]

RESULTS

Search results and risk-of-bias assessment

The combined and preliminary deduplicated total was n = 583. We also identified 11 records from other sources (reference lists, etc). See PRISMA flow diagram for inclusion and exclusion details of these references (Figure 1).

FOI 26-3132 - Document 5

The supplementary search for the BEC identified 17 studies, of which 4 were retrieved in full. No full trial- or model-based economic evaluations (cost–utility analyses, cost–effectiveness analyses, or cost–benefit analyses) were identified.

Twenty-one trials in treatment and 2 trials in prophylaxis of COVID-19 met review inclusion. One further study[47] reported separate treatment and prophylaxis components; we label this study "Elgazzar" under both questions. In effect, there were 22 trials in treatment and 3 in prophylaxis. All of these contributed data to at least one review outcome and meta-analysis. Fifteen trials contributed data for the primary outcome for ivermectin treatment (death); 3 studies reported the primary outcome for prophylaxis (COVID-19 infection). Characteristics of included studies are given in Table 1. Seventeen studies[47–63] were excluded as they were not RCTs and we identified 39 ongoing studies[64–102] and 2 studies[103,104] are awaiting classification.

A risk-of-bias summary graph is given in Figure 2. Eleven studies[23,24,44,47,105,106–111] used satisfactory random sequence generation and allocation concealment. Two trials described satisfactory sequence generation, but it was unclear whether allocation was concealed.[112,113]

Ten trials reported adequate blinding of the participants/personnel and/or the outcome assessors.[23,24,44,105,107,109,110,111,113,114] The others were either unclear or high risk for blinding. We considered blinding to be a less important criterion for evaluation of evidence related to the review's primary outcomes, namely death and laboratory-confirmed COVID-19 infection, which are objective outcomes.

We did not consider publication on preprint web sites to constitute a risk of bias because all studies were scrutinized and peer reviewed by us during the review process and, where additional information was needed, we contacted the authors for clarification.

Main findings

Twenty-four RCTs (including 3 quasi-RCTs) involving 3406 participants were included, with sample sizes ranging from 24 to 476 participants. Twenty-two trials in treatment and 3 trials in prophylaxis met review inclusion, including the trial of Elgazzar et al, which reported both components. For trials of COVID-19 treatment, 16 evaluated ivermectin among participants with mild to moderate COVID-19 only; 6 trials included patients with severe COVID-19. Most compared ivermectin with placebo or no ivermectin; 3 trials included an active comparator (Table 1). Three RCTs involving 738 participants

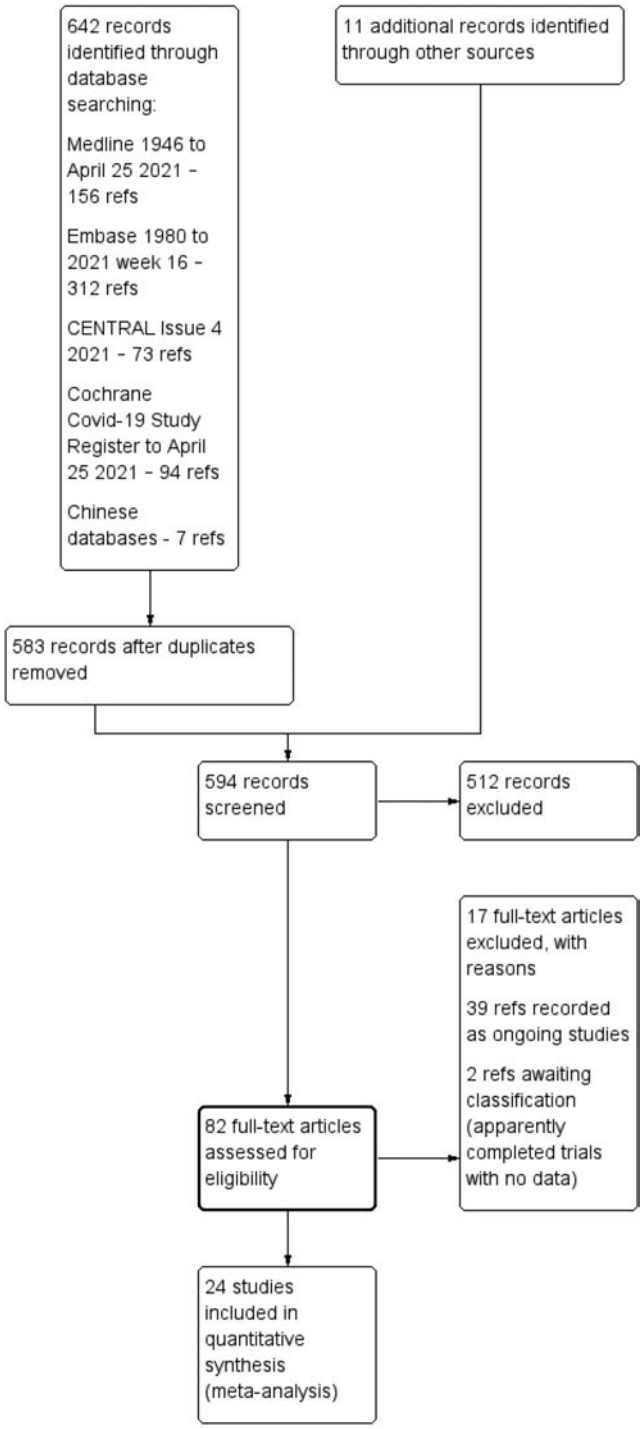

FIGURE 1. Study flow diagram from search on 25 April 2021.

were included in the prophylaxis trials. Most trials were registered, self-funded, and undertaken by clinicians working in the field. There were no obvious conflicts of interest noted, with the exception of two trials.[85,139]

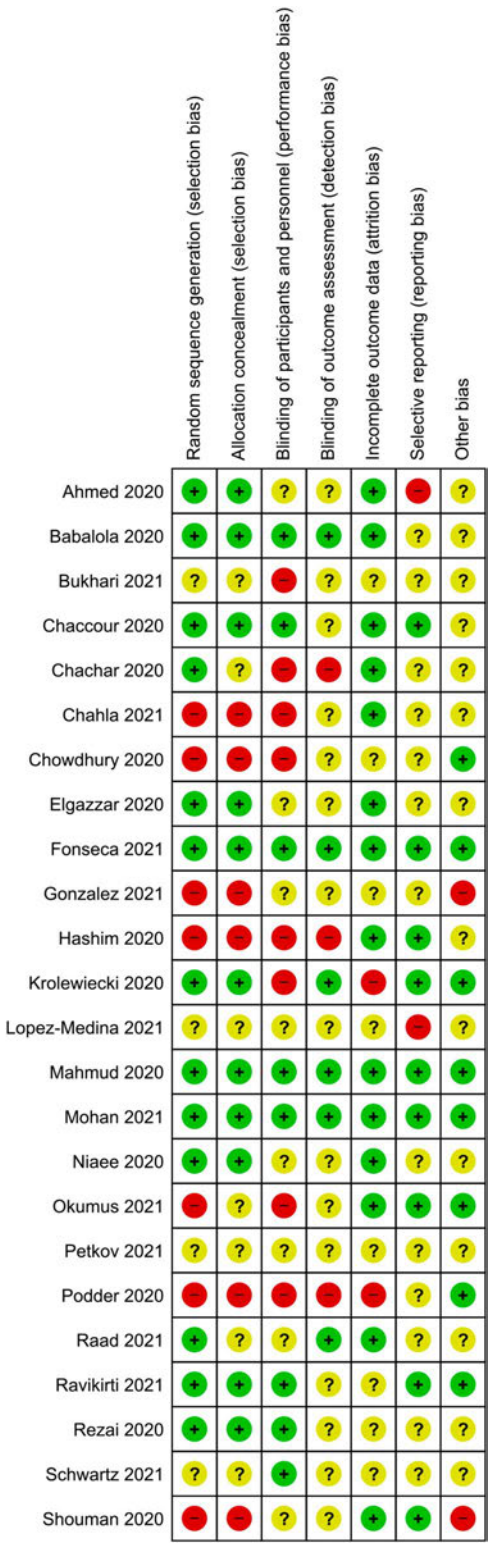

FIGURE 2. Risk-of-bias summary: review authors' judgments about each risk of bias item for each included study.

Ivermectin treatment versus no ivermectin treatment

Twenty-two trials (2668 participants) contributed data to the comparison ivermectin treatment versus no ivermectin treatment for COVID-19 treatment.

All-cause mortality

Meta-analysis of 15 trials, assessing 2438 participants, found that ivermectin reduced the risk of death by an average of 62% (95% CI 27%–81%) compared with no ivermectin treatment [average RR (aRR) 0.38, 95% CI 0.19 to 0.73; $I^2 = 49\%$]; risk of death 2.3% versus 7.8% among hospitalized patients in this analysis, respectively (SoF Table 2 and Figure 3). Much of the heterogeneity was explained by the exclusion of one trial[44] in a sensitivity analysis (average RR 0.31, 95% CI 0.17–0.58, n = 2196, $I^2 = 22\%$), but because this trial was at low risk of bias, it was retained in the main analysis. The source of heterogeneity may be due to the use of active comparators in the trial design. The results were also robust to sensitivity analyses excluding 2 other studies with an active treatment comparator (average RR 0.41, 95% CI 0.23–0.74, n = 1809, $I^2 = 8\%$). The results were also not sensitive to the exclusion of studies that were potentially at higher risk of bias (average RR 0.29, 95% CI 0.10–0.80, 12 studies, n = 2095, $I^2 = 61\%$), but in subgroup analysis, it was unclear as to whether a single dose would be sufficient. The effect on reducing deaths was consistent across mild to moderate and severe disease subgroups. Subgrouping data according to inpatient and outpatient trials was not informative because few outpatient studies reported this serious outcome. The conclusions of the primary outcome were also robust to a series of alternative post hoc analyses that explored the impact of numerous trials that reported no deaths in either arm. Extreme sensitivity analyses using a treatment arm continuity correction of between 0.01 and 0.5 did not change the certainty of the evidence judgments (Table 3).

Trial sequential analysis

TSA, using the DL random-effects method, showed that there may have been sufficient evidence accrued before the end of 2020 to show significant benefit of ivermectin over control for all-cause mortality. The cumulative z-curve in Figure 8 crossed the trial sequential monitoring boundaries after reaching the required IS, implying that there is firm evidence for a beneficial effect of ivermectin use over no ivermectin use in mainly hospitalized participants with mild to moderate COVID-19 infection.

Table 2. Summary of findings table of ivermectin versus no ivermectin for COVID-19 treatment in any setting.

Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)
	Assumed risk No ivermectin	Corresponding risk Ivermectin			
Death from any cause	78 per 1000 (all disease severity)	48 fewer deaths per 1000 (21–63)	RR = 0.38 (0.19–0.73)	2438 (15)	Moderate†
Recovery time to negative PCR test, in days	Absolute risks were not computed due to certainty of evidence being low and, in some cases, number of events being sparse		MD = −3.20 (−5.99 to −0.40)	375 (6)	Very low†,‡,§
Time to clinical recovery, in days (outpatients)			MD = −1.06 (−1.63 to −0.49)	176 (2)	Very low†,‡,§
Time to clinical recovery, in days (mild to moderate COVID-19 inpatients)			MD = −7.32 (−9.25 to −5.39)	96 (1)	Very low†,¶
Time to clinical recovery, in days (severe COVID-19 inpatients)			MD = −3.98 (−10.06 to 2.10)	33 (1)	Very low†,¶
Admission to ICU			RR=1.22 (0.75–2.00)	379 (2)	Very low¶,‖
Need for mechanical ventilation			RR=0.66 (0.14–3.00)	431 (3)	Low§,‖
Length of hospital stay, in days			MD= 0.13 (−2.04 to 2.30)	68 (1)	Very low†,¶
Admission to hospital			RR 0.16 (0.02–1.32)	194 (2)	Very low†,¶
Duration of mechanical ventilation	Not reported				
Improvement (mild to moderate COVID-19)*	635 improved per 1000	159 more per 1000 (from 51 more to 286 more)	RR 1.25 (1.08–1.45)	681 (5)	Low†,‡
Deterioration (any disease severity)	143 per 1000	93 fewer per 1000 (from 50 fewer to 116 fewer)	RR 0.35 (0.19–0.65)	1587 (7)	Low†,‡
Serious adverse events	7/867 (0.8%) had an SAE in ivermectin group and 2/666 (0.3%) in control		RR=1.65 (0.44–6.09)	1533 (11)	Low†,‡

*Only one study contributed to the "severe" COVID-19 subgroup and subgroup data were not pooled due to subgroup differences.
†Downgraded −1 for study design limitations.
‡Downgraded −1 for inconsistency.
§Downgraded −1 for imprecision.
¶Downgraded −2 for imprecision/sparse data.
‖Downgraded −1 for indirectness.

The TSA was used to calculate the IS required to demonstrate or reject a 62% RRR of death in the ivermectin group, as observed in the primary meta-analysis. This estimate is similar to effect estimates reported in other reviews.[10] We assumed a 7.8% event proportion in the control group, which was the average control group

FOI 26-3132 - Document 5

Table 3. Sensitivity analyses for death from any cause considering methods for dealing with zero events in trials.

Method	Measure	Model	Effect size (95% CI)	Details
Peto	OR	FE	0.35 (0.24 to 0.53)	Handles single-zero trials

0.5	RR	FE	0.54 (0.37 to 0.79)	0.55 (0.35–0.78)
0.5	RR	RE	0.45 (0.27 to 0.74)	0.47 (0.29–0.75)

FE, fixed effects; IV, inverse variance; M-H, Mantel-Haenszel; RD, risk difference; RE, random effects; TACC, treatment arm continuity correction.

event rate from the primary meta-analysis. We used a model variance-based estimate of 49.1% (diversity estimate) to correct for heterogeneity. The required IS was 1810 participants (Figure 8), which was exceeded by the total number of observed participants in the meta-analysis (n = 2438). In the TSA plots, the red dashed lines in Figure 8 represent the trial sequential monitoring boundaries using the O'Brien–Fleming alpha-spending function. The solid blue line is the cumulative z-curve and represents the observed trials in the cumulative meta-analysis. The adjusted significance boundaries for the cumulative z-curve were constructed under the assumption that significance testing may have been performed each time a new trial was added to the meta-analysis. In Figure 8, the z-curve crosses the boundary after reaching the required IS, thereby supporting the previous conclusion in RevMan 5.4.1[31] using the DL method that ivermectin is superior to control in reducing the risk of death.

Sensitivity analyses

Sensitivity analysis excluding the trial of Fonseca[44] significantly reduced heterogeneity in the meta-analysis and thus the diversity estimate in the TSA using the DL model. This strengthened the suggestion in the primary core analysis that the required IS had been reached (Figure 9). Because the DL estimator could potentially underestimate the between-trials variance,[43] we performed further sensitivity analyses using 2 alternative random-effects model approaches. The results of the primary TSA analysis were robust to sensitivity analysis using the BT method with the same parameters, excluding the Fonseca[44] trial, which was a cause of substantial heterogeneity (Figure 10). The TSA

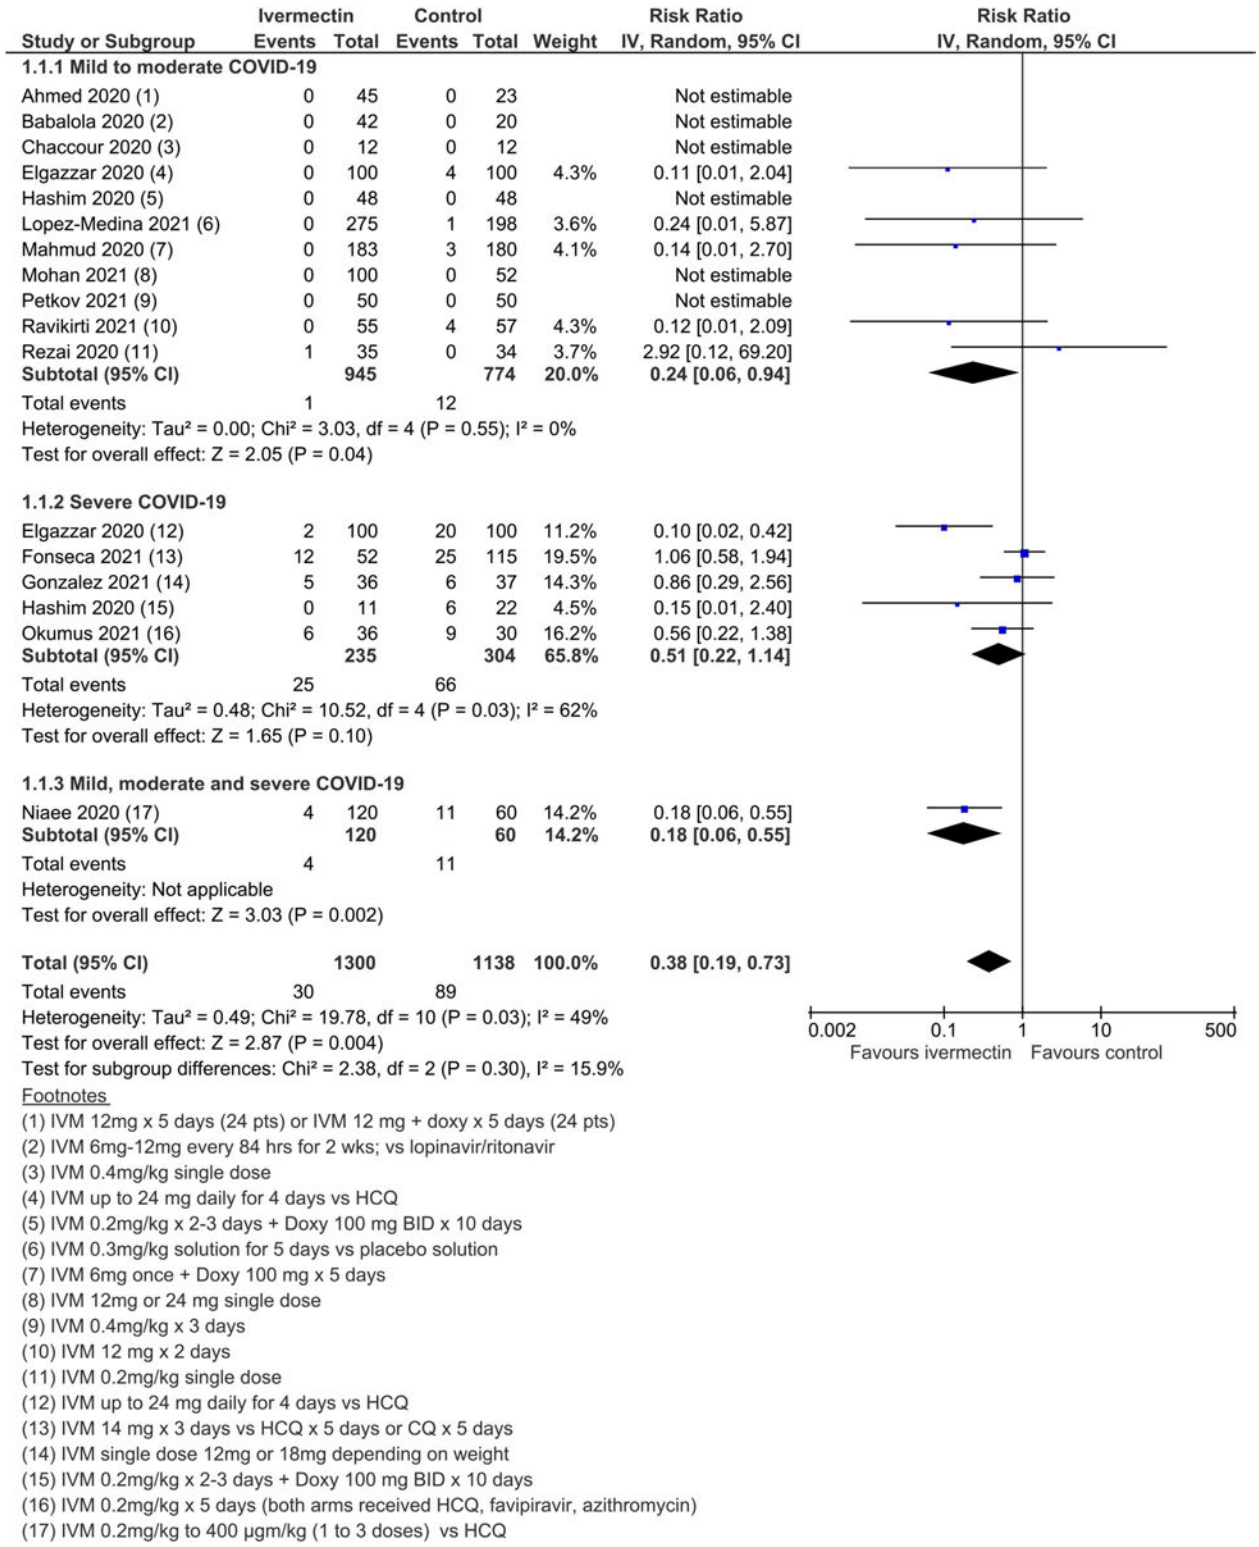

FIGURE 3. Death due to any cause.

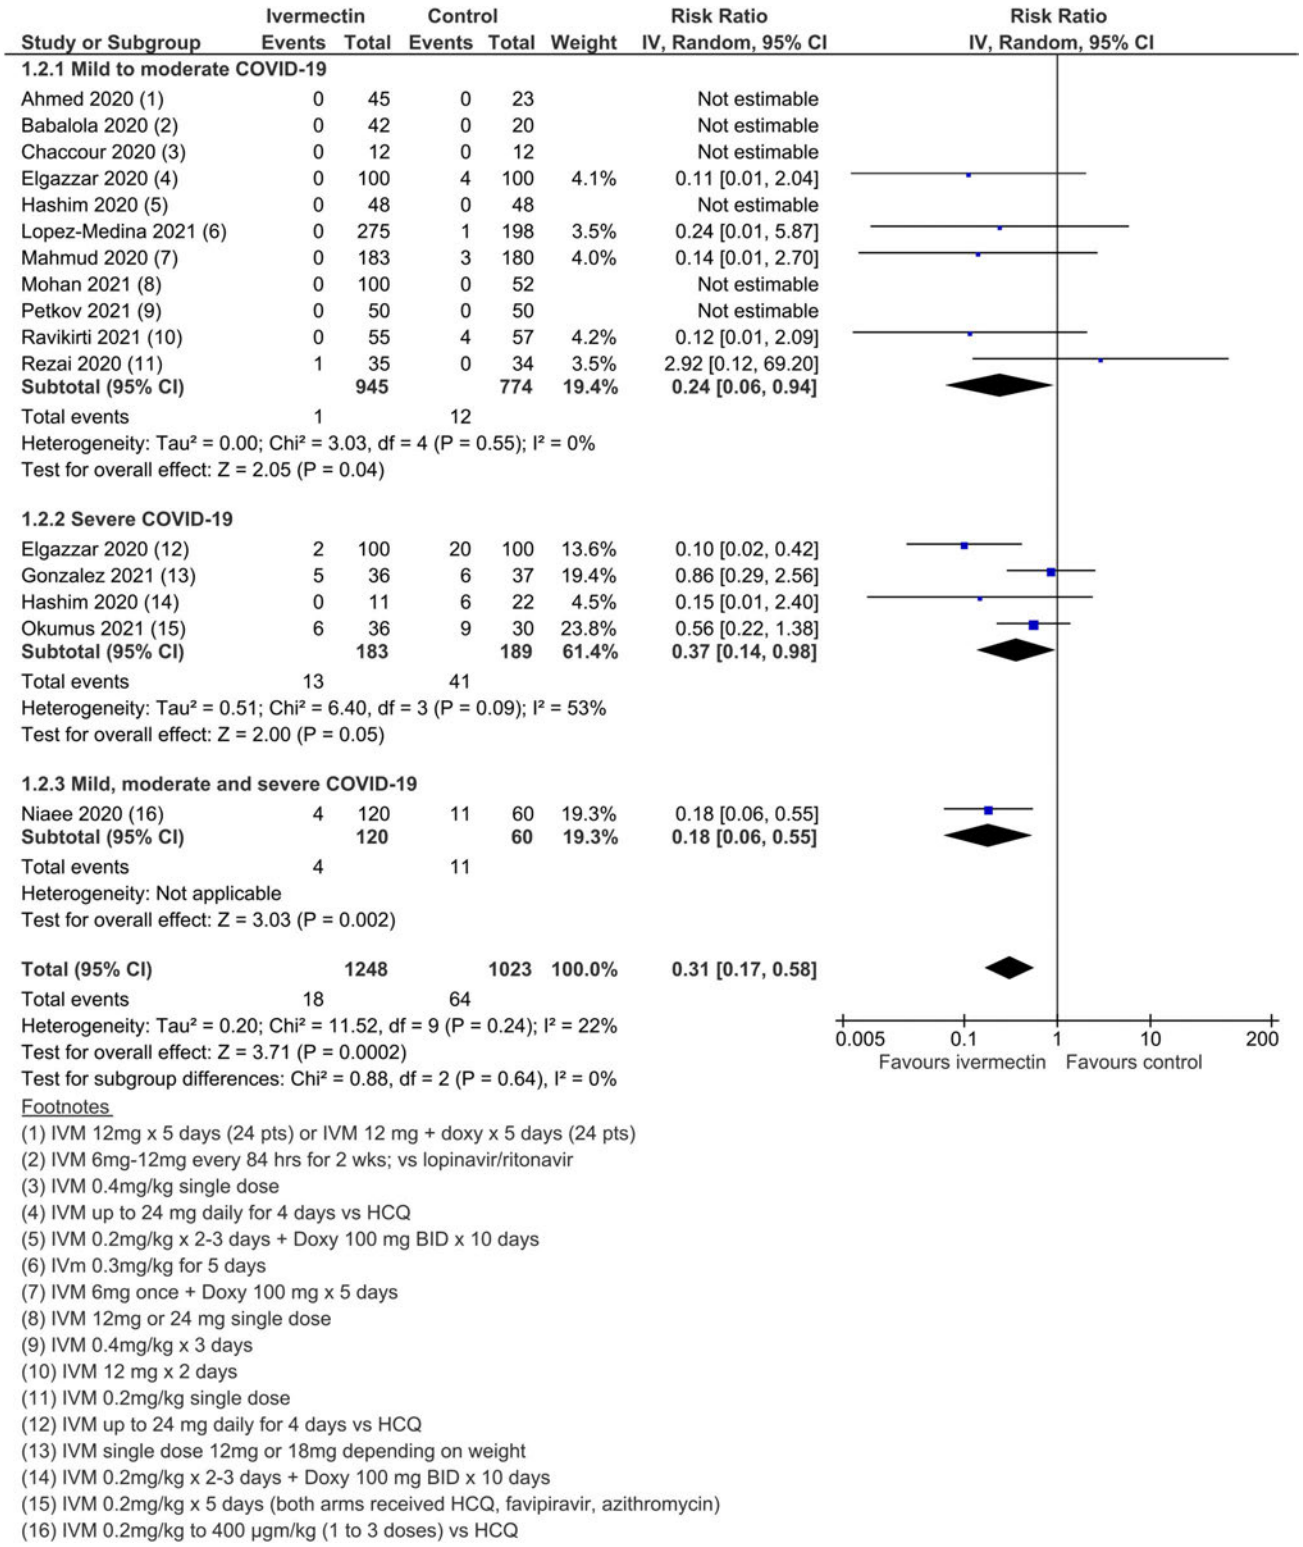

FIGURE 4. Death due to any cause, excluding an outlier study responsible for the heterogeneity.

FOI 26-3132 - Document 5

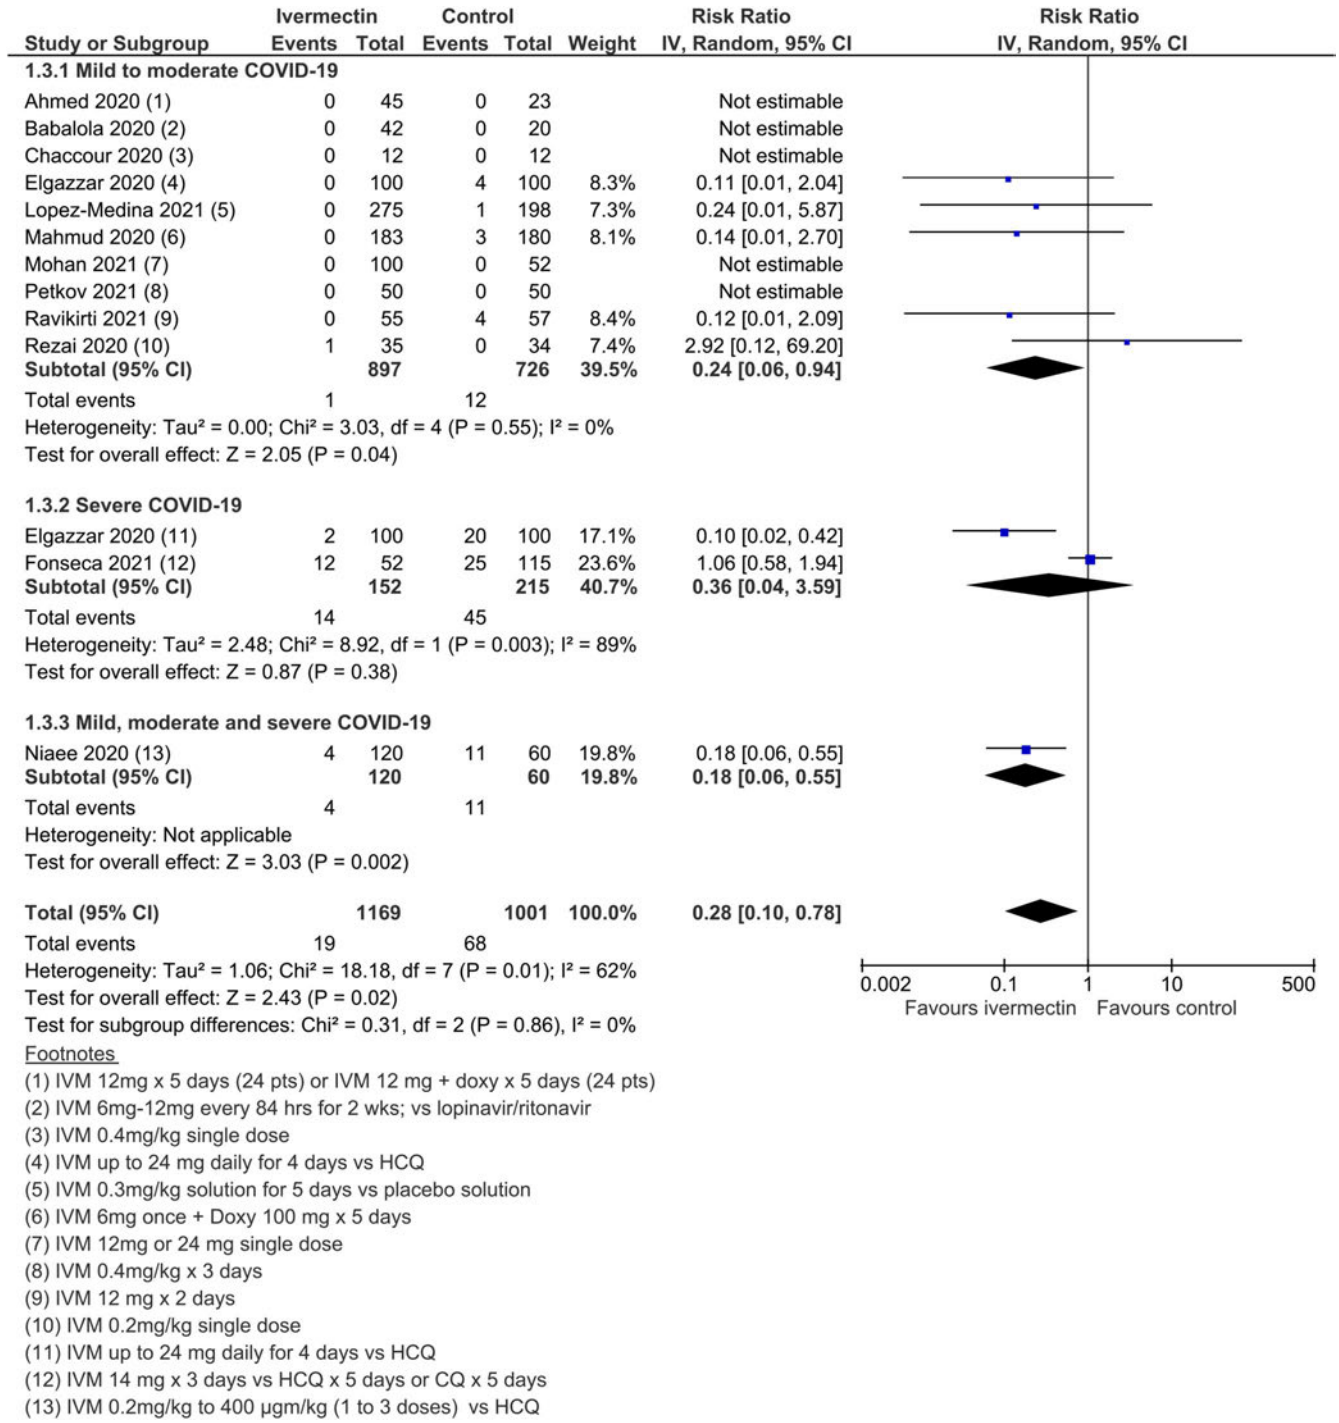

FIGURE 5. Death due to any cause, excluding high risk-of-bias studies.

comprehensively confirms the result of the conventional meta-analysis. The required IS was 1064.

The required IS was not reached in the TSA using the SJ method, largely because diversity from the model was high (Figure 11). The SJ estimator may overestimate the between-trials variance in meta-analyses with mild heterogeneity, thus producing artificially wide confidence intervals.[43] When the diversity estimate was reduced to the same as in the DL model, the required IS was reached in the SJ model (data not shown). There was no evidence of futility using the SJ method in any scenario.

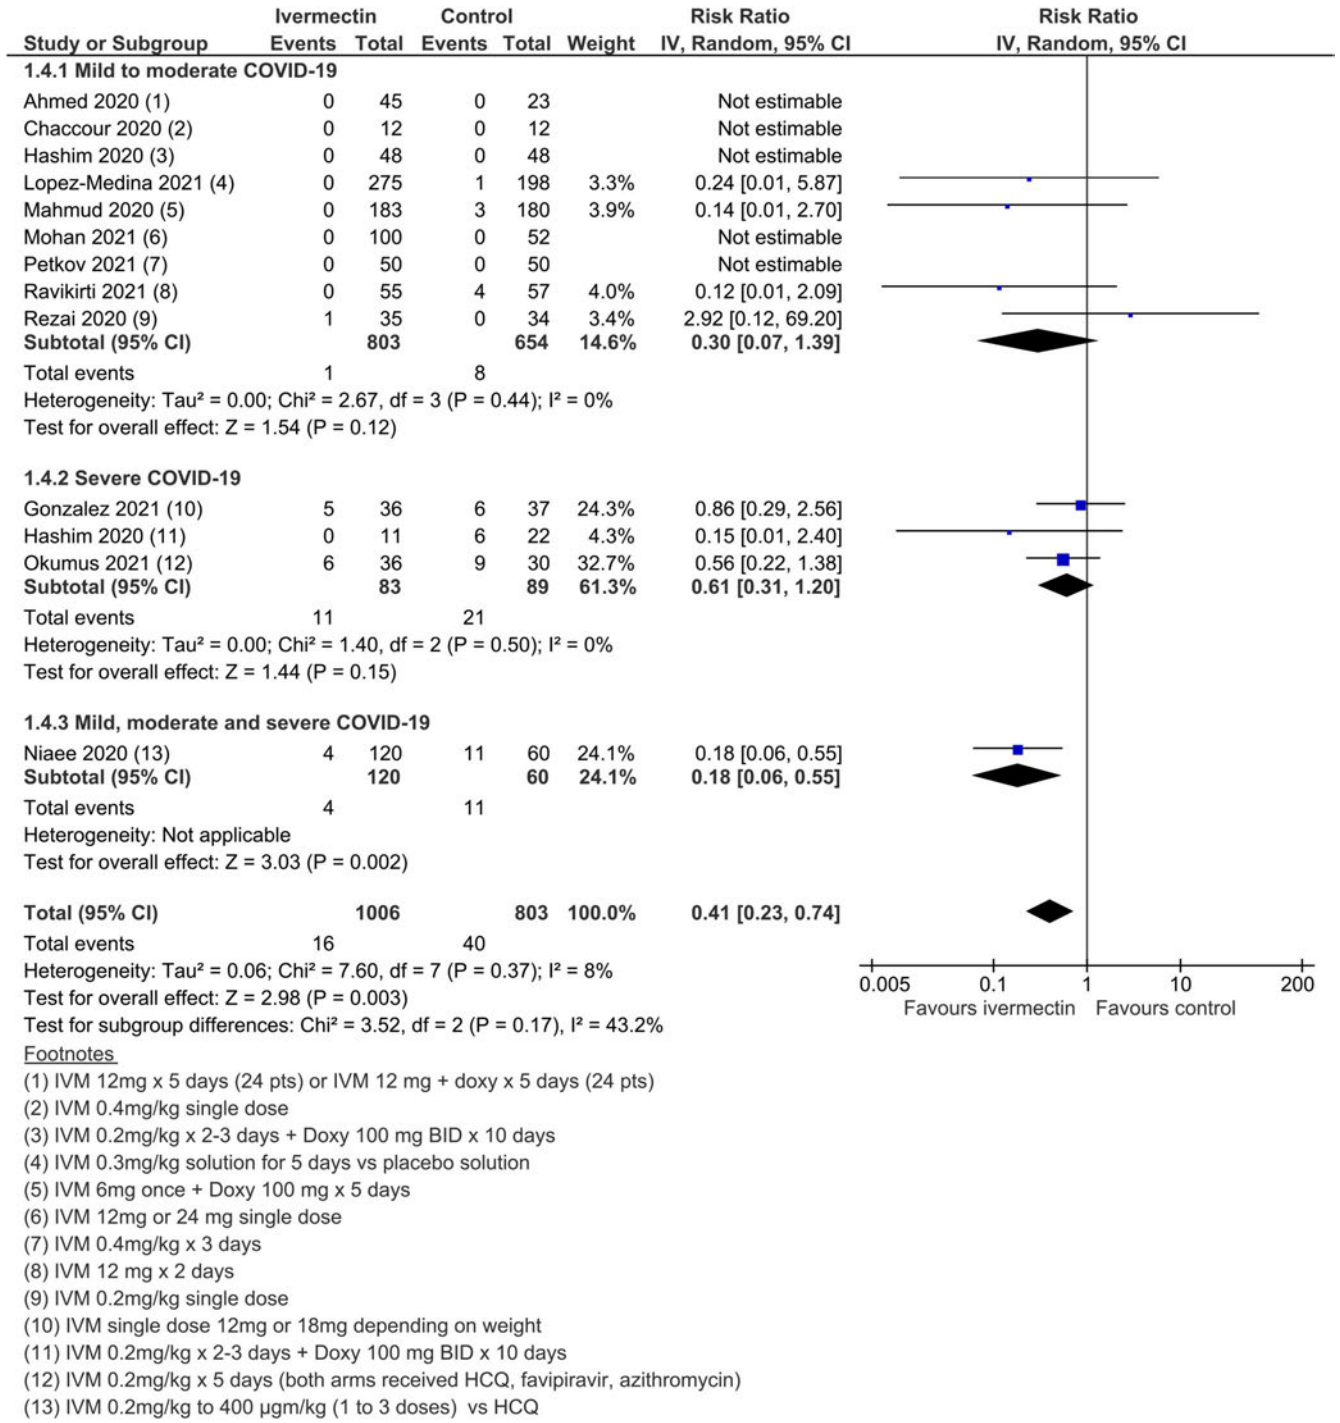

FIGURE 6. Death due to any cause, excluding studies with active controls.

Certainty of the evidence for all-cause mortality

Overall, death from any cause, taking into account all composite analyses, was judged to provide moderate-certainty evidence (SoF Table 2 and Figures 4–11). A funnel plot corresponding to the primary outcome of death from any cause did not seem to suggest any evidence of publication bias (Figure 7). Furthermore, the ease with which trial reports can be uploaded as preprints should reduce this risk.

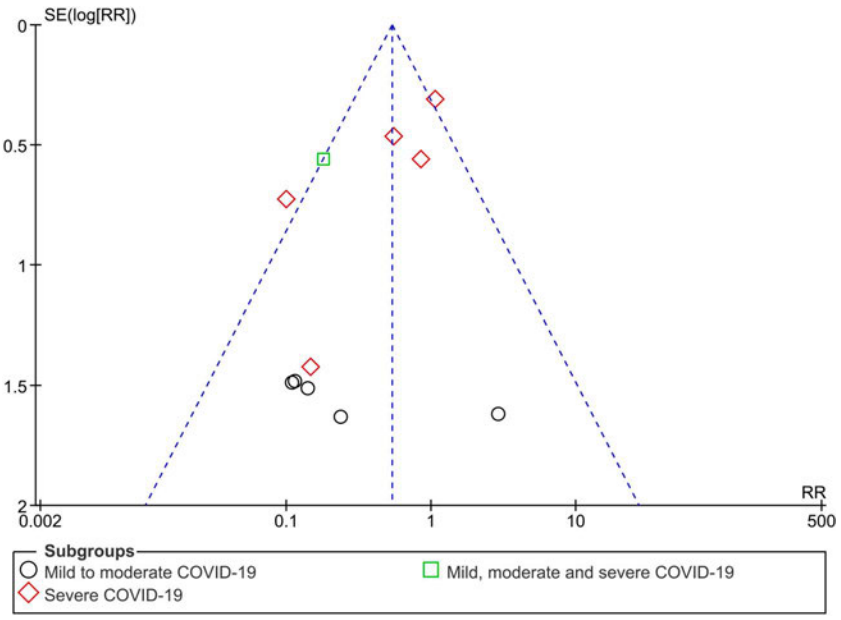

FIGURE 7. Funnel plot of ivermectin versus control for COVID-19 treatment for all-cause death (subgrouped by severity).

Secondary outcomes

Secondary outcomes provided low to very low certainty evidence (SoF Table 2). Low-certainty findings suggested that there may be no benefit with ivermectin for "need for mechanical ventilation," whereas effect estimates for "improvement" and "deterioration" favored ivermectin but were graded as low certainty due to study design limitations and inconsistency (Figures 12–14). All other secondary outcome findings were assessed as very low certainty.

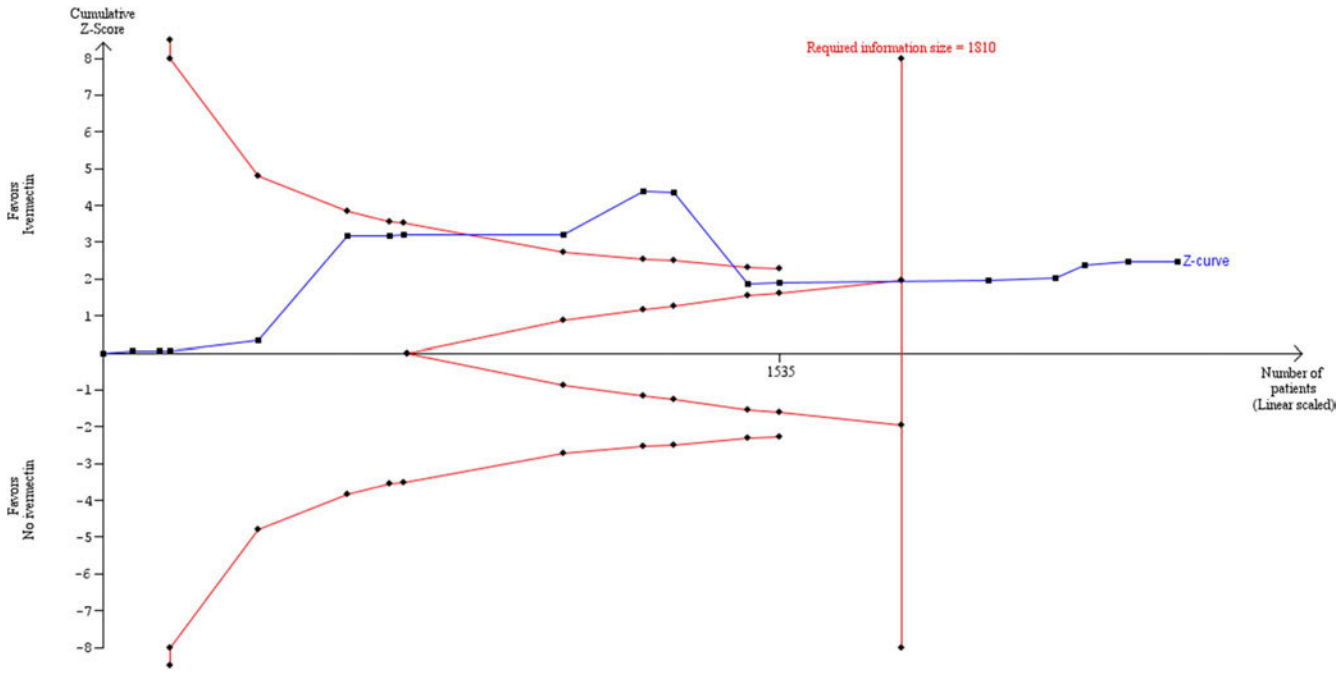

FIGURE 8. Trial sequential analysis using DL random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, RRR = 62%, and diversity = 49.5%.

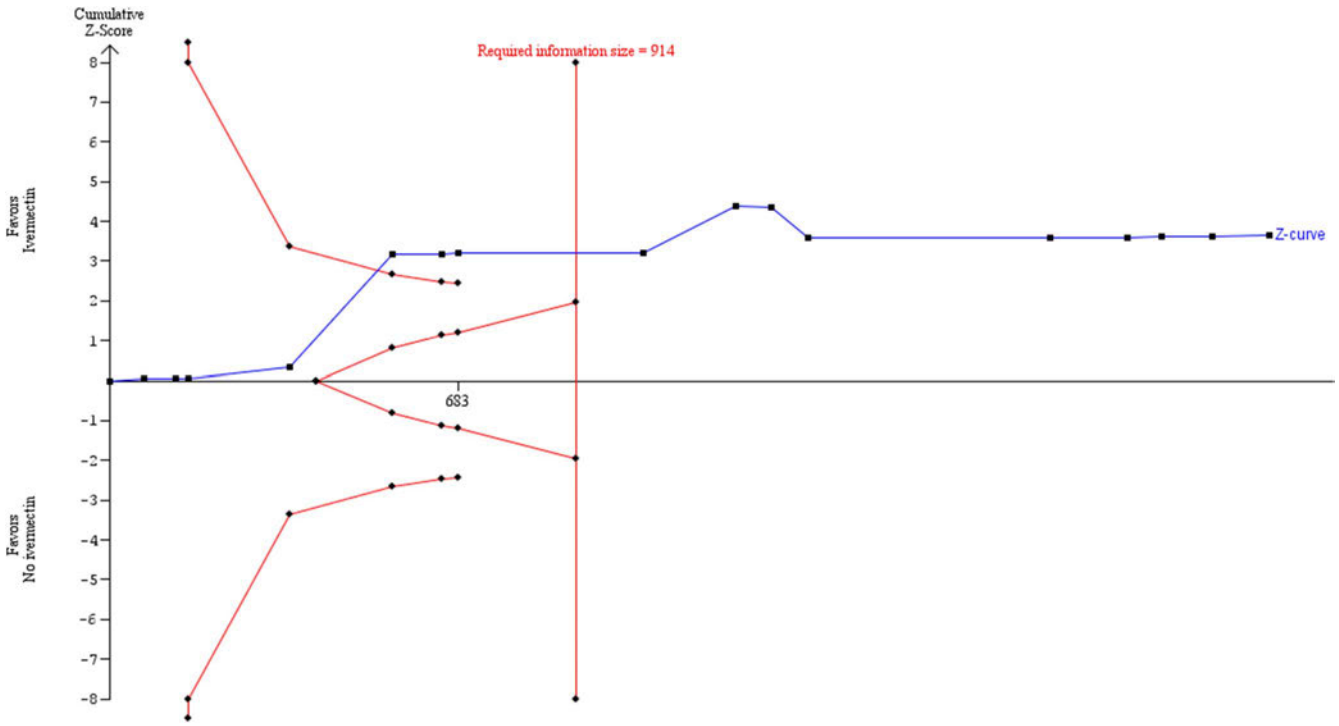

FIGURE 9. Sensitivity analysis excluding an outlier study responsible for the heterogeneity, showing trial sequential analysis using DL random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, = 62%, and diversity = 0%.

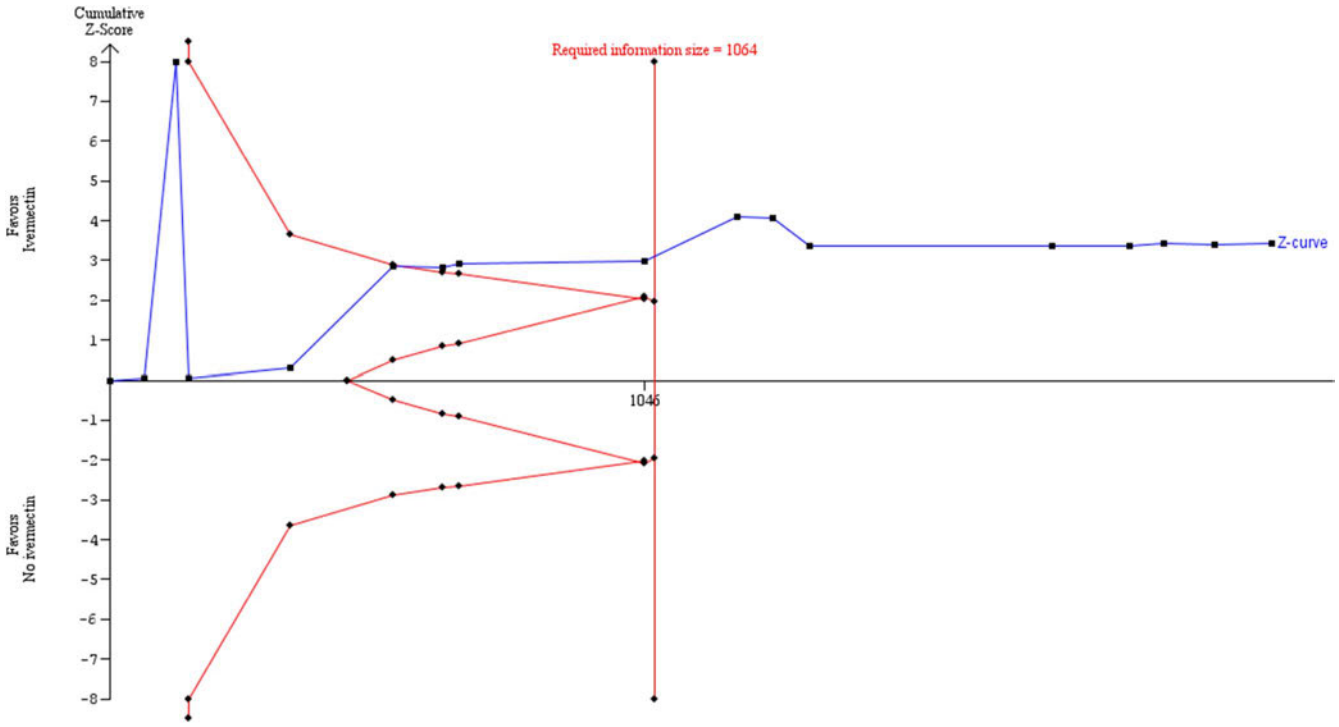

FIGURE 10. Sensitivity analysis excluding an outlier study responsible for the heterogeneity, showing trial sequential analysis using Biggerstaff–Tweedie random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, RRR = 62%, and diversity = 14.2%.

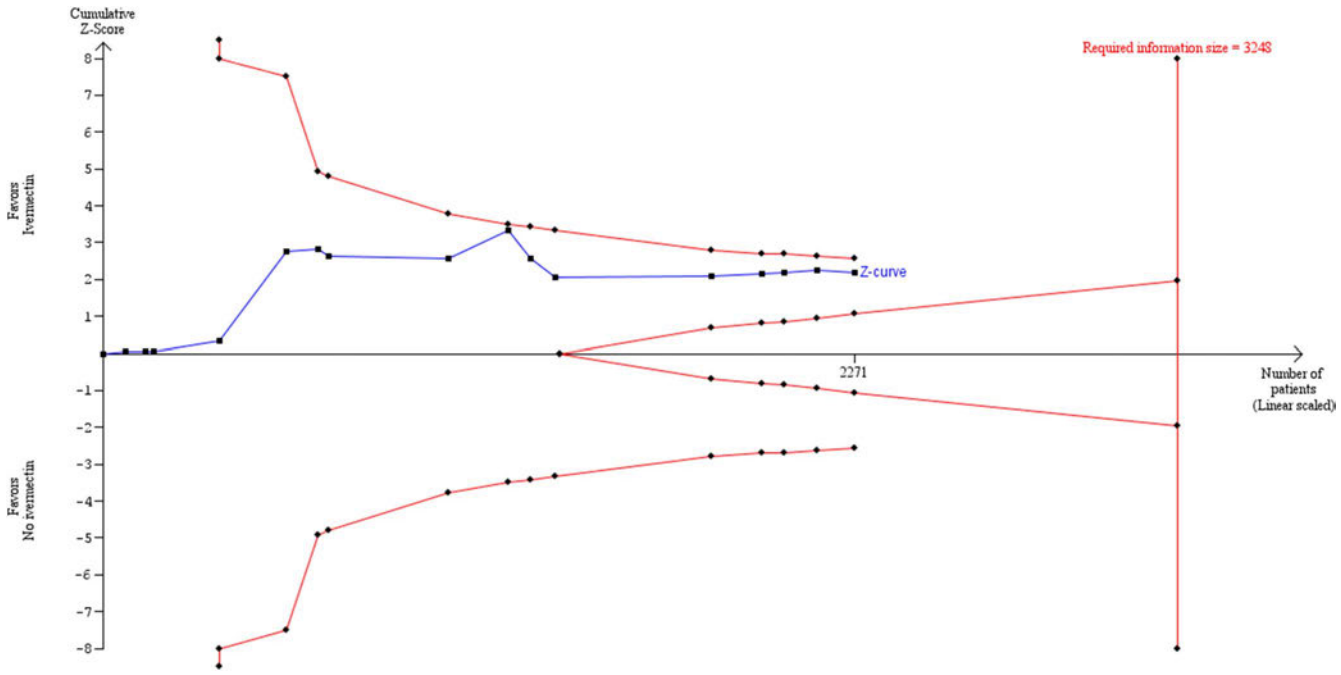

FIGURE 11. Sensitivity analysis excluding an outlier study responsible for the heterogeneity, showing trial sequential analysis using Sidik–Jonkman random-effects method with parameter estimates of $\alpha = 0.05$, $\beta = 0.1$, control rate = 7.8%, RRR = 62%, and diversity = 71.9%.

Meta-analysis of 11 trials, assessing 1533 participants, found that there was no significant difference between ivermectin and control in the risk of severe adverse events (aRR 1.65, 95% CI 0.44–6.09; $I^2 = 0\%$; *low certainty evidence*, downgraded for imprecision and study design limitations). Seven severe adverse events were reported in the ivermectin group and 2 in controls. The SAEs were as follows: 2 patients in the Mahmud trial[107] had esophagitis (this is a known side effect of doxycycline, which was coadministered with ivermectin in this trial); one patient in the study by Krolewiecki et al[106] had hyponatremia (this trial used high-dose ivermectin for 5 days); and 2 patients in a study from Turkey[115] had serious "delirium-like behavior, agitation, aggressive attitude, and altered state of consciousness," which the authors attributed to metabolic insufficiencies in MDR-1/ABCB1 or CYP3A4 genes, screening for which was a study feature. In the Lopez-Medina et al[85] trial, there were 2 SAEs in each arm (SoF Table 2).

Ivermectin prophylaxis versus no ivermectin prophylaxis

Three studies involving 738 participants evaluated ivermectin for COVID-19 prophylaxis among health care workers and COVID-19 contacts. Meta-analysis of these 3 trials, assessing 738 participants, found that ivermectin prophylaxis among health care workers and COVID-19 contacts probably reduces the risk of

COVID-19 infection by an average of 86% (79%–91%) (3 trials, 738 participants; aRR 0.14, 95% CI 0.09–0.21; 5.0% vs. 29.6% contracted COVID-19, respectively; *low-certainty evidence*; downgraded due to study design limitations and few included trials) (Figure 15). In 2 trials involving 538 participants, no severe adverse events were recorded (SoF Table 4).

DISCUSSION

The findings indicate with moderate certainty that ivermectin treatment in COVID-19 provides a significant survival benefit. Our certainty of evidence judgment was consolidated by the results of trial sequential analyses, which show that the required IS has probably already been met. Low-certainty evidence on improvement and deterioration also support a likely clinical benefit of ivermectin. Low-certainty evidence suggests a significant effect in prophylaxis. Overall, the evidence also suggests that early use of ivermectin may reduce morbidity and mortality from COVID-19. This is based on (1) reductions in COVID-19 infections when ivermectin was used as prophylaxis, (2) the more favorable effect estimates for mild to moderate disease compared with severe disease for death due to any cause, and (3) on the evidence demonstrating reductions in deterioration.

The evidence on severe adverse events in this review was graded as low certainty, partly because there were too few events to reach statistical significance. Evidence from a recent systematic review of ivermectin use among people with parasitic infections suggests that ivermectin administered at the usual doses (0.2 or 0.4 mg/kg) is safe and could be safe at higher doses.[7,116] A recent World Health Organization document on ivermectin use for scabies found that adverse events with ivermectin were primarily minor and transient.[22]

We restricted the included studies to the highest level of evidence, that is, RCTs, as a policy. This was despite there being numerous observational but nonrandomized trials of ivermectin, which one could argue could also be considered in an emergency. We included preprint and unpublished data from completed but not yet published trials due to the urgency related to evidence synthesis in the context of a global pandemic.[117] Although there is the potential for selective reporting of outcomes and publication bias, we have factored in these considerations in interpreting results and forming conclusions. We adhered to PRISMA guidelines and the WHO statement on developing global norms for sharing data and results during public health emergencies.[117]

There are a number of limitations with this review. Several of the studies contributing data did not

FOI 26-3132 - Document 5

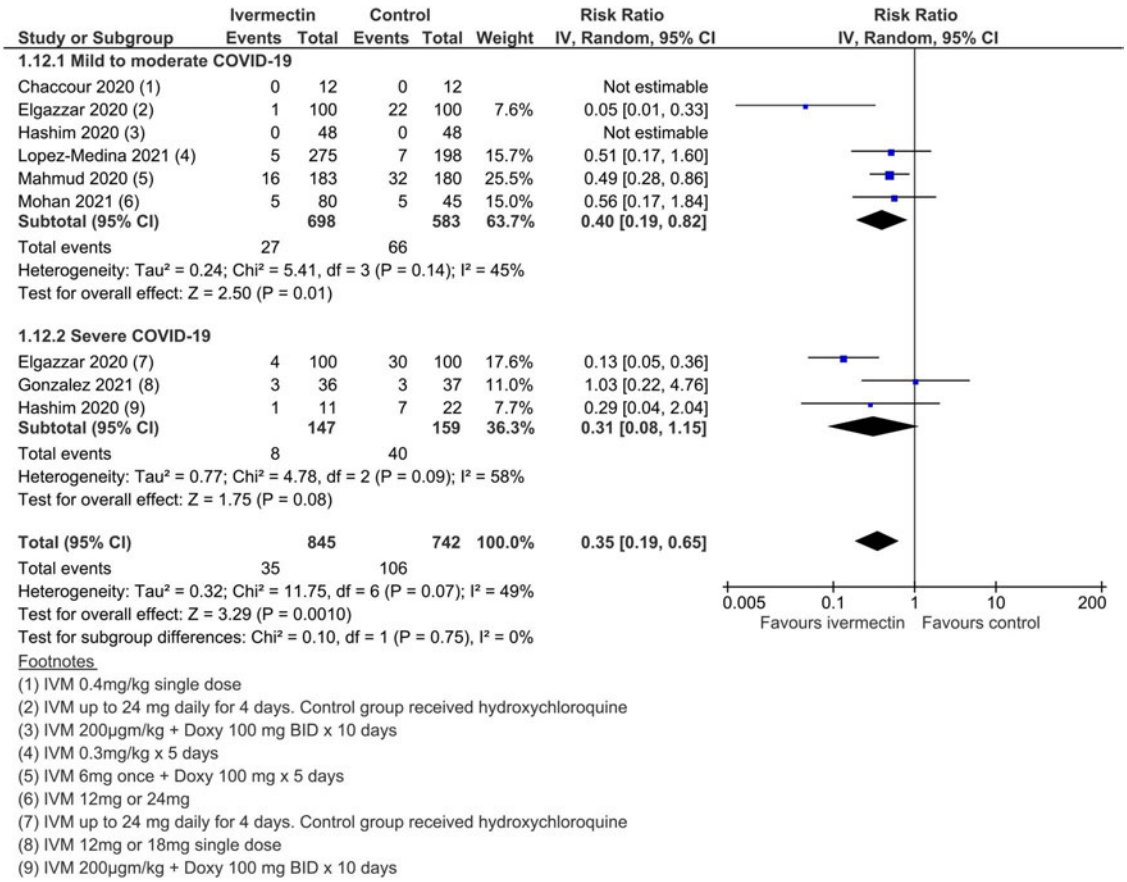

FIGURE 14. Deterioration.

provide full descriptions of methods, so assessing risk of bias was challenging. Where descriptions of study methods were sparse or unclear, we attempted to contact authors to clarify methods, but lack of information led us to downgrade findings in several instances. Overall interpretation of findings was hampered due to variability in the participants recruited, treatment regimen, and the care offered to those in control groups. We have tried to take this variation into account through subgroup and sensitivity analyses. Nevertheless, dosing and treatment regimens and the use of ivermectin with other components of "standard care" require further research. We did not include laboratory outcome measures, such as viral clearance. The latter and other biochemical outcomes have been reported in several studies and reviews and tend to favor ivermectin.[10,47,105,108] Several trials reported continuous data, such as length of hospital stay, as medians and interquartile ranges; therefore, we were unable to include these data in meta-analysis. Because we did not undertake in our protocol to perform narrative evidence synthesis, and because these data tended to favor ivermectin, the certainty of the effects of ivermectin on these continuous outcomes may be underestimated.

At least 5 other reviews of ivermectin use for COVID-19 have been published, including one coauthored with Nobel Laureate Professor Satoshi Ōmura, discoverer of ivermectin,[9,10,118,119,120] but only 3 have been peer-reviewed[9,118,120] and only 2 attempt full systematic review.[10,119] We applied AMSTAR 2,[121] a critical appraisal tool for systematic reviews of health care interventions, to the 2 nonpeered systematic reviews[10,119] and both were judged to be of low quality (Table 5). However, there was also a suggestion that ivermectin reduced the risk of death in treatment of COVID-19 in these reviews.

The recently updated WHO therapeutics guidelines[12] included 7 trials and 1419 people in the analysis of mortality. Reporting a risk reduction of 81% (odds ratio 0.19, 95% CI 0.09–0.36), the effect estimate favoring ivermectin was downgraded by 2 levels for imprecision, although the justification for this is unclear as the reported CI is precise (64%–91%).

In addition to the evidence from systematic reviews, the findings of several controlled observational studies

FOI 26-3132 - Document 5

Table 4. Summary of findings table of ivermectin versus no ivermectin for COVID-19 prophylaxis in healthy population (people without COVID-19 infection).

	Illustrative comparative risks* (95% CI)				
	Assumed risk	Corresponding risk			
Outcomes	No ivermectin	Ivermectin	Relative effect (95% CI)	No of participants (studies)	Quality of the evidence (GRADE)
COVID-19 infection	296 per 1000	245 fewer infections per 1000 (234–269)	RR = 0.14 (0.09–0.21)	738 (3)	Low†
Admission to hospital	Not reported				
Death from any cause	Not reported				
Serious adverse events	No events occurred in 538 participants (2 studies), therefore the effect could not be estimated.				

GRADE working group grades of evidence; High quality: Further research is very unlikely to change our confidence in the estimate of effect; Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate; Low quality: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate; Very low quality: We are very uncertain about the estimate.
*The basis for the assumed risk (eg, the median control group risk across studies) is provided in footnotes. The corresponding risk (and its 95% CI) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).
†Downgraded −2 for study design limitations.
NNT, number needed to treat.

are consistent with existing evidence and suggest improved outcomes with ivermectin treatment.[55,57,59] Similarly, with respect to ivermectin prophylaxis of frontline workers and those at risk, controlled observational studies from Bangladesh and Argentina (the latter which involved 1195 health care workers) have shown apparent reductions in COVID-19 transmission with ivermectin prophylaxis, including in some reports total protection (zero infections) where infection rates in the control group exceeded 50%.[122,123] A very large trial of ivermectin prophylaxis in health care workers in India[124] covered 3532 participants and reported risk ratios not significantly different from this meta-analysis (prophylaxis outcome).

Clarifying ivermectin safety in pregnancy is a key question in patient acceptability for pregnant women contracting COVID-19. A recent meta-analysis[5] found little evidence of increased risk of abnormal pregnancies but similarly weak evidence of absence of risk. For (pre-exposure) prophylaxis in pregnancy, where vaccines may be contraindicated, the alternative of hydroxychloroquine has been advocated.[125,126] In addition to safety and relative efficacy, different risk–benefit judgments may be presented for prophylaxis

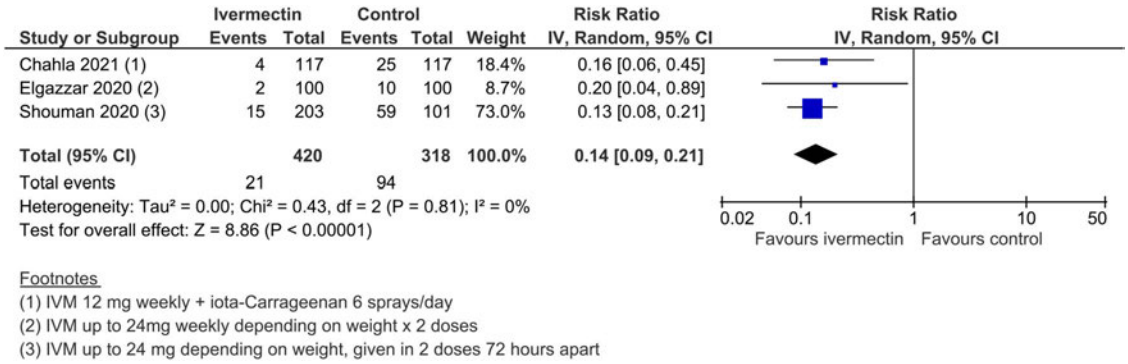

FIGURE 15. COVID-19 infection (prophylaxis studies).

Table 5. Methodological quality of other systematic reviews (AMSTAR 2).

Hill et al, 2021[10]	−‡	−	−§	−*	−¶	−*	NA	−
Castañeda-Sabogal et al 2021[119]	−**	−	−††	−‡‡	−*	+	NA	+

Assessed using AMSTAR 2[121]; +, adequately assessed; −, inadequately assessed; ?, unclear assessment; NA, not applicable (less than 10 included studies in meta-analysis).

*Not documented or inadequately reported.

†Participant population, description of comparator interventions, and time frame for follow-up were not described or inadequately reported.

‡No summary of risk-of-bias assessment was given in the main text in the review, other than stating trials were of poor, fair, or high quality. There were some further details about bias in the discussion, but these were largely generic and did not follow the recommended Cochrane tool used to assess risk of bias in RCTs.

§A meta-analysis for all-cause death was presented but authors did not specify why meta-analyses were not conducted for other outcomes, which included at least 2 trials reporting the same comparison and outcome, other than in some parts of the discussion. For example, if viral clearance was reported in most trials, there would have been scope to have performed subgroup analyses and/or split the time point for each comparison to account for the varying duration of follow-up across trials. Instead, they gave a vote count-type narrative of the results, which did not follow synthesis without meta-analysis (SWiM) in systematic review reporting guidelines.[144]

¶There was some further details about bias in the discussion, but this was largely generic and did not follow the recommended Cochrane tool used to assess risk of bias in RCTs. Similarly, in terms of certainty/quality of the evidence, the authors used terms in a summary table that included "good," "fair," and "limited," without offering any explanation or justification.

‖Outcomes were reported but lacked definitions.

#A significant number of pertinent RCTs have not been included in the review. Given the adequate due diligence of review process, the comprehensive nature of the search strategy is questionable.

**No description of risk-of-bias assessment in any domain apart from missing outcome data but attrition rates not documented to justify judgment.

††Authors did not report data from RCTs that we obtained from various sources and some conclusions were not reflective of the observed data. It was reported that in an analysis of 4 preprint retrospective studies at high risk of bias, ivermectin was not associated with reduced mortality (logRR 0.89, 95% CI 0.09–1.70, $P = 0.04$). Although the caveat of studies being at high risk of bias and statistical heterogeneity should be added to any interpretation, it is incorrect to interpret these results as not demonstrating a potential association based on the observed result. Furthermore, the high risk of bias judgment is not adequately justified.

‡‡A sensitivity analysis was performed excluding those studies without adjustment for confounding but no details are provided. Given that there was some evidence of a potential association with ivermectin treatment and survival in 4 retrospective studies (although downplayed as no association due to concerns about attrition), it is highly implausible that any sensitivity analysis would not remove any suggestion of association.

FOI 26-3132 - Document 5

(pre- and post-exposure), and for treatment, with pregnancy a high-risk status for COVID-19.

RCTs in this review did not specifically examine use of ivermectin in the elderly, although this is a known high-risk group for severe COVID-19. In the setting of care homes, it is also notorious for rapid contagion. A standard indication for ivermectin in the elderly is scabies. We identified 2 recent reports suggesting that ivermectin may be efficacious as prevention and treatment of COVID-19 in this age group.[50,127] A letter on positive experience in 7 elder care facilities in Virginia covering 309 patients was sent to NIH[127] and has recently been submitted for publication.

There is also evidence emerging from countries where ivermectin has been implemented. For example, Peru had a very high death toll from COVID-19 early on in the pandemic.[128] Based on observational evidence, the Peruvian government approved ivermectin for use against COVID-19 in May 2020.[128] After implementation, death rates in 8 states were reduced between 64% and 91% over a two-month period.[128] Another analysis of Peruvian data from 24 states with early ivermectin deployment has reported a drop in excess deaths of 59% at 30+ days and of 75% at 45+ days.[129] However, factors such as change in behavior, social distancing, and face-mask use could have played a role in this reduction.

Other considerations related to the use of ivermectin treatment in the COVID-19 pandemic include people's values and preferences, equity implications, acceptability, and feasibility.[130] None of the identified reviews specifically discussed these criteria in relation to ivermectin. However, in health care decision making, evidence on effectiveness is seldom taken in isolation without considering these factors. Ultimately, if ivermectin is to be more widespread in its implementation, then some considerations are needed related to these decision-making criteria specified in the GRADE-DECIDE framework.[130]

There are numerous emerging ongoing clinical trials assessing ivermectin for COVID-19. The trade-off with policy and potential implementation based on evidence synthesis reviews and/or RCTs will vary considerably from country to country. Certain South American countries, Indian states, and, more recently, Slovakia and other countries in Europe have implemented its use for COVID-19.[129,131,132,133,134] A recent survey of global trends[118] documents usage worldwide. Despite ivermectin being a low-cost medication in many countries globally, the apparent shortage of economic evaluations indicates that economic evidence on ivermectin for treatment and prophylaxis of SARS-CoV-2 is currently lacking. This may impact more on LMICs that are potentially waiting for guidance from organizations like the WHO.

Given the evidence of efficacy, safety, low cost, and current death rates, ivermectin is likely to have an impact on health and economic outcomes of the pandemic across many countries. Ivermectin is not a new and experimental drug with an unknown safety profile. It is a WHO "Essential Medicine" already used in several different indications, in colossal cumulative volumes. Corticosteroids have become an accepted standard of care in COVID-19, based on a single RCT of dexamethasone.[1] If a single RCT is sufficient for the adoption of dexamethasone, then a fortiori the evidence of 2 dozen RCTs supports the adoption of ivermectin.

Ivermectin is likely to be an equitable, acceptable, and feasible global intervention against COVID-19. Health professionals should strongly consider its use, in both treatment and prophylaxis.

ACKNOWLEDGMENTS

This work was inspired by the prior literature review of Dr Pierre Kory.

The authors thank Information Specialist, Jo Platt, of the Cochrane Gynaecological, Neuro-oncology, and Orphan Cancer (CGNOC) group for designing the search strategy and running the search, as well as Anna Noel Storr for reviewing the strategy. The authors also thank Isabella Rushforth for her voluntary assistance with the preparation of the reference lists.

The authors thank Gill Gyte for detailed comments, feedback, and involvement in this review, and Michael Grayling and David Tovey for useful peer review comments before submission. The authors also thank the external peer reviewers for their helpful comments and Peter Manu for the opportunity to publish our findings.

ABSTRACT

High concentrations of ivermectin demonstrated antiviral activity against SARS-CoV-2 in vitro. The aim of this study was to assess the safety and efficacy of high-dose ivermectin in reducing viral load in individuals with early SARS-CoV-2 infection. This was a randomised, double-blind, multicentre, phase II, dose-finding, proof-of-concept clinical trial. Participants were adults recently diagnosed with asymptomatic/oligosymptomatic SARS-CoV-2 infection. Exclusion criteria were: pregnant or lactating women; CNS disease; dialysis; severe medical condition with prognosis <6 months; warfarin treatment; and antiviral/chloroquine phosphate/hydroxychloroquine treatment. Participants were assigned (ratio 1:1:1) according to a randomised permuted block procedure to one of the following arms: placebo (arm A); single-dose ivermectin 600 μg/kg plus placebo for 5 days (arm B); and single-dose ivermectin 1200 μg/kg for 5 days (arm C). Primary outcomes were serious adverse drug reactions (SADRs) and change in viral load at Day 7. From 31 July 2020 to 26 May 2021, 32 participants were randomised to arm A, 29 to arm B and 32 to arm C. Recruitment was stopped on 10 June because of a dramatic drop in cases. The safety analysis included 89 participants and the change in viral load was calculated in 87 participants. No SADRs were registered. Mean (S.D.) $\log_{10}$ viral load reduction was 2.9 (1.6) in arm C, 2.5 (2.2) in arm B and 2.0 (2.1) in arm A, with no significant differences ($P = 0.099$ and 0.122 for C vs. A and B vs. A, respectively). High-dose ivermectin was safe but did not show efficacy to reduce viral load.

1. Introduction

The vaccine roll-out has certainly played a key role in the fight against COVID-19 (coronavirus disease 2019). However, the emergence of SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2) variants and the (slow) pace of vaccination have

FOI 26-3132 - Document 5

hampered the expected drop in cases in most parts of the world [1,2]. Thus, the pandemic is still hitting hard and antiviral drugs, preferably at low cost and widely available, are still badly needed.

Initially, research has been oriented towards drug repurposing, which is time-saving compared with new drug discovery [3]. Several compounds have been tested against SARS-CoV-2 in vitro and subsequently in vivo, including drugs not primarily used as antiviral agents. In particular, chloroquine/hydroxychloroquine and ivermectin were of interest for use in low- and middle-income countries as these drugs are widely available (for treatment of parasitic infections) and inexpensive [3]. Although recent evidence has globally shifted attention towards novel (and much more expensive) ad hoc medications [4–7], interest in a possible role for cheaper and older compounds remains.

In March 2020, Australian researchers demonstrated that ivermectin, a drug used for decades to combat parasitic infections, had antiviral activity against SARS-CoV-2 in vitro in Vero cell cultures, virtually reducing the viral load to zero in 48 h [8]. This sparked considerable interest in this 'old' drug as a potential cure for COVID-19, resulting on one hand in a consistent number of clinical trials testing ivermectin efficacy, and on the other in an uncontrolled procurement of the drug for self-treatment [9]. However, a plasma concentration of ivermectin compatible with the IC_{50} (half maximal inhibitory concentration) found in vitro (~2.5 μM, equivalent to 2190 ng/mL) is far from being achievable with the usual doses of this drug [10] (40–80 ng/mL after a dose of 200–400 μg/kg). Based on this, we would expect ivermectin to show neither clinical nor virological efficacy against COVID-19 unless higher doses are administered.

The aim of this study was to assess the efficacy and safety of high doses of ivermectin (namely doses of 600 μg/kg and 1200 μg/kg for 5 consecutive days) for the treatment of SARS-CoV-2 infection. The doses were chosen based on the following considerations: (i) according to the reported pharmacokinetic (PK) profile in plasma [11,12], it can be supposed that repeated daily administrations result in drug accumulation, with predicted plasma levels only slightly higher than those observed with single administration of 2000 μg/kg in fasted state (248 ng/mL), which was well tolerated [11]; and (ii) studies in mammals [13,14] showed much higher ivermectin levels in pulmonary tissue than in plasma.

The primary objectives of this study were to define: (i) whether ivermectin, administered at two different high dosages, is safe in participants with initial, asymptomatic or oligosymptomatic SARS-CoV-2 infection; and (ii) whether ivermectin, administered at the dosage(s) found to be safe decreases the viral load of SARS-CoV-2 at Day 7.

2. Materials and methods

2.1. Study design

The COVER study was a randomised, investigator-initiated, double-blind, multicentre, phase II, dose-finding, proof-of-concept clinical trial carried out in outpatients consecutively diagnosed in four sites in Italy. The study protocol (available in the Supplementary material) was approved by the national Ethics Committee of INMI–Spallanzani in Rome, which is competent for all COVID-19 trials in Italy (resolution 139/2020 of 28 May 2020) and by the Italian drug agency AIFA (resolution 136BIS/2020 of 18 May 2020). The protocol was also registered with ClinicalTrials.gov (NCT04438850). The study complied with the Declaration of Helsinki and was performed in accordance with Good Clinical Practice guidelines. All participants provided written informed consent.

2.2. Participants and study sites

Participants were adult (≥18 years) subjects newly diagnosed with SARS-CoV-2 infection by real-time PCR analysis of nasopharyngeal swabs, not requiring hospitalisation or oxygen supplementation (COVID-19 severity score <3 [15]) and providing their informed consent to the study. The main exclusion criteria were: pregnant or lactating women; known central nervous system disease; participants receiving dialysis; any severe medical condition with a prognosis of <6 months; warfarin treatment; antiviral treatment; and chloroquine phosphate or hydroxychloroquine treatment.

2.3. Randomisation and masking

The study arms were as follows: placebo arm (arm A); single-dose ivermectin 600 μg/kg plus placebo for 5 days (arm B); and single-dose ivermectin 1200 μg/kg for 5 days (arm C).

Participants were randomly assigned by a centralised computer system to one of the three arms with an allocation ratio of 1:1:1. The study biostatistician prepared the sequence of treatments, generated using SAS 9.4 software according to a randomised permuted blocks procedure. The treatment ID was obtained through REDCap, used as a web-based clinical data management system for the study. Following randomisation, the treatment ID and the patient's weight were communicated to the hospital pharmacist who was in charge to prepare the study treatment according to the randomisation list. In order to keep investigators and participants blinded, the number of tablets to be administered was the same, irrespective of the study arm in which the participant was randomised. Placebo tablets were identical in appearance and taste to ivermectin. Also, the staff in charge of the laboratory analyses were blinded.

Following randomisation, participants were provided the daily therapy in five packs, numbered 1 to 5 with the respective dates and labelled with the randomisation code. The division into single doses and the labelling were done by the study pharmacists under controlled conditions. The daily doses were self-administered on an empty stomach with water.

2.4. Study procedures

Starting with Day 1 (day of first dose), investigators contacted the participants daily by phone until Day 5 in order to check for the correct intake of the drug and for the occurrence of any adverse events (AEs) based on a pre-specified list. At Day 7, the participant was re-assessed at an in-person visit and a nasopharyngeal swab was performed and examined locally by RT-PCR, then stored at –80°C until the final (centralised) analysis. Full blood count and transaminases were also checked locally. Further onsite visits were scheduled on Day 14 (in all similar to Day 7) and Day 30 (final follow-up visit). Nasopharyngeal swabs were performed if positive at previous visit, and the leftover material was stored as above. Unscheduled visits for any reason were also foreseen. Participants were provided with a dedicated phone number so that they could contact the investigators in case of need.

AEs were assessed for severity according to National Cancer Institute's Common Terminology Criteria for Adverse Events (CTCAE) grading v.4.03, and the causal relationship to the study treatment or to SARS-CoV-2 infection was established by the study physician and recorded in the electronic case report form (eCRF).

Serious adverse events (SAEs) or serious adverse drug reactions (SADRs) had to be immediately (not later than 24 h) reported to the sponsor as well as to the Study Safety Desk. The same applied to suspected unexpected serious adverse reactions (SUSARs).

FOI 26-3132 - Document 5

2.5. Study outcomes

Primary outcomes were: (i) number of SADRs; and (ii) change in viral load at Day 7 with respect to baseline.

Secondary outcomes were: (i) trend over time in quantitative viral load at Days 7, 14 and 30; (ii) time to clinical resolution (TCR) (if symptomatic); (iii) proportion of participants with virological clearance at Days 14 and 30; (iv) hospitalisation rate; and (v) COVID-19 severity score at Days 14 and 30.

2.6. Statistical analysis

The statistical study design was conceived in two steps.

Step 1 aimed at testing the safety of the two experimental arms, in terms of SADRs occurrence, on the first 60 evaluable participants (20 per arm). If the experimental arm failed to be demonstrated as safe, the allocation of participants was planned to be interrupted. At the same time, interim analyses on efficacy and futility were planned comparing control and experimental arms. Futility and efficacy criteria for prematurely stopping the trial are detailed in the study protocol.

Step 2 aimed at testing the efficacy of experimental arms, considered safe at first stage, compared with the control arm in terms of viral load decrease.

The primary safety endpoint was the occurrence of a SADR. According to A'Hern's [16] single-stage design, setting a type I error rate of 10% and power of 80% and hypothesising that the true toxicity rate (SADRs) was 5%, 20 participants in each experimental arm were needed to test the null hypothesis that the toxicity rate was 30% against a one-sided alternative.

The primary efficacy endpoint was the difference in viral load decline from baseline to Day 7. Viral load was measured as $\log_{10}$ of genome copies per μL, ascertained by droplet digital quantitative PCR (dd-PCR) [17,18]. To et al. [19] reported a difference in mean viral load decline of 1.05 $\log_{10}$ copies [standard deviation (S.D.) 0.69 $\log_{10}$ copies]. The desired difference in decrease between each experimental group and control was at least 0.47 $\log_{10}$ copies/mL (effect size $\Delta = 0.68$, considered to be of moderate-large magnitude according to Cohen [20]). According to these hypotheses, with 34 participants per arm the study had a power of 80% to detect a difference between control and experimental arms, at 0.025 α level, one-sided. Therefore, if both experimental treatments proceeded to step 2 and were compared with the control group, the total number of participants to be analysed had to be 102. Considering a potential 20% loss to follow-up, including missing or inadequate specimens, it was planned to enrol 129 participants.

Data were analysed according to the Statistical Analysis Plan (Supplementary material) using SAS 9.4 software. The primary safety analysis was performed on the safety analysis set including participants who received at least one dose of study treatment.

Analysis of the primary efficacy endpoint was performed on the evaluable analysis set, considering all participants as originally assigned to the treatment arms without major violations of eligibility criteria and having the viral load evaluable at Day 7.

A per-protocol (PP) analysis set was defined including only participants who took the allocated treatment as specified in the protocol for 5 days in order to check for consistency with the primary analysis.

2.6.1. Analysis of primary outcomes

The proportion of participants in each experimental group experiencing at least one SADR was described by means of frequency and percentage.

The mean of the differences in viral load decline from baseline to Day 7 between each experimental group and the control group was described by standard summary measures for continuous data and was compared by Student's *T*-test and Wilcoxon test (according to Shapiro–Wilk test for normality).

2.6.2. Analysis of secondary outcomes

A full description of the statistical analyses of all secondary outcomes is reported in the Statistical Analysis Plan (Supplementary material). Assessment of the tolerability profile was mainly based on adverse drug reactions and the frequency and nature of SAEs. The proportion of participants in each group experiencing AEs was compared by χ^2 test (or Fisher's exact test when appropriate). Generalised longitudinal mixed models were used to analyse the trend over time in viral load at the different time points. TCR was calculated as the time from randomisation to clinical resolution or death. TCR was analysed with Cox regression models and was described by the Kaplan–Meier method. The proportion of participants with virological clearance was described by frequencies and proportions with their relative exact 95% confidence interval (CI). The χ^2 test was used to test the proportion of participants with virological clearance at Day 14, and Fisher's exact test was used at Day 30.

2.6.3. Ancillary study on pharmacokinetics

Measurement of plasma concentrations of ivermectin was included as an ancillary study to inform on the maximal drug levels and drug accumulation following repeated doses, on the interindividual variability and, possibly, on the association between blood drug concentration and clinical endpoints. In fact, a high variability in absorption has been described [11]. Peak plasma concentrations (C_{max}) are observed at approximately 4 h after dosing, with an elimination half-life of 18–35 h [11,12]. For these reasons and for feasibility considerations, it was planned to collect blood samples in a subset of participants at three timepoints: just before and 4 h and 48 h after the fifth dose. Plasma aliquots were stored at –20°C (or lower temperature) until analysis.

Ivermectin was measured by high-performance liquid chromatography–tandem mass spectrometry (HPLC-MS/MS) at the laboratory of the IRCCS Sacro Cuore Don Calabria Hospital using a method validated according to the European Medicines Agency (EMA) guidelines. Details on the procedure are reported in the study protocol.

2.7. Role of the funding sources

The sponsor was IRCCS Sacro Cuore Don Calabria Hospital, which received funds for this trial from the Italian Ministry of Health in the framework of 'Ricerca corrente'. Tablets of 9 mg ivermectin and placebo were donated by Insud Pharma (Madrid, Spain). The funders had no role in study design, data collection, analysis and interpretation, or writing of the report.

3. Results

From 31 July 2020 to 26 May 2021, 93 participants were randomised to the three study arms: 32 to arm A; 29 to arm B; and 32 to arm C. IRCCS Ospedale Sacro Cuore Don Calabria of Negrar contributed 79 participants, Ospedale 'Luigi Sacco' ASST Fatebenefratelli Sacco of Milano contributed 8 participants, Azienda Ospedaliera-Universitaria–Policlinico S. Orsola-Malpighi of Bologna contributed 4 participants and Azienda Provinciale Servizi Sanitari Trento–Ospedale of Rovereto contributed 2 participants.

In March 2021, at the interim analysis performed after the enrolment of 64 participants, no SADRs were observed. Furthermore, none of the experimental arms were stopped for efficacy or futility.

Recruitment was stopped on 10 June 2021 because of a dramatic drop in cases. The last follow-up visit was carried out on 29 June 2021.

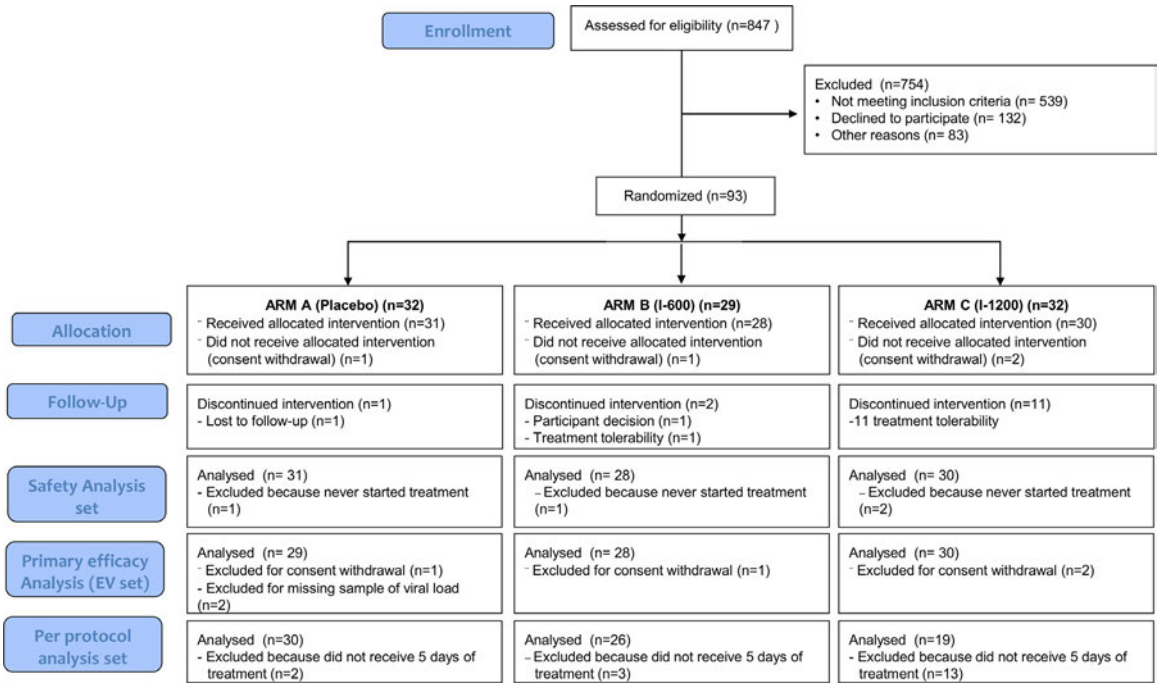

Fig. 1. Study flow chart. Information regarding arm of randomisation, number of subjects screened and enrolled, and detailed reasons for missing inclusion are presented.

Detailed information on screened participants and the reasons for missing inclusions were retrieved from the screening log handled by the centres and is summarised in the study flow chart (Fig. 1; Supplementary Table S1). This information was provided by all centres but one (Rovereto, which contributed two randomised participants). Among the other centres, 845 participants were screened and 91 (10.8%) were randomised. The main reasons for exclusion were infection not recent (56.9%), patient refusal (15.4%), severity score >2 (7.8%) and organisational reasons (7.2%). The 93 participants were randomly assigned to the treatment arms. Of the 93 participants, 4 never started the treatment and withdrew consent and the other 89 received at least 1 day of study treatment and were therefore included in the analysis of the primary endpoints. Moreover, 2 participants (both in arm A) had a missing sample for viral load at Day 7, therefore 87 participants (93.5%) were included in the primary endpoint for efficacy. Moreover, 75 participants (80.6%) received 5 days of treatment and were included in the PP analysis set.

The main baseline demographic and clinical characteristics of the study population are summarised in Table 1 for all randomised participants and in Supplementary Table S2 for participants included in the evaluable analysis set. Male sex was more represented (58.1%). The median age was 47.0 years [interquartile range (IQR) 31.0–58.0]. The majority of participants were European (96.8%). Co-morbidities were reported by one-third of participants. Eighty participants (86.0%) were symptomatic with a median duration of 4 days, with cough being the most frequent symptom, followed by fever and fatigue. The severity score was 1 for 78 participants (83.9%) and 2 for 15 participants (16.1%).

Details of the main physical findings, baseline laboratory examinations and concomitant treatments are summarised in Supplementary Tables S3–S5.

Summary of treatment compliance is reported in Table 2. Fourteen participants (15.1%) discontinued treatment: 1 (3.1%) in arm A; 2 (6.9%) in arm B; and 11 (34.4%) in arm C. The interruptions in arm C were all due to tolerability. Seven participants received only 1 day of treatment, three participants received 2 days and 3 days, respectively, and one participant received 4 days (Supplementary Table S6).

No SADRs were observed in any of the study groups. Results for viral load ($\log_{10}$) at Day 7 versus baseline are summarised in Table 3. The mean reduction in viral load was 2.9 (SD 1.6) in arm C versus 2.5 (SD 2.2) in arm B and 2.0 (SD 2.1) in arm A. The observed effect size (versus arm A) was 0.48 for arm C and 0.21 for arm B. Differences were not normally distributed (Shapiro–Wilk test P-value <0.0001 for both comparisons), thus Wilcoxon exact test was also performed. The differences were not significant ($P = 0.099$ and 0.122 for arm C vs. arm A and arm B vs. arm A, respectively). Results according to PP analysis, summarised in Supplementary Table S7, are superimposable.

The trend over time of the quantitative viral load is summarised in Supplementary Tables S8 and S9. In both non-adjusted and multivariate mixed model, a significant interaction was found between arm C and Day 7 (P-value = 0.035 and 0.036, respectively). TCR was described in symptomatic participants (80 participants). The median TCR was 14 days (IQR 13–30 days), 29 days (IQR 13.5–32.0 days) and 14 days (IQR 7–37 days) for arms A, B and C, respectively. Kaplan–Meier curves for TCR comparisons between arms are reported in Supplementary Fig. S1. Differences between arms were not significant [hazard ratio (HR) = 0.69, 95% CI 0.36–1.32 ($P = 0.262$) and HR = 0.79, 95% CI 0.42–1.47 ($P = 0.456$) for arm B vs. arm A and for arm C vs. arm A, respectively] (Supplementary Table S10). The proportion of participants with virological clearance at Days 14 and 30 is summarised in Supplementary Table S11. Within 14 days, 59% (95% CI 22.4–61.2%), 70% (95% CI 13.2–52.9%) and 58% (95% CI 23.4–63.1%) of participants in arms A, B and C achieved virological clearance.

As an exploratory analysis, the same proportion for Day 7 was also added. No significant difference between arms was observed at any of the time points. The hospitalisation rate was 3/30 (10.0%) for arm C, 1/29 (3.4%) for arm B and 0 for arm A. Regarding the COVID-19 severity score, at Day 14 all participants had a score of 1, except for two participants in arm B with severity scores of 2 and 3. At Day 30 all participants had a severity score of 1.

Table 1
Demographic and baseline characteristics of the study participants, overall and by study arm

Characteristic	Arm A (N = 32)	Arm B (N = 29)	Arm C (N = 32)	Overall (N = 93)
Age (years) [median (IQR)]	50.0 (26.0–57.0)	47.0 (31.0–62.0)	44.5 (31.0–55.5)	47.0 (31.0–58.0)

Participant decision	0 (0.0)	1 (50.0)	0 (0.0)	1 (7.1)
Lost to follow-up	1 (100.0)	0 (0.0)	0 (0.0)	1 (7.1)
Treatment completed [n (%)]	30 (93.8)	26 (89.7)	19 (59.4)	75 (80.6)

NOTE: Arm A, placebo; arm B, ivermectin 600 μg/kg + placebo for 5 days; and arm C, ivermectin 1200 μg/kg for 5 days.

The maximum grade of each AE per participant is summarised in Table 4 and in Supplementary Table S12. Overall, 229 AEs were recorded, 46 in arm A (20.1%), 69 in arm B (30.1%) and 114 in Arm C (49.8%). Only two AEs were grade 3 and no AEs of grades 4 or 5 were observed. The most reported AE concerned transient eye disorders [21/30 participants (70.0%) in arm C, 13/28 participants (46.4%) in arm B and 1/31 participants (3.2%) in arm A], followed by nervous system disorders, fatigue and gastrointestinal symptoms.

Four AEs were recorded as serious (SAEs): in all cases they required hospitalisation for worsening of the disease with no causal relationship to the study drug. Three SAEs occurred in arm C, 1 in arm B and none in arm A. All events resolved.

3.1. Ancillary study on pharmacokinetics

Concentrations of ivermectin were measured, in blind, in the plasma of 15 participants. The results are summarised in Fig. 2. The drug was not detectable in the plasma of five participants of arm A (placebo). Seven participants belonged to arm B and three to arm C, and in two of the latter the third time point was 72 h after the fifth dose. At T4 (4 h after the fifth dose), i.e. the time corresponding to the published C_{max}, the concentration ranged from 79.2 to 414.8 ng/mL for arm B and from 337.1 to 1082.0 ng/mL for arm C. The area under the concentration–time curve (AUC), calculated for the observed 0–48 h period (that is AUC_{96-144} if taking into account that measurements were done after the fifth dose)

Fig. 2. Pharmacokinetic results for ivermectin concentrations in 15 participants (Key). The drug concentration was measured at baseline (T0) and at 4 h (T4), 48 h (T48) and 72 h (T72) after the fifth dose administration (where applicable). The area under the concentration–time curve (AUC) is also reported both graphically and numerically for the 10 participants for whom concentrations were measured.

ranged from 2478 to 12097 for arm B and from 13304 to 50096 for arm C. The decline in viral load at Day 7 and the AEs observed in participants with PK evaluations are listed in Supplementary Table S13. No significant relationship was observed between viral load changes and plasma levels of ivermectin.

4. Discussion

This was the study with the highest dose of ivermectin ever used in a clinical trial for the treatment of COVID-19 or, indeed, for any other condition. The higher dosage (1200 μg/kg for 5 days) showed no safety concerns as no SADRs were observed. The co-primary efficacy outcome was the reduction in viral load on Day 7. The reduction (expressed in $\log_{10}$) was 2.9 for the higher dose (arm C), 2.5 for the lower dose (arm B) and 2.0 for placebo, but the differences were not statistically significant. No significant differences were observed in the clinical outcome either, although the study was not powered sufficiently to detect differences in the secondary outcomes. Concerning AEs, three of the four SAEs (hospitalisation for worsening of the disease) reported were in arm C and 1 in arm B.

Mild or moderate AEs were numerous and reported in all three groups, with the highest proportion in arm C. Of 14 treatment interruptions, 12 were due, precisely, to side effects, of which 11 were in the higher-dose arm (arm C).

The rationale for using a very high dosage was based on the in vitro study published by Caly et al. [8]. The foreseeable plasma concentration after the fifth day of treatment made effective drug levels in pneumocytes plausible, also considering that much higher levels are likely to be achieved in pneumocytes than in plasma [21]. The dosages used in our study were selected according to the PK considerations reported in the study protocol and in the Introduction: the C_{max} after the fifth dose should be of the same order as after a single dose of 2 mg/kg, already found to be safe in healthy volunteers [11]. Our PK results, albeit on a limited number of participants, confirmed our initial hypotheses, indeed showing slightly higher concentrations than foreseen, and reaffirm the biological plausibility of high-dose ivermectin for COVID-19. However, our study failed to show a significant effect on viral load decline.

This study confirms that ivermectin at high dose can be considered safe. However, a high proportion of dropouts, albeit for mild or moderate side effects, was observed in the higher-dose treatment arm. It is true that symptomatic subjects at greater risk of illness progression might be more motivated to continue a treatment in the presence of minor side effects. However, other considerations make a new trial on high-dose ivermectin problematic. First of all, no sign of a possible positive clinical outcome was highlighted. On the contrary, the four participants whose disease worsened enough to cause hospitalisation were all in the treatment arms, and three of these were in the higher-dose arm. Although this is an observation, rather than a statistically valid conclusion, it might be questioned whether ivermectin itself could have at least partly contributed to the clinical worsening. Indeed, there are concerns due to its mechanism of action, which is not directly against the virus but implies inhibition of a host protein involved in intracellular transport [22]. However, the clinical features of the hospitalised participants here were deemed compatible with COVID-19 evolution, and no major neurological signs were observed, as reported previously in cases of serious ivermectin toxicity [23].

Self-administration of veterinary formulations of ivermectin has been widely reported since the initial (and weak) evidence about its possible efficacy against COVID-19. Toxic effects (mostly gastrointestinal distress and neurological symptoms) have been reported following such misuse [24], and the World Health Organization (WHO) has recommended to limit the administration of ivermectin for COVID-19 only for clinical trials [25].

Different groups have carried out systematic reviews with meta-analysis on the use of ivermectin for COVID-19 [26–29]. Results between different works are inconsistent, and the quality of clinical trials included in some reviews has been questioned. On one hand, fraudulent data have been detected; on the other, the sample size of many trials was too small or the study quality was assessed as low [28,30]. Amongst other reviews, a Cochrane meta-analysis has been published [28]. It analysed 14 randomised trials with ivermectin for COVID-19 published until 26 May 2021 including a total of 1678 participants, finding no evidence favouring ivermectin for clinical outcomes or for viral clearance. In all studies, the dosage used was much lower than that of our lower dosage arm, with the exception of the study by Krolewiecki et al. in Argentina [31] that used the same dose as our lower-dose arm (600 μg/kg). The latter study showed a reduction in viral load in treated subjects versus controls in a subgroup of participants in whom the plasma concentration of the drug, measured 4 h after dosing, exceeded 160 ng/mL.

Our study has some limitations. The first is that it failed to reach the planned sample size. However, the conditional power (CP) analysis showed that even reaching the target sample size, the hypothesised effect would hardly be demonstrated (arm B vs. arm A, CP = 0.001; arm C vs. arm A, CP = 0.27). Another limitation was the extreme difficulty in recruiting participants. Approximately 90% of subjects screened were not eligible to be included for various reasons, including a high proportion of refusal to give their consent. Moreover, 79 (84.9%) of the 93 study participants were recruited by the co-ordinating site. Major strengths of this study were the double-blind design, the inclusion of a placebo arm and the lack of any other major deviations from the study protocol.

In conclusion, we did not demonstrate a significant reduction in viral load between ivermectin and placebo, although a trend for the highest dose is apparent. Whether this drug might have clinical efficacy at lower doses remains debated. We believe that our findings further support the WHO recommendation [25] suggesting that it is currently advisable to refrain from administrating ivermectin for the treatment of COVID-19 outside of clinical trials. Considering the reduced tolerability, large, high-dose clinical trials should not be recommended.

Contributors

A complete list of investigators/contributors is reported in the Supplementary material.

Acknowledgments

The authors acknowledge the Data and Safety Monitoring Board (DSMB) members for their enthusiastic and highly professional support: Piero Olliaro, Simone Accordini and Cristiano Chiamulera.

Funding

Insud Pharma & Mundo Sano are thanked for the donation of study medication (ivermectin and placebo), and Alpine Lions Cooperation for the contribution. The study was partly funded by the Italian Ministry of Health 'Fondi Ricerca Corrente' to IRCCS Sacro Cuore Don Calabria Hospital.

Competing interests

None declared.

Ethical approval

The protocol received clearance from the Ethics Committee of INMI–Spallanzani in Rome, which is competent for all COVID-19 trials in Italy [resolution 139/2020 of 28 May 2020].

Zinc, aging, and immunosenescence: an overview

Ángel Julio Romero Cabrera*

Department of Internal Medicine and Geriatrics, Academic Hospital "Dr. Gustavo Aldereguía Lima", Cienfuegos, Cuba

Zinc plays an essential role in many biochemical pathways and participates in several cell functions, including the immune response. This review describes the role of zinc in human health, aging, and immunosenescence. Zinc deficiency is frequent in the elderly and leads to changes similar to those that occur in oxidative inflammatory aging (oxi-inflamm-aging) and immunosenescence. The possible benefits of zinc supplementation to enhance immune function are discussed.

Keywords: *zinc*; *aging*; *immunosenescence*

Received: 29 July 2014; Revised: 22 October 2014; Accepted: 9 December 2014; Published: 5 February 2015

The importance of micronutrients in nutrition and human health is unquestionable and, among them, zinc (Zn) is an essential trace element whose importance has been especially prominent in the current literature. Its deficiency can play an important role in the aging process and in the etiology of several age-related chronic illnesses such as atherosclerosis, degenerative diseases of the nervous system, immunosenescence, and cancer (1). Zinc is involved in the maintenance of many homeostatic mechanisms, including efficiency of the immune system, acting as a structural and regulatory catalyst ion for the biological activity of many enzymes, proteins, and signal transcription factors, as well as cell proliferation and genome stability (2).

Biological aging is a complex process that, in humans, is associated with changes in all cells, especially in the immune system. Immunosenescence is characterized by a progressive abnormal regulation of immune responses (innate, adaptive) that causes a low-grade inflammatory systemic condition, susceptibility to infections, and a lower efficacy of vaccines (3,4). Currently, much of the physical and biological characteristics of aging are being explained by the unbalance among oxidizing mechanisms (free radicals, oxygen reactive species), antioxidant defenses (5), and inflammatory and antiinflammatory mechanisms. This results in a low-grade, pro-inflammatory state, referred to as inflammatory aging ('inflamm-aging') (6).

The main objective of this review is to approach the recent updates on the role of zinc in human health, the aging process, and immunosenescence. The PubMed, Hinari, Ebsco, Embase, and Dinamed international data bases were searched using the descriptors *zinc, zinc and immunosenescence, zinc and aging, zinc and the immune responses,* and *zinc supplementation.* The searches were conducted between July and December 2013; 968 published articles were found, of which 106 articles that matched the required criteria for the topics included in this review were used. The searches were limited to studies published in the English language, and the priority was articles with systematic review, randomized clinical trials, and clinical reviews.

Homeostasis of zinc

The intracellular homeostasis of Zn (Fig. 1) is regulated by buffer proteins called metallothioneins (MT) which act as storage and transporting proteins of Zn (ZnT and ZIP families) that mediate the sign spotting of intracellular zinc, assigning this element the role of the 'second messenger' (7). The release of ionic Zn is produced through the reduction of thiol groups in the MT molecule. The homeostasis of Zn is altered in the aging process in part as a result of nutritional deficiency common in the elderly, causing them to have decreased levels of this ion (8) and, in addition, high MT levels that cause the sequestration of zinc. This leads to less availability of intracellular ionic Zn (9). Zinc ions are closely linked to various structural and catalytic proteins, enzymes, and transcription factors activated by signal transduction pathways, especially in

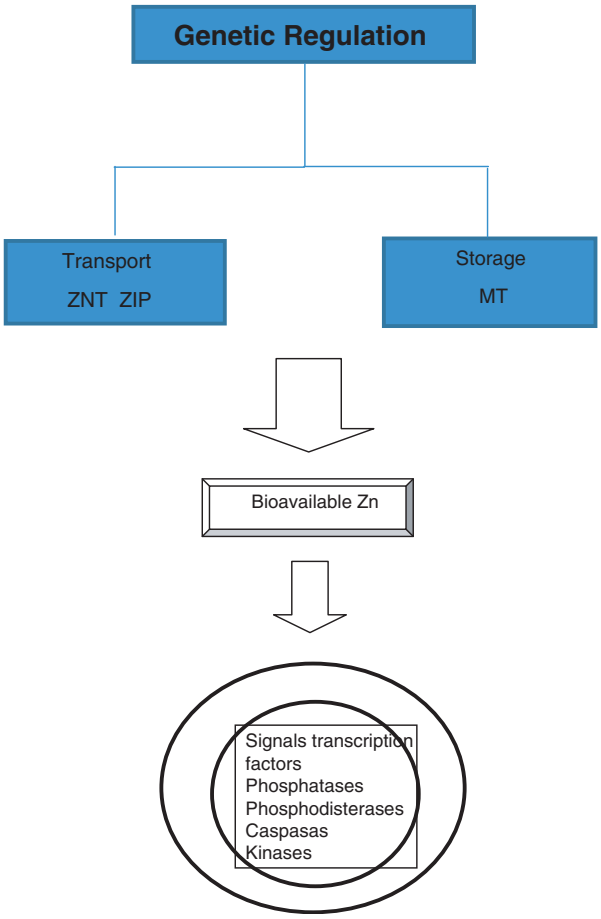

Fig. 1. Homeostasis of zinc.

cells of the immune system. Possible cellular targets of zinc include phosphatases, phosphodiesterases, caspases, kinases, and transcription factors such as nuclear factor kappa B (NF-κB) (10).

Zn activity is genetically regulated as shown by microarray analysis of the total blood ribonucleic acid (RNA) that reveals genes that respond to Zn, particularly those associated with the regulation of the cellular cycle and immune responses. The micronutrients (Zn, Cu, Fe, Mn) play a pivotal role both in maintaining and reinforcing immune and antioxidant performance and in affecting the complex system of genes implicated in encoding necessary proteins for a correct inflammatory immune response (11,12).

Zinc in human health

The importance of zinc for humans was acknowledged in the Middle East (Iran, Egypt), in the early 1960s, in patients with growth retardation, hypogonadism, hepatomegaly, splenomegaly, dry and wrinkled skin, and severe iron deficiency anemia (13). Patients with Zn deficiency had severe immune dysfunction because of which they died from opportunistic infections before the age of 25 (14). In recent years, the data about the effects of Zn deficiency and its supplementation in human health disorders has increased. Zn deficiency causes dysfunction of humoral and cell-mediated immune responses and increases susceptibility to infections. It has also been related to diarrheic diseases with therapeutic benefits being reported in acute diarrhea in children (15,16). A recent review (17) indicates that the Zn supplementation produces reduction in diarrhea and pneumonia mortality in children aged less than 5 in developing countries. There have also been reports of benefits with regard to other illnesses such as enteropathic acrodermatitis, Wilson's disease (in asymptomatic and pre-symptomatic stages), chronic hepatitis C, shigellosis, leprosy, leishmaniasis, and the common cold (18,19).

Current investigations suggest that Zn deficiency increases the risk of neurodegenerative disorders, affecting neurogenesis and increasing neuronal apoptosis, which can cause deficiency in learning and memory. This links Zn deficiency to cerebral aging, depression, Parkinson's disease, and Alzheimer's disease (20–22). It has been postulated that the increased intake of inorganic copper in drinking water can be important in the pathogenesis of Alzheimer's disease. The elevation of the levels of Zn leads to a decrease of copper levels. It has been reported that the treatment with Zn offers protection to patients older than 70 years against the cognitive decline by decreasing the levels of free copper (23). A clinical essay indicates more improvement of symptoms in patients suffering from depression supplemented with Zn and antidepressants than in those who were administered a placebo and antidepressants (24).

Several studies have revealed an association between Zn intake and gastrointestinal cancer. A systematic review of 19 studies up to April 2013 that included 400,000 participants pointed out that a larger intake of zinc led to a reduced risk of colorectal cancer, and a small intake of this microelement was linked to a higher risk of esophageal–gastric cancer in Asia but not in Europe (25). Some authors talk of a possible link between the trace elements copper and zinc (mostly an increase in their association) and the transitional cell carcinoma of the bladder (26,27).

Other studies indicate that Zn can be effective in decreasing the risk of incidence of ocular diseases correlated to aging (28) and the progression of age-related macular degeneration (29). The role of Zn in the distortion of the sense of taste in the elderly is still being discussed (30). In addition, Zn supplementation has proven to be beneficial in decreasing the incidence of infections in the elderly (18) and in sickle cell anemia patients (31).

Abnormal T cell regulation of the inflammatory immune response in aging

The immune system develops significant changes related to age (immunosenescence), which manifest both in innate and adaptive immunity, but they are mainly reflected in

Citation: Pathobiology of Aging & Age-related Diseases 2015, **5**: 25592 - http://dx.doi.org/10.3402/pba.v5.25592

alterations in the bone marrow and in the thymus that cause a change in the composition of the immune cell repertory. This is more significant in T cells (32–34).

Studies performed in healthy octogenarians and nonagenarians have identified an immune risk profile (IRP) of immunosenescence that is distinguished by high numbers of CD8+T cells and low numbers of CD4+T cells (inversion of the index CD4+/CD8+), an increase in the number of dysfunctional and differentiated terminal T cells that were previously exposed to antigens (effectors and memory cells) and the exhaustion of cells that are capable of recognizing and neutralizing new antigens (native or virgins cells) (35–37). Currently, it is being argued whether these changes arise from an intrinsic abnormal regulation of the aging process or from a response to a lifelong continued exposure of the immune system to external stimuli such as infections or other antigenic stimulants (38,39).

In other words, immunosenescence is explained by two hypotheses that are not mutually exclusive: first, the anatomic–physiological decrease of the immune system with aging (intrinsic abnormal regulation) produced, in particular, by the involution of the thymus gland and the decrease of the capacity of auto renovation of the cells of the bone marrow (40,41), and second, the decay that is produced in the immune system due to a lifelong exposure to prolonged or latent infections (42–44) and to a chronic antigenic stimulation (45).

Oxidative inflammatory aging (oxi-inflamm-aging)

Several studies show evidence that a systemic low-grade inflammation characterizes aging with several inflammatory markers, which are significant predictors of mortality in the elderly (46,47). Currently, it is being postulated that immunosenescence is associated with oxidative stress in such a way that the oxidation of proteins alters functionality of immune cells; how this oxidative stress contributes to the chronic inflammatory process is known as oxi-inflamm-aging (48). The oxi-inflamm-aging theory states that oxidative stress associated with aging affects all of the organism's cells, but particularly the cells of regulatory systems (nervous, endocrine, and immune). As a result, there is an inability to preserve redox balance resulting in functional losses that limit the preservation of homeostasis. In the immune system, these changes would be associated with immunosenescence. Activation of improperly regulated transcription factors stimulates the expression of genes that program the production of large quantities of oxidative and inflammatory compounds (cytokines) (49–51).

Other authors believe that inflammatory aging is a consequence and not a cause of immunosenescence. In this sense, it is pointed out that abnormal immune regulation of CD4+ T helper cells in advanced age has been suggested to cause an imbalance of TH1 and TH2 cytokines, with an increase in pro-inflammatory cytokines such as IL-6, IL 1, IL 8, and IL 18, and consequently a chronic systemic inflammation at 'low intensity' (52,53).

Role of zinc in aging and inmunosenescence

Zn is an essential micronutrient required in many cellular processes especially in the normal performance and functioning of the immune system (54). Zn deficiency causes significant decline in the innate and adaptive immune responses and promotes systemic inflammation (55,56). The human adult has a total body content of 2–3 g of Zn, and around 1% of it is replaced daily (57). The recommendations of daily requirements of Zn vary according to different authors and regions. In Spain, 15 mg of elementary Zn for men and 12 mg for women are recommended (58). The daily intake recommended by several reviews for people aged more than 70 are 11 mg for males and 8 mg for women with 40 mg being the top tolerable dosage (56,59). Nine European reports indicate needs of Zn that range from 7 to 14 mg in males and 4.9–9 mg in women (60). Elderly people are a particularly susceptible population to zinc deficiency. Although to this day data are insufficient to determine the frequency of Zn deficiency in the elderly (61), it has been estimated that people older than 65 have an intake of zinc below the 50% recommended level (2). A recent study in a group of 102 elderly European people revealed that 44% of them had Zn deficiency and 20% had high Zn deficiency (62).

Zn deficiency is quite common in elderly, frail people since they often avoid meats and other foods that contain this metal to avoid increasing blood cholesterol levels. In addition, they increase the consumption of refined wheat products deficient in Zn and other fiber-rich foods that contain fitates, which limit the intestinal absorption of this trace element (61,63). Other causes of deficiency of this micronutrient in the elderly include inadequate food chewing, intestinal malabsorption, psychosocial factors such as depression, pharmacologic interactions, and altered subcellular processes (zinc carriers, metallothioneins, divalent metal carrier-1) (2,64). A study performed at nursing homes detected that the lowest serum levels of zinc were found in those patients whose daily life activities were greatly compromised, such as being bed ridden, a low body mass index, and/or increased cognitive decline (65).

Age-related conditions may be related to Zn deficiency by the alteration of intracellular Zn homeostasis, because metallothioneins are unable to release zinc, and transporting proteins (ZIP families) are defective resulting in a low content of intracellular Zn (7). The upregulation of the ZIP genes has some influence in the entrance of Zn into cells, which is more pronounced in lymphocytes from young adults than in lymphocytes from old donors (66). Metallothioneins are antioxidant proteins that release Zn ions for several proteins and enzymes implicated in

FOI 26-3132 - Document 5

antioxidant responses and in the restoration of DNA. In several models of senescent cells, a decreased expression of metallothioneins and intracellular Zn takes place (67).

There is a significant parallel between changes described in immunosenescence and those that are associated with Zn deficiency, among them a reduction of thymus activity and its hormones, a deviation of T helper cells to type TH2 cell activity, a decrease of the response to vaccines, and a deterioration of innate immune cell (phagocytes and NK cells) function (8). The role of Zn and metallothioneins is crucial as they affect NK/NKT development and function. In particular, some of the polymorphisms of metallothioneins are involved in maintaining the innate immune response. The availability of intracellular Zn in aging, many times decreased, compromises this response (68). It has also been demonstrated that Zn deficiency decreases the thymic hormone thymuline, which is necessary for the maturation of T helper cells. This, along with the deviation of the function of TH1 to TH2, causes dysfunction of the immune response mediated by cells (69). Zn is involved in the genetic expression of melatonin recipients and in the proliferation and apoptosis of cells of the thymus and the reactivation of thymuline (70).

Currently, Zn is regarded as a molecule of intracellular signposting, that is, its status becomes altered in response to an extracellular stimulus, acting like a neurotransmitter (71,72). Two types of intracellular signaling of Zn have been identified: an early one, which is induced directly by an extracellular stimulus, and a late one, that depends on changes of expression of the zinc carriers (73,74). In immune cells, the signaling of intracellular Zn modulates its activity (75,76) through the inhibition of NF-κB, a transcription factor that can control many genes of immune response (77,78). In its latent state, NF-κB is sequestered in the cytosol by inhibitory protein IkB, and it is stimulated through the activation of the Ik kinase (IKK) mediated by Zn (79). In cell culture studies, it has been observed that Zn leads protein A 20 that inhibits the enzyme IkB kinase (IKK). This enzyme is capable of inactivating NF-κB, causing a decrease of inflammatory cytokine generation (13,80).

The zinc carrier (ZIP 8) is a transcriptional target of NF-κB and negatively regulates the inflammatory response through modulation of the activity of IKK (80). Recent opinions suggest that during evolution, host defenses and the aging process have been intimately linked with the mechanisms and defensive factors related to the NF-κB system suggesting a common point between aging and immunosenescence (81). As part of new techniques of cell therapy, the induction of metallothioneins provides better protection of the cells because they act as antioxidant, antiinflammatory, and anti-apoptotic agents, increasing the transcriptional regulation of genes implicated in proliferation and cell differentiation (82). Experimental studies in mice, in particular mice with Zn deficiency, have consistently proven that expression of ZIP 8 is remarkably induced in immune innate cells at the beginning of infections with a concomitant increase of signals mediated by NF-κB. This was associated with increased inflammation and an increase in the severity of sepsis (83).

A system of signals has been described in monocytes where a complex interaction occurs among Zn, nitric oxide, cyclic nucleotide signaling, and the IL-1 receptor associated with kinase-1. These act against the production of inflammatory cytokines (84). Also, the function of dendritic cells is affected by disorders in the homeostasis of Zn implicating the transporting proteins (ZIP) during the upregulation induced by lipopolysaccharides and stimulating molecules (85). A study on the effect of Zn ions in the promonocytic leukemia HL-CZ cell line showed that treatment with Zn caused the release of chemokine and inflammatory cytokines through activation of multiple transcription factors related to the immune response (86). Figure 2 illustrates the role of Zn as a signal molecule in the immune system.

Immune cells show a decline in function when there is a decrease in Zn content. Cytotoxicity decreases in monocytes, phagocytosis is reduced in neutrophils, and in B cells apoptosis increases and standard functions of T cells deteriorate, but auto reactivity increases. This has been demonstrated in cell culture studies where the concentrations of Zn vary from 100 to 500 mmol (87). B and T cells with zinc deficiency reveal different patterns of reaction compared to Zn-sufficient cells, consistent with a strong proliferative response followed by stimulation of IL-6 and IL-2 in the first case, with less proliferation followed by stimulation of IL-4 in the second case (88). The closest link among aging, immunosenescence, and Zn deficiency seems to be through the oxi-inflamm-aging process. It has been documented that Zn deficiency increases oxidative stress and causes the generation of inflammatory cytokines, such as IL-1β IL-2, IL-6 and TNF α (1,10,13,14,19,53,61,62,89,90), both *in vitro* and *in vivo*.

Bao et al., using models of sepsis in small animals, noticed that Zn deficiency increased the number of bacteria and the activity of NF-κB in vital organs, including the lungs, with an increase in inflammation, pulmonary damage, and mortality. Zn supplementation right after the initiation of sepsis reversed these effects (91). Wong et al. also found in their studies on aged rats that Zn deficiency, particularly the reduction of intracellular Zn in immune cells, was associated with an increase in inflammation with increasing age (92).

Zinc supplementation in humans

There have been few studies on the effects of Zn supplementation on the human immune response. A clinical trial that included 55 people of both genders (aged between 57 and 87) who were supplemented daily with 45 mg of oral elementary zinc for 12 months reported that the

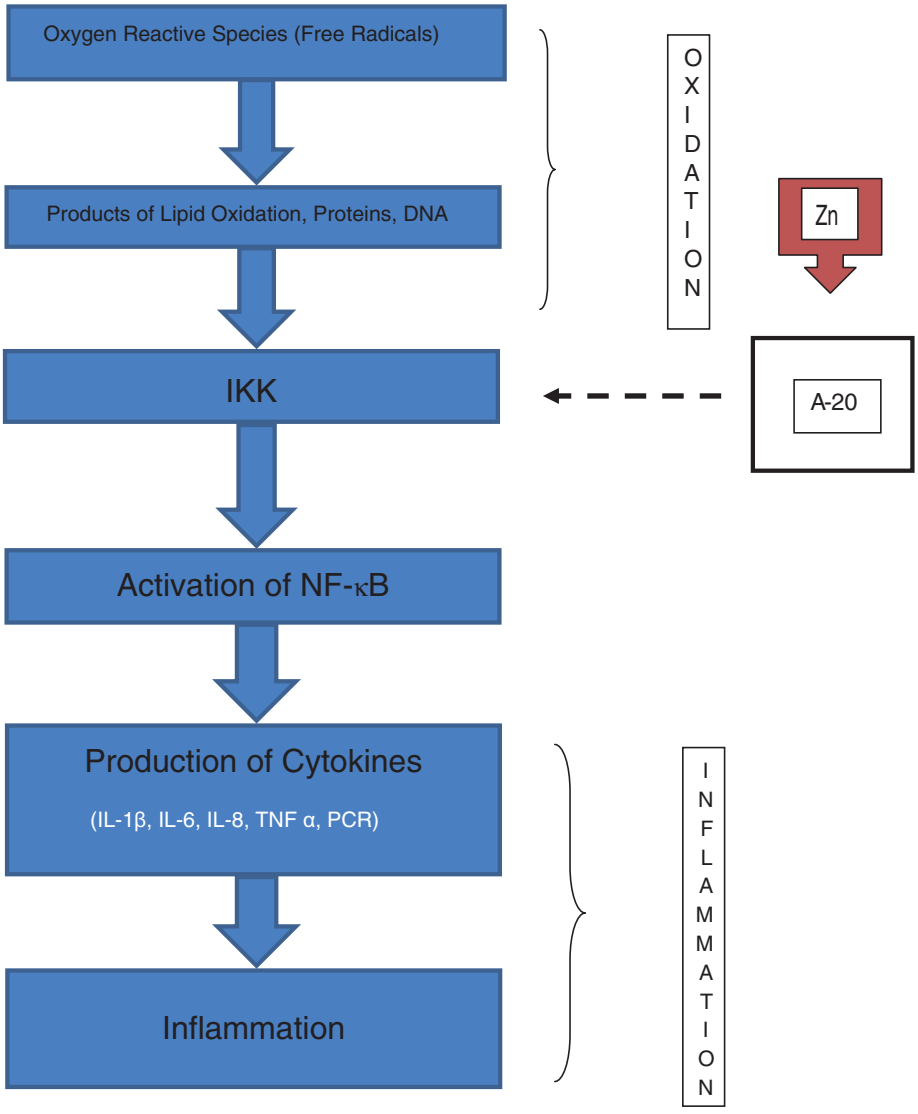

Fig. 2. Zinc, through the activation of protein A-20 inhibits (discontinuous arrow) the IkB kinase (IKK) causing inhibition of the inflammatory cascade. In zinc deficiency, the protein A-20 is 'free', and the activation of NF-κB and the generation of inflammatory cytokines are induced.

incidence of infections and the generation of oxidative stress markers and inflammatory cytokines were remarkably lower in the supplemented group than in the control group (93). Zn deficiency is common in adults suffering from sickle cell anemia. In a study that included 36 sickle cell patients, half received 25 mg of oral Zn once a day for 3 months and the rest a placebo. In the supplemented group, the incidence of infections and the induction of inflammatory cytokines (TNF α, IL-1 β) decreased, while the antioxidant power increased (as shown by a decrease in plasmatic nitrate and nitrite and the products of oxidation of lipids and DNA) (31).

An observational study performed including 420 residents of nursing homes in Boston compared the ones who had low levels of plasmatic Zn (<70 μg/dL) with those with normal levels (≥ 70 μg /dL). In those who had normal concentrations of zinc, the incidence of pneumonia was lower and of decreased duration, with less prescription of new antibiotics, fewer days with the use of antibiotics, and reduction of all causes mortality, compared with the low level group (94). To demonstrate the antiinflammatory and antioxidant effects of Zn, a double-blind randomized trial was performed in 40 people aged 56–83, distributed in a group that received 45 mg of oral Zn gluconate for 6 months and another that received a placebo. In the supplemented group, the inflammatory cytokines (PCR, IL 6) and the markers of oxidative stress (secretory phospholipase A, malondialdehyde, hydroxyalkenals) decreased (95). In a study of long-term hemodialysis patients who had concentrations of serum Zn below the normal (<80 mg/dL), those who were supplemented with Zn for 8 weeks showed remarkably larger percentages of CD4

FOI 26-3132 - Document 5

and CD19 lymphocytes, a higher proportion of CD4/CD8, and a decrease in the proportion Cu/Zn and of the oxidative stress and the inflammatory response (96).

The nutritional state of Zn can influence response to vaccination. A cross-sectional study of 80 elderly people who were inoculated with pneumococcal vaccine revealed that in those who prior to the vaccination had higher levels of Zn, the immune response (IgM) to the vaccine increased by over 10% (97). The supplementation of Zn in children with heart disorders vaccinated against influenza had beneficial effects in decreasing their discomfort (98), which is one of the adverse effects of this vaccine, and also decreased the serum levels of TNF-α. However, in another clinical study in which 140 elder people were vaccinated against hepatitis B, those who were supplemented with Zn sulfate did not show benefits in increasing immunity levels (99).

In an updated systematic review of Zn fortification in diet, only 11 studies were found including 771 participants, mainly children, none on the elderly, with reports of growth rate increase, mostly in those with low weight at birth (100). Efforts have been made to determine the effects of Zn supplements in diarrhea and pneumonia in children where they have demonstrated beneficial effects (18,101).

Other difficulties arise in planning the supplementation of Zn in the elderly, the daily needs vary among populations, the therapeutic dosages are not standardized, and over-administration of Zn can cause toxic effects and side effects on immunity (102). Zn toxicity is relatively unusual. High dietary intake can cause nausea, vomiting, epigastric pain, lethargy, fatigue, and a decline in the immune response, hypocupremia, neutropenia, macrocytic anemia, and sideroblastic anemia (59,103). Currently, it is thought that the evaluation of nutritional Zn is complex due to the fact that the biochemical measurements of this element have limitations in sensitivity and specificity (57). Recently, the measurement of Zn concentrations in fingernails has been used in a unique study in the elderly with and without Alzheimer's disease, but without finding significant differences between these two groups (104). Some authors consider that the selection of elderly people for the supplementation of Zn must be based on low blood concentrations. It is necessary to take into account the genetic background in relation to the polymorphisms of metallothioneins and IL-6. Elderly people who are bearers of the genotype GG (called C negative) in locus IL 6-147G/G develop high levels of IL-6 and metallothioneins, low contents of intracellular Zn, and deterioration of immunity and are the most adequate for Zn supplementation. The bearers of genotypes GC and CC (named C positive) have a satisfactory content of intracellular Zn, and its supplementation can be inappropriate (2,7,105).

Areas of uncertainty for further investigations

Based on what has been investigated thus far, some gaps remain which might be approached in future investigations.

1. A wide field is open relating to nutritional aspects that involve Zn as an essential trace element, and the clinical and biochemical aspects of its deficiency that contribute to a better evaluation and more precise determination of plasma concentrations.
2. The research on the pathogenic mechanisms of Zn deficiency in aging, frailty, immunosenescence, and age-related chronic and degenerative diseases should be continued, in addition to the search for possible therapeutic targets.
3. Clinical trials related to the effects of Zn and its deficiency in the health of the elderly are needed.
4. There is a need for more precise determination of elderly people at risk for Zn deficiency and compounds and ideal dosage for the supplementation of this element.
5. Further studies are needed to determine the efficiency of Zn in fighting infections in the elderly.

Conclusion

Zn is an essential micronutrient for human health in general, and particularly for the elderly, with evidence in cell culture experiments of its involvement as a signaling molecule in the oxidation and inflammatory process that occurs in cell senescence and in immune system dysfunction. Although the body of proof is limited in determining the efficacy of the supplementation of Zn in the prevention and treatment of infections and degenerative processes that accompany old age, promising perspectives are open in the homeostatic regulation of this trace element as a therapeutic objective and an attractive field of anti-aging research. Current evidence suggests that educating the elderly to consume an appropriate diet with foods that contain the necessary Zn requirements would be a health-promoting activity. Clinically, we should not lose sight of the nutritional demands of geriatric patients, taking into account the elements discussed in this review, which possess indisputable practice value.

Conflict of interest and funding

The author has not received any funding or benefits from industry or elsewhere to conduct this study.

The Advantages And Challenges Of Fixed-Dose Combination Products

Source: Cambrex

The advantages and challenges of fixed-dose combination products: Considerations for design, formulation, manufacturing and analysis

FDC products offer significant advantages for the pharmaceutical industry, including the potential to extend protection of patents and market share, reduce overall manufacturing costs, and add new NDAs to a company's drug development portfolio with shorter and less costly paths to regulatory approval.

The many advantages of fixed-dose combination (FDC) drug products have made them an increasingly attractive option for patients, pharmaceutical companies, physicians, and regulatory agencies. These potential benefits include, but are not limited to, better patient compliance, more convenient dosing associated with improved clinical performance, cost savings for both patients (fewer co-pays) and drug manufacturers (reduced production costs), and extended patent protection and market positioning in the face of competition from generics. These advantages cannot be taken for granted, however. Producing safe and effective FDC products that are also cost-effective and have a high probability of a regulatory approval requires thoughtful product design, access to state-of-the-art formulation and manufacturing technology, and advanced analytical tools.

Introduction

Understanding both the significant competitive advantages that FDC products can offer and the difficulties and potential pitfalls associated with development and manufacturing of FDC drugs in oral solid dosage forms is a critical first step for companies exploring this approach. Recognizing that cost savings, lower risk, and accelerated timelines can be achieved by partnering with a CDMO that has a proven track record of successfully producing FDC products is an important next step. Cambrex has collaborated and partnered with pharmaceutical customers to develop and manufacture FDC drugs that are US FDA approved and are currently in the various stages of clinical development. The experience, know-how, and team of skilled experts that Cambrex brings to these partnerships, combined with its wide range of specialized equipment and technological competencies, ensure the production of high quality FDC drug products that meet their clinical endpoints and receive final approvals from regulatory agencies.

Over the past decade, we have established a vast knowledge base in the area of FDC drugs. Cambrex continues to expand our formulation and manufacturing capabilities through collaborative agreements and by bringing on-stream specialty equipment to enable the production of FDCs. Some examples include hot melt extrusion, wet granulation/ roller compaction, extrusion-spheronization, and fluid bed technology. These manufacturing capabilities provide greater flexibility for our clients in terms of a variety of manufacturing platforms for the production of FDC oral solid dosage forms. These choices include multi-layer tablets, mini-tablets that can be compressed together or combined in capsules, sachets, or stick packs, and microparticulate systems filled into capsules. Cambrex also offers a variety of polymer-coating options to enable controlled release of the different drug substances in an FDC product. Cambrex also has hands-on experience in taste masking that relies on ion exchange technology.

More FDC products flowing into pharma pipelines

The numbers tell the story. Pharmaceutical companies – and the FDA – are embracing FDCs. From 1990 through 2013, the FDA approved 131 FDC products, on average 5.7 per year, the largest number targeting indications related to cardiovascular disease, followed by endocrinology products and treatments for infectious diseases.[1] Of those 131 approved FDCs, 98 were oral dosage forms.

Between 2010 and the end of 2015, of the 655 New Drug Applications (NDAs) approved by the FDA, 63 were for FDCs.[2] This represents nearly 10% of the NDAs approved during that 5-year period and, on average, 12.6 new FDC products per year. As the numbers of FDC products in development and coming to the market increase, the pharmaceutical industry is looking to FDCs as a promising strategy to repurpose, repackage, and expand indications for existing and novel therapeutic agents. The potential to extend the patent life and market exclusivity of a company's APIs is a potent financial incentive.

FDC products can extend patent life and market dominance

Downloading for conversion...
The Advantages And Challenges ...

For pharmaceutical companies, FDC products represent an attractive strategy to gain additional patent protection and market exclusivity for a drug approaching patent expiration. "In the US, if an FDC is novel, nonobvious, d the exclusion of competitors from the market can be enforced."[3] Further, "The FDA provides three years of market exclusivity to new [new molecular entity] NME-FDC when the application contains new clinical investigations. If the r ıt and exclusivity life of the FDC will typically be equal to the three year market exclusivity or the of the individual components."[3]

Cambrex et al. compared the effective patent and exclusivity life of FDCs with that of single active ingredients from 1980 through 2012.[3] The FDA approved 28 FDC products containing a NME and 117 FDC products containing only already approved products during the study period. Overall, FDC products without a NME added a median of 9.7 years of patent and market exclusivity protection to that of the single active ingredients. When the company producing the non-NME-FDC was also the sponsor of the single ingredient drugs included in the combination, the non-NME-FDC added a median of 7.73 years; whereas, if those companies differed, the non-NME-FDC added a median of 11.48 years of patent and market exclusivity protection.

Improved convenience and safety

Among the numerous advantages FDCs offer patients, physicians, and pharmaceutical companies, several are particularly noteworthy. One of these is convenience. For patients affected by diseases that require treatment with multiple medications, replacing two or three pills with a single pill can substantially reduce a patient's pill burden. Examples include hypertension (often treated with a combination of beta blockers, ACE inhibitors, and diuretics), diabetes, HIV and other viral infections (typically treated with multi-drug cocktails), cholesterol disorders, and cancer. Pain management is another therapeutic area in which FDCs are gaining increased attention. An emerging strategy combines an opioid drug with an opioid antagonist to counter the "high" brought on by the opioid. This approach achieves effective pain relief, but with a reduced risk of addiction. In addition, FDCs can be used to develop abuse deterrent formulations (ADFs).

FDC products comprise multiple drug substances that are taken in a single dose. The components of an FDC cannot be changed or separated. A physician can prescribe more or less of the combination product, but the ratio of the individual drug components cannot be altered. As a result, FDC products may help prevent medication errors and enable better control of dosing. Dosing is not left up to physicians; it is built into the FDC product and based on clinical trial results.

The goal of combination drug treatment is not only the delivery of two or more therapeutic agents that have different mechanisms of action. FDC products can also take advantage of potential synergistic effects between the individual drug substances, which could improve overall effectiveness and perhaps allow for simplified and reduced dosing, which may lower the risk of adverse effects.

Cost savings

A decreased pill burden is only one example of how FDCs are more convenient for patients. Replacing two or three pills with a single FDC drug product also translates into less time spent filling (and refilling) prescriptions. With an FDC product, physician offices also have fewer prescriptions and renewals to process. Taking this a step further, fewer prescriptions means fewer co-pays for patients, saving them money. Theoretically, at least, pharmaceutical companies should also be able to save money producing a single-dose FDC product, compared to what it would cost to manufacture, package, and market two or three individual drugs.

Accelerated regulatory pathway

Furthermore, compared to the cost of developing a new API, substantial savings can be realized when developing an FDC comprised of previously approved new chemical entities or their generic counterparts. The FDA allows for an abbreviated clinical development program that can speed the path to approval if sufficient drug safety and tolerability data and supporting efficacy data are already available. Companies can save valuable time and resources as well by taking advantage of the FDA's 505(b)(2) approval pathway.

Over the past several years, many approved FDC products have used the 505(b)(2) pathway. In more than half of those cases, the companies still had to perform at least some Phase II and III clinical studies.[4] Specifically, about two thirds of the FDCs approved using the 505(b)(2) route have required at least one Phase II or Phase III study, and approximately one-third needed more than four Phase II/III studies.[4]

> Examples of FDA-approved oral solid dosage form FDC products that greatly reduce the pill burden for patients with HIV infection are:
>
> - Gilead's Genvoya (elvitegravir 150mg/obicistat 150mg/emtricitabine 200mg/tenofovir alafenamide 10mg)
> - Viiv Healthcare's Triumeq (abacavir 600mg/ dolutegravir 50mg/lamivudine 300mg)

An updated European Medicines Agency (EMA) guideline on the clinical development of FDC drugs is expected to be issued during the fourth quarter of 2017. It details the evidence that companies need to present to support authorization of FDCs that contain two or more already approved or new active substances, whether small molecule drugs or biologics.[5] Initially adopted in March 2017, the newly revised EMA guidelines require data to "support the rationale for combined use of the active substances." Simply providing previous evidence of combined use "will not suffice to establish the positive benefit/risk of the combination."

FOI 26-3132 - Document 5

Adobe Acrobat

Downloading for conversion...

The Advantages And Challenges …

The EMA states: "Specific considerations apply for fixed combination medicinal products where the active substances have different – but related – therapeutic indications and different pharmacological targets, e.g. a fixed combinatic patients at high cardiovascular risk containing a lipid-modifying agent and an antihypertensive agent. A relevant contribution of all active substances and existence of a positive benefit/risk for these fixed combination medicinal Furthermore, "as a minimum requirement, in the absence of clinical trial data studying the spec combination on clinical outcome, the potential for PK and PD interactions should be establishec individual active substances may be modified by their combination. Usually, PK data (a DDI study) will suffice."

Developing and manufacturing FDCs factors to consider

At the outset, when designing an FDC drug, API selection is the foundation on which creating a successful product rests. Selecting the APIs to include in a two-drug or three-drug FDC product should focus on maximizing the benefit-to-risk ratio by identifying combinations that have the potential to improve efficacy while avoiding any new safety or tolerability issues. Key drivers for pharmaceutical companies include the ability to repurpose already approved therapeutic agents with a low risk of toxicity, to combine and repackage drugs commonly prescribed together, and to pair their APIs with popular off-patent drugs or generic compounds.

Important factors to consider in designing an FDC product include the following:

- Differing pharmacokinetic and target release profiles of the component drug substances
- Physical and chemical compatibility of the APIs
- The target patient population (age, severity of illness and/or disability)
- The full range of oral solid dosage form options
- Total development and production costs, including formulation, manufacturing, and packaging

Collaboration with ExxPharma Therapeutics

Hot melt extrusion is a technique used to enhance the solubility of drug substances. Cambrex entered into a collaboration with ExxPharma Therapeutics LCC, a pioneer in HME, to apply the technique in the development and manufacturing of drug products. The aim of HME is to minimize exposure of a drug substance to elevated temperatures during manufacturing – temperatures above a drug's melting point that could lead to degradation. HME may offer the advantage of higher drug loading versus a spray-dried dispersion containing the same API. This is particularly useful in an FDC where higher drug loading may be necessary. HME also helps ensure the stability of a drug substance by eliminating air during melt extrusion, thereby limiting oxidative degradation.

HME technology offers additional advantages as well as:[6]

- *Small footprint of the extruder*
- *Process uses no organic solvents, is continuous, and is easily scalable*
- *HME does not require an extra densification step*
- *Unlike with spray-dried solid dispersion technology, the material generated can be blended directly with other FDC components and compressed into tablets*

The use of HME to produce FDC drug products simplifies technology transfer and scale-up, accelerating the time to market, and contributes to improved overall product quality.

Working with a CDMO partner

Theoretically, at least, there should be a cost advantage in the production of a single FDC drug compared to the costs of manufacturing, analyzing, testing, packaging, and marketing two or three individual products. However, the need for specialized equipment and advanced methods and technologies across the formulation, analytical, and manufacturing workflows in order to produce these more complex combination dosage forms can increase capital equipment costs. Outsourcing FDC product formulation and manufacturing, and partnering with an experienced CDMO that has the infrastructure, capital equipment (and competency to run said equipment), technology, and skilled personnel can reduce the costs – both capital (capex) and operating (opex) expenses – and the risks associated with creating high quality FDC products.

The main challenges in FDC product development, which a knowledgeable CDMO partner can help overcome, include the following:

- Designing a stable formulation
- Optimizing the bioavailability and delivery of the individual drug substances
- Understanding the potential for – and avoiding – unwanted interactions and interferences between the API components
- Acquiring the necessary capital equipment – investment of millions of dollars in new equipment required for production of an FDC product

Access to Cambrex's wide range of formulation and manufacturing technologies allows our sponsor partners to identify the most appropriate, efficient, and cost-effective development approach for any particular FDC product. Cambrex can apply all of its technologies and approaches from development scale (500g) through to full-scale commercial manufacturing. This high degree of

FOI 26-3132 - Document 5

flexibility, combined with ease of access to the equipment and technological resources all in one location, not only helps ensure a productive and highly collaborative partnership, but also allows Cambrex to offer aggressive timel

Adobe Acrobat

Downloading for conversion...

The Advantages And Challenges …

Cambrex's specialized equipment and techniques include bilayer presses, wet granulation/rolle solvent pellet layering, and extrusion-spheronization. Through a partnership with ExxPharma T lt extrusion (see "Collaboration with ExxPharma Therapeutics") to improve manufacturing of dru ıtive formulation development and cutting-edge manufacturing technology, Cambrex can create solid dosage forms that include multi-layer tablets, tablet-in-tablet configurations, mini-tablets, and microparticulate systems. Mini-tablets can be combined in capsules, or packaged into sachets or stick packs for resuspension and use in pediatric delivery systems. Similarly, microparticulate systems of individual APIs can be combined in various dosage forms and strengths for adult or pediatric dosing.

Cambrex can use a range of polymer coating techniques to segregate FDC product components that may be incompatible and to provide sustained- or delayed release control of component APIs. Traditional sugar and polymer-coating methods and Cambrex's novel ion exchange technique offer a range of effective options for taste masking.

Cambrex has in place a full range of analytical capabilities to develop and validate stability-indicating methods for final release of an FDC product. One commonly used technique is ultra-high pressure liquid chromatography (UPLC), which is very effective in separating actives and their respective related substances. The ability to use a single analytical method to obtain the necessary data reduces the time and cost associated with generating final or stability quality control (QC) results.

Finally, from a regulatory perspective, Cambrex's strong record of collaborating with pharmaceutical companies to bring FDC products to the market includes the knowledge and experience in gathering and preparing the data and accompanying analysis and reports needed for regulatory filing.

Conclusions

A recent case study describing specific projects that Cambrex completed for two large pharmaceutical customers demonstrates the broad-ranging technological capabilities and expertise Cambrex can offer.7 In one collaboration, Cambrex developed and manufactured a complex three-API FDC product in which one of the APIs was incompatible with the other 2. In the second project, the challenge involved combining 2 APIs with different release profiles. These examples, and the creative solutions Cambrex was able to deliver using multi-layer tablets, mini-tablets, and polymer-coating technology, exemplify the novel types of FDC products on the market and in development that offer important advantages for patients, physicians, and the pharmaceutical industry.

The FDA-approved drug ivermectin inhibits the replication of SARS-CoV-2 *in vitro*

Leon Caly[a], Julian D. Druce[a], Mike G. Catton[a], David A. Jans[b], Kylie M. Wagstaff[b,*]

[a] *Victorian Infectious Diseases Reference Laboratory, Royal Melbourne Hospital, At the Peter Doherty Institute for Infection and Immunity, Victoria, 3000, Australia*
[b] *Biomedicine Discovery Institute, Monash University, Clayton, Vic, 3800, Australia*

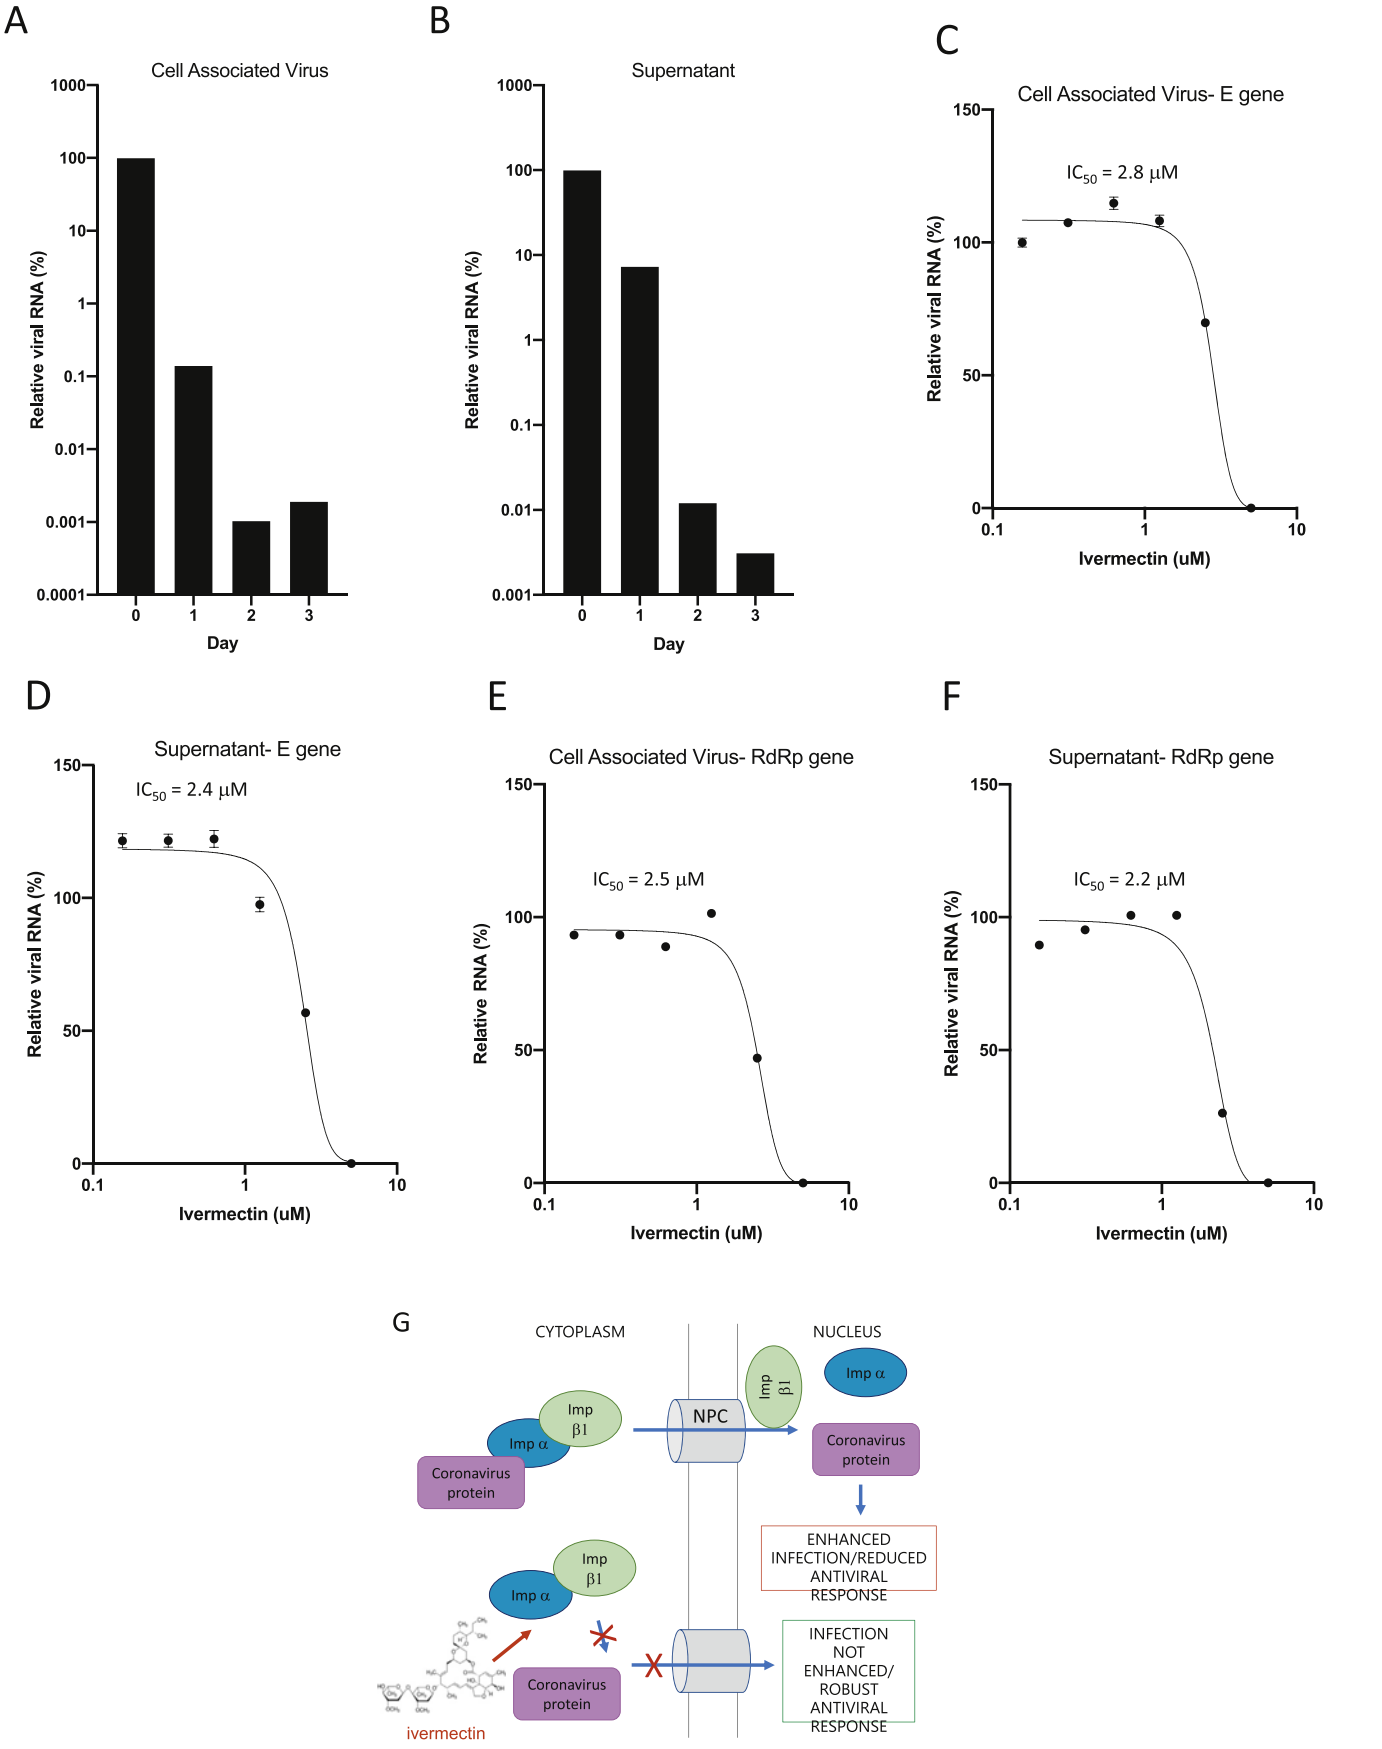
A B S T R A C T

Although several clinical trials are now underway to test possible therapies, the worldwide response to the COVID-19 outbreak has been largely limited to monitoring/containment. We report here that Ivermectin, an FDA-approved anti-parasitic previously shown to have broad-spectrum anti-viral activity *in vitro*, is an inhibitor of the causative virus (SARS-CoV-2), with a single addition to Vero-hSLAM cells 2 h post infection with SARS-CoV-2 able to effect ~5000-fold reduction in viral RNA at 48 h. Ivermectin therefore warrants further investigation for possible benefits in humans.

1. Introduction

Ivermectin is an FDA-approved broad spectrum anti-parasitic agent (Gonzalez Canga et al., 2008) that in recent years we, along with other groups, have shown to have anti-viral activity against a broad range of viruses (Gotz et al., 2016; Lundberg et al., 2013; Tay et al., 2013; Wagstaff et al., 2012) *in vitro*. Originally identified as an inhibitor of interaction between the human immunodeficiency virus-1 (HIV-1) integrase protein (IN) and the importin (IMP) α/β1 heterodimer responsible for IN nuclear import (Wagstaff et al., 2011), Ivermectin has since been confirmed to inhibit IN nuclear import and HIV-1 replication (Wagstaff et al., 2012). Other actions of ivermectin have been reported (Mastrangelo et al., 2012), but ivermectin has been shown to inhibit nuclear import of host (eg. (Kosyna et al., 2015; van der Watt et al., 2016)) and viral proteins, including simian virus SV40 large tumour antigen (T-ag) and dengue virus (DENV) non-structural protein 5 (Wagstaff et al., 2012, Wagstaff et al., 2011). Importantly, it has been demonstrated to limit infection by RNA viruses such as DENV 1-4 (Tay et al., 2013), West Nile Virus (Yang et al., 2020), Venezuelan equine encephalitis virus (VEEV) (Lundberg et al., 2013) and influenza (Gotz et al., 2016), with this broad spectrum activity believed to be due to the reliance by many different RNA viruses on IMPα/β1 during infection (Caly et al., 2012; Jans et al., 2019). Ivermectin has similarly been shown to be effective against the DNA virus pseudorabies virus (PRV) both *in vitro* and *in vivo*, with ivermectin treatment shown to increase survival in PRV-infected mice (Lv et al., 2018). Efficacy was not observed for ivermectin against Zika virus (ZIKV) in mice, but the authors acknowledged that study limitations justified re-evaluation of ivermectin's anti-ZIKV activity (Ketkar et al., 2019). Finally, ivermectin was the focus of a phase III clinical trial in Thailand in 2014–2017, against DENV infection, in which a single daily oral dose was observed to be safe and resulted in a significant reduction in serum levels of viral NS1 protein, but no change in viremia or clinical benefit was observed (see below) (Yamasmith et al., 2018).

The causative agent of the current COVID-19 pandemic, SARS-CoV-2, is a single stranded positive sense RNA virus that is closely related to severe acute respiratory syndrome coronavirus (SARS-CoV). Studies on SARS-CoV proteins have revealed a potential role for IMPα/β1 during infection in signal-dependent nucleocytoplasmic shutting of the SARS-CoV Nucleocapsid protein (Rowland et al., 2005; Timani et al., 2005; Wulan et al., 2015), that may impact host cell division (Hiscox et al., 2001; Wurm et al., 2001). In addition, the SARS-CoV accessory protein ORF6 has been shown to antagonize the antiviral activity of the STAT1 transcription factor by sequestering IMPα/β1 on the rough ER/Golgi membrane (Frieman et al., 2007). Taken together, these reports suggested that ivermectin's nuclear transport inhibitory activity may be effective against SARS-CoV-2.



To test the antiviral activity of ivermectin towards SARS-CoV-2, we infected Vero/hSLAM cells with SARS-CoV-2 isolate Australia/VIC01/2020 at an MOI of 0.1 for 2 h, followed by the addition of 5 μM ivermectin. Supernatant and cell pellets were harvested at days 0–3 and analysed by RT-PCR for the replication of SARS-CoV-2 RNA (Fig. 1A/B).

(caption on next page)

Fig. 1. Ivermectin is a potent inhibitor of the SARS-CoV-2 clinical isolate Australia/VIC01/2020. Vero/hSLAM cells were in infected with SARS-CoV-2 clinical isolate Australia/VIC01/2020 (MOI = 0.1) for 2 h prior to addition of vehicle (DMSO) or Ivermectin at the indicated concentrations. Samples were taken at 0–3 days post infection for quantitation of viral load using real-time PCR of cell associated virus (**A**) or supernatant (**B**). IC_{50} values were determined in subsequent experiments at 48 h post infection using the indicated concentrations of Ivermectin (treated at 2 h post infection as per **A/B**). Triplicate real-time PCR analysis was performed on cell associated virus (**C/E**) or supernatant (**D/F**) using probes against either the SARS-CoV-2 E (**C/D**) or RdRp (**E/F**) genes. Results represent mean ± SD (n = 3). 3 parameter dose response curves were fitted using GraphPad prism to determine IC_{50} values (indicated). **G.** Schematic of ivermectin's proposed antiviral action on coronavirus. IMPα/β1 binds to the coronavirus cargo protein in the cytoplasm (top) and translocates it through the nuclear pore complex (NPC) into the nucleus where the complex falls apart and the viral cargo can reduce the host cell's antiviral response, leading to enhanced infection. Ivermectin binds to and destabilises the Impα/β1 heterodimer thereby preventing Impα/β1 from binding to the viral protein (bottom) and preventing it from entering the nucleus. This likely results in reduced inhibition of the antiviral responses, leading to a normal, more efficient antiviral response.

At 24 h, there was a 93% reduction in viral RNA present in the supernatant (indicative of released virions) of samples treated with ivermectin compared to the vehicle DMSO. Similarly a 99.8% reduction in cell-associated viral RNA (indicative of unreleased and unpackaged virions) was observed with ivermectin treatment. By 48 h this effect increased to an ~5000-fold reduction of viral RNA in ivermectin-treated compared to control samples, indicating that ivermectin treatment resulted in the effective loss of essentially all viral material by 48 h. Consistent with this idea, no further reduction in viral RNA was observed at 72 h. As we have observed previously (Lundberg et al., 2013; Tay et al., 2013; Wagstaff et al., 2012), no toxicity of ivermectin was observed at any of the timepoints tested, in either the sample wells or in parallel tested drug alone samples.

To further determine the effectiveness of ivemectin, cells infected with SARS-CoV-2 were treated with serial dilutions of ivermectin 2 h post infection and supernatant and cell pellets collected for real-time RT-PCR at 48 h (Fig. 1C/D). As above, a > 5000 reduction in viral RNA was observed in both supernatant and cell pellets from samples treated with 5 μM ivermectin at 48 h, equating to a 99.98% reduction in viral RNA in these samples. Again, no toxicity was observed with ivermectin at any of the concentrations tested. The IC50 of ivermectin treatment was determined to be ~2 μM under these conditions. Underlining the fact that the assay indeed specifically detected SARS-CoV-2, RT-PCR experiments were repeated using primers specific for the viral RdRp gene (Fig. 1E/F) rather than the E gene (above), with nearly identical results observed for both released (supernatant) and cell-associated virus.

Taken together these results demonstrate that ivermectin has antiviral action against the SARS-CoV-2 clinical isolate *in vitro*, with a single dose able to control viral replication within 24–48 h in our system. We hypothesise that this is likely through inhibiting IMPα/β1-mediated nuclear import of viral proteins (Fig. 1G), as shown for other RNA viruses (Tay et al., 2013; Wagstaff et al., 2012; Yang et al., 2020); confirmation of this mechanism in the case of SARS-CoV-2, and identification of the specific SARS-CoV-2 and/or host component(s) impacted (see (Yang et al., 2020)) is an important focus future work in this laboratory. Ultimately, development of an effective anti-viral for SARS-CoV-2, if given to patients early in infection, could help to limit the viral load, prevent severe disease progression and limit person-person transmission. Benchmarking testing of ivermectin against other potential antivirals for SARS-CoV-2 with alternative mechanisms of action (Dong et al., 2020; Elfiky, 2020; Gordon et al., 2020; Li and De Clercq, 2020; Wang et al., 2020) would thus be important as soon as practicable. This Brief Report raises the possibility that ivermectin could be a useful antiviral to limit SARS-CoV-2, in similar fashion to those already reported (Dong et al., 2020; Elfiky, 2020; Gordon et al., 2020; Li and De Clercq, 2020; Wang et al., 2020); until one of these is proven to be beneficial in a clinical setting, all should be pursued as rapidly as possible.

Ivermectin has an established safety profile for human use (Gonzalez Canga et al., 2008; Jans et al., 2019; Buonfrate et al., 2019), and is FDA-approved for a number of parasitic infections (Gonzalez Canga et al., 2008; Buonfrate et al., 2019). Importantly, recent reviews and meta-analysis indicate that high dose ivermectin has comparable safety as the standard low-dose treatment, although there is not enough evidence to make conclusions about the safety profile in pregnancy (Navarro et al., 2020; Nicolas et al., 2020). The critical next step in further evaluation for possible benefit in COVID-19 patients will be to examine a multiple addition dosing regimen that mimics the current approved usage of ivermectin in humans. As noted, ivermectin was the focus of a recent phase III clinical trial in dengue patients in Thailand, in which a single daily dose was found to be safe but did not produce any clinical benefit. However, the investigators noted that an improved dosing regimen might be developed, based on pharmacokinetic data (Yamasmith et al., 2018). Although DENV is clearly very different to SARS-CoV-2, this trial design should inform future work going forward. Altogether the current report, combined with a known-safety profile, demonstrates that ivermectin is worthy of further consideration as a possible SARS-CoV-2 antiviral.

2. Methods

2.1. Cell culture, viral infection and drug treatment

Vero/hSLAM cells (Ono et al., 2001) were maintained in Earle's Minimum Essential Medium (EMEM) containing 7% Fetal Bovine Serum (FBS) (Bovogen Biologicals, Keilor East, AUS) 2 mM L-Glutamine, 1 mM Sodium pyruvate, 1500 mg/L sodium bicarbonate, 15 mM HEPES and 0.4 mg/ml geneticin at 37 °C, 5% CO_2. Cells were seeded into 12-well tissue culture plates 24 h prior to infection with SARS-CoV-2 (Australia/VIC01/2020 isolate) at an MOI of 0.1 in infection media (as per maintenance media but containing only 2% FBS) for 2 h. Media containing inoculum was removed and replaced with 1 mL fresh media (2% FBS) containing Ivermectin at the indicated concentrations or DMSO alone and incubated as indicated for 0–3 days. At the appropriate timepoint, cell supernatant was collected and spun for 10 min at 6,000 g to remove debris and the supernatant transferred to fresh collection tubes. The cell monolayers were collected by scraping and resuspension into 1 mL fresh media (2% FBS). Toxicity controls were set up in parallel in every experiment on uninfected cells.

2.2. Generation of SARS-CoV-2 cDNA

RNA was extracted from 200 μL aliquots of sample supernatant or cell suspension using the QIAamp 96 Virus QIAcube HT Kit (Qiagen, Hilden, Germany) and eluted in 60 μl. Reverse transcription was performed using the BioLine SensiFAST cDNA kit (Bioline, London, United Kingdom), total reaction mixture (20 μl), containing 10 μL of RNA extract, 4 μl of 5x TransAmp buffer, 1 μl of Reverse Transcriptase and 5 μl of Nuclease free water. The reactions were incubated at 25 °C for 10 min, 42 °C for 15 min and 85 °C for 5 min.

2.3. Detection of SARS-CoV-2 using a TaqMan Real-time RT-PCR assay

TaqMan RT-PCR assay were performed using 2.5 μl cDNA, 10 μl Primer Design PrecisonPLUS qPCR Master Mix 1 μM Forward (5′- AAA TTC TAT GGT GGT TGG CAC AAC ATG TT-3′), 1 μM Reverse (5′- TAG GCA TAG CTC TRT CAC AYT T-3′) primers and 0.2 μM probe (5′-FAM-TGG GTT GGG ATT ATC-MGBNFQ-3′) targeting the BetaCoV RdRp (RNA-dependent RNA polymerase) gene or Forward (5′-ACA GGT ACG

TTA ATA GTT AAT AGC GT -3′), 1 μM Reverse (5′-ATA TTG CAG CAG TAC GCA CAC A-3′) primers and 0.2 μM probe (5′-FAM-ACA CTA GCC ATC CTT ACT GCG CTT CG-286 NFQ-3′) targeting the BetaCoV E-gene (Corman et al., 2020). Real-time RT-PCR assays were performed on an Applied Biosystems ABI 7500 Fast real-time PCR machine (Applied Biosystems, Foster City, CA, USA) using cycling conditions of 95 °C for 2 min, 95 °C for 5 s, 60 °C for 24 s. SARS-CoV-2 cDNA (Ct~28) was used as a positive control. Calculated Ct values were converted to fold-reduction of treated samples compared to control using the ΔCt method (fold changed in viral RNA = 2^ΔCt) and expressed as % of DMSO alone sample. IC50 values were fitted using 3 parameter dose response curves in GraphPad prism.

Zinc sulfate in combination with a zinc ionophore may improve outcomes in hospitalized COVID-19 patients

Philip M. Carlucci[1], Tania Ahuja[2], Christopher Petrilli[1,3], Harish Rajagopalan[3], Simon Jones[4,5] and Joseph Rahimian[1,*]

Abstract

Introduction. COVID-19 has rapidly emerged as a pandemic infection that has caused significant mortality and economic losses. Potential therapies and prophylaxis against COVID-19 are urgently needed to combat this novel infection. As a result of *in vitro* evidence suggesting zinc sulphate may be efficacious against COVID-19, our hospitals began using zinc sulphate as add-on therapy to hydroxychloroquine and azithromycin.

Aim. To compare outcomes among hospitalized COVID-19 patients ordered to receive hydroxychloroquine and azithromycin plus zinc sulphate versus hydroxychloroquine and azithromycin alone.

Methodology. This was a retrospective observational study. Data was collected from medical records for all patients with admission dates ranging from 2 March 2020 through to 11 April 2020. Initial clinical characteristics on presentation, medications given during the hospitalization, and hospital outcomes were recorded. The study included patients admitted to any of four acute care NYU Langone Health Hospitals in New York City. Patients included were admitted to the hospital with at least one positive COVID-19 test and had completed their hospitalization. Patients were excluded from the study if they were never admitted to the hospital or if there was an order for other investigational therapies for COVID-19.

Results. Patients taking zinc sulphate in addition to hydroxychloroquine and azithromycin (n=411) and patients taking hydroxychloroquine and azithromycin alone (n=521) did not differ in age, race, sex, tobacco use or relevant comorbidities. The addition of zinc sulphate did not impact the length of hospitalization, duration of ventilation or intensive care unit (ICU) duration. In univariate analyses, zinc sulphate increased the frequency of patients being discharged home, and decreased the need for ventilation, admission to the ICU and mortality or transfer to hospice for patients who were never admitted to the ICU. After adjusting for the time at which zinc sulphate was added to our protocol, an increased frequency of being discharged home (OR 1.53, 95% CI 1.12–2.09) and reduction in mortality or transfer to hospice among patients who did not require ICU level of care remained significant (OR 0.449, 95% CI 0.271–0.744).

Conclusion. This study provides the first *in vivo* evidence that zinc sulphate may play a role in therapeutic management for COVID-19.

INTRODUCTION

The World Health Organization has declared a pandemic due to the spread of the coronavirus disease of 2019 (COVID-19) caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV2) [1, 2]. Despite limited and conflicting data, the U.S. Food and Drug Administration authorized the emergency use of hydroxychloroquine for the treatment of COVID-19 with or without azithromycin. Hydroxychloroquine was thought to be efficacious partly based on *in vitro* activity against SARS-CoV-2 [3]. However, clinical data in humans has yielded mixed and disappointing results [4–7]. In spite of this, hydroxychloroquine may still have a role at blocking coronavirus replication, when used in combination with zinc, which inhibits coronavirus RNA polymerase activity.

Zinc is an essential trace element that is required for the maintenance of adaptive and innate immune responses [8].

The benefits of zinc have previously been recognized for its therapeutic use against other respiratory viruses including those that cause the common cold [9–11]. Zinc has also been observed to improve pneumonia in children and its deficiency is associated with pneumonia in the elderly [9, 12, 13]. Implicating a role for zinc in COVID-19, zinc inhibits viral RNA-dependent RNA polymerase, and has been shown to do this *in vitro* against SARS-CoV [14]. When combined with a zinc ionophore, such as hydroxychloroquine, cellular uptake is increased making it more likely to achieve suitably elevated intracellular zinc concentrations for viral inhibition [10, 15]. This combination is already being tested as a prophylactic regimen in a prospectively followed cohort (NCT04326725) and in a randomized clinical trial (NCT04377646). Other trials are also investigating this regimen for therapeutic efficacy (NCT04370782, NCT04373733).

As New York became the epicentre of the pandemic, hospitals in the area quickly adopted investigational therapies, including the use of hydroxychloroquine and azithromycin. Given this proposed synergistic effect of zinc with hydroxychloroquine, practices at NYULH changed and the addition of zinc sulphate 220 mg PO BID along with hydroxychloroquine 400 mg once followed by 200 mg PO BID with azithromycin 500 mg once daily became part of the treatment approach for patients admitted to the hospital with COVID-19. This study sought to investigate outcomes among patients who received hydroxychloroquine and azithromycin alone compared to those who received triple therapy of hydroxychloroquine and azithromycin plus zinc sulphate.

METHODS

We performed a retrospective analysis of data from patients hospitalized with confirmed SARS-CoV-2 infection at NYU Langone Health. Data was collected from electronic medical records (Epic Systems, Verona, WI, USA) for all patients being treated with admission dates ranging from 2 March 2020 through 11 April 2020. Patients were admitted to any of four acute care NYU Langone Health hospitals across New York City. COVID-19 positivity was determined by real-time reverse-transcriptase PCR (RT-PCR) of nasopharyngeal or oropharyngeal swabs.

Patients were included in the study if they were admitted to the hospital, had at least one positive test for COVID-19, were ordered to receive hydroxychloroquine and azithromycin, and had either been discharged from the hospital, transitioned to hospice or expired. Patients were excluded from the study if they were never admitted to the hospital or if there was an order for other investigational therapies for COVID-19, including tocilizumab, nitazoxanide, rituximab, anakinra, remdesivir or lopinavir/ritonavir during the course of their hospitalization to avoid potential confounding effects of these medications. We collected demographics as reported by the patient and any past medical history of hypertension, hyperlipidemia, coronary artery disease, heart failure, chronic obstructive pulmonary disease, asthma, malignancy other than non-melanoma skin malignancy and diabetes. We also recorded vital signs on admission, the first set of laboratory results as continuous variables, and relevant medications as categorical variables, including NSAIDs, anticoagulants, antihypertensive medications and corticosteroids ordered at any point during the course of the hospitalization. We compared clinical outcomes of patients who received a combination of zinc sulphate plus hydroxychloroquine, a zinc ionophore, to those that received hydroxychloroquine without zinc supplementation.

Statistics

Patients were categorized based on their exposure to hydroxychloroquine (400 mg load followed by 200 mg twice daily for 5 days) and azithromycin (500 mg once daily) alone or with zinc sulphate (220 mg capsule containing 50 mg elemental zinc twice daily for 5 days) as treatment in addition to standard supportive care. Descriptive statistics are presented as mean and standard deviation or mean and interquartile range for continuous variables and frequencies for categorical variables. Normality of distribution for continuous variables was assessed by measures of skewness and kurtosis, deeming the dataset appropriate for parametric or nonparametric analysis. A two-tailed Student's *t*-test was used for parametric analysis, and a Mann–Whitney U test was used for nonparametric data analysis. Pearson's chi-squared test was used to compare categorical characteristics between the two groups of patients. Linear regression for continuous variables or logistic regression for categorical variables was performed with the presence of zinc as the predictor variable and outcome measures [duration of hospital stay, duration of mechanical ventilation, maximum oxygen flow rate, average oxygen flow rate, average FiO2, maximum FiO2, admission to the intensive care unit (ICU), duration of ICU stay, death/hospice, need for intubation, and discharge destination], as dependent variables. Data was log transformed where appropriate to render the distribution normal for linear regression analysis. Multivariate logistic regression was used to adjust for the timing that our protocol changed to include zinc therapy using admission before or after 25 March as a categorical variable. *P* values less than 0.05 were considered to be significant. All analyses were performed using STATA/SE 16.0 software (STATA Corp.).

Study approval

The study was approved by the NYU Grossman School of Medicine Institutional Review Board. A waiver of informed consent and a waiver of the Health Information Portability Privacy act were granted.

RESULTS

Patients taking zinc sulphate in addition to hydroxychloroquine and azithromycin (n=411) and patients taking hydroxychloroquine and azithromycin alone (n=521) did not differ in age, race, sex, tobacco use or past medical history (Table 1). On hospital admission, vital signs differed by respiratory rate and baseline systolic blood pressure. The

first laboratory measurements of inflammatory markers including white blood cell count, absolute neutrophil count, ferritin, D-dimer, creatine phosphokinase, creatinine and C-reactive protein did not differ between groups. Patients treated with zinc sulphate had higher baseline absolute lymphocyte counts [median (IQR), zinc: 1 (0.7–1.3) vs. no zinc: 0.9(0.6–1.3), *P* value: 0.0180] while patients who did not receive zinc had higher baseline troponin [0.01 (0.01–0.02) vs. 0.015 (0.01–0.02), *P* value: 0.0111] and procalcitonin [0.12 (0.05–0.25) vs 0.12 (0.06–0.43), *P* value: 0.0493] (Table 1).

In univariate analysis, the addition of zinc sulphate to hydroxychloroquine and azithromycin was not associated with a decrease in length of hospital stay, duration of mechanical ventilation, maximum oxygen flow rate, average oxygen flow rate, average fraction of inspired oxygen or maximum fraction of inspired oxygen during hospitalization (Table 2). In bivariate logistic regression analysis, the addition of zinc sulphate was associated with decreased mortality or transition to hospice (OR 0.511, 95% CI 0.359–0.726), need for ICU (OR 0.545, 95% CI 0.362–0.821) and need for invasive ventilation (OR 0.562, 95% CI 0.354–0.891) (Table 3). However, after excluding all non-critically ill patients admitted to the intensive care unit, zinc sulphate no longer was found to be associated with a decrease in mortality (Table 3). Thus, this association was driven by patients who did not receive ICU care (OR 0.492, 95% CI 0.303–0.799). We also found that the addition of zinc sulphate was associated with likelihood of discharge to home in univariate analysis (OR 1.56, 95% CI 1.16–2.10) (Table 3). We performed a logistic regression model to account for the time-period when the addition of zinc sulphate to hydroxychloroquine plus azithromycin became utilized at NYULH. After adjusting for this date (25 March), we still found an association for likelihood of discharge to home (OR 1.53, 95% CI 1.12–2.09) and decreased mortality or transition to hospice however the other associations were no longer significant (Table 3). The decrease in mortality or transition to hospice was most striking when considering only patients who were not admitted to the ICU (OR 0.449, *P* value: 0.002) (Table 3).

DISCUSSION

While practicing at the epicentre of the pandemic in the United States, we were faced with unprecedented challenges of adopting investigational therapies quickly into clinical practice. Initially, antiviral options at our institution consisted of clinician preference for either ritonavir/lopinavir or hydroxychloroquine plus azithromycin. After the findings of ritonavir/lopinavir, we noticed an increase in the use of hydroxychloroquine plus azithromycin [16]. Our providers within the infectious diseases division, clinical pharmacy and hospitalists discussed the use of zinc sulphate as an addition to hydroxychloroquine, based on the potential synergistic mechanism, and low risk of harm associated with this therapy.

There has been significant interest in the use of zinc sulphate to treat and prevent COVID-19 infection and its use is being considered in several trials (NCT04326725, NCT04377646, NCT04370782, NCT04373733, NCT04351490) [9, 17, 18]. To our knowledge, we provide the first *in vivo* evidence on the efficacy of zinc sulphate in addition to hydroxychloroquine in COVID-19 patients. The main finding of this study is that the addition of zinc sulphate to hydroxychloroquine and

azithromycin was found to be associated with a decrease in mortality or transition to hospice among patients who did not require ICU level of care, but this association was not seen for patients who were treated in the ICU. This result may reflect one of the proposed mechanisms by which zinc sulphate may provide protection against COVID-19. Zinc has been shown to reduce SARS-CoV RNA-dependent RNA polymerase activity *in vitro* [14]. As such, zinc may have a role in preventing the virus from progressing to severe disease, but once the aberrant production of systemic immune mediators is initiated, known as the cytokine storm, the addition of zinc may no longer be effective [19]. To further examine the ability of zinc to prevent viral replication and disease progression, future studies should measure viral RNA levels in clinical specimens before and after zinc administration. Our findings suggest a potential protective effect of zinc, potentially enhanced by a therapeutic synergistic mechanism of zinc sulphate with hydroxychloroquine, if used early on in presentation with COVID-19.

After adjusting for the timing of zinc sulphate treatment, the negative associations between zinc and the need for ICU and invasive ventilation were no longer significant but we did still observe a trend. This observation may be because patients with COVID-19 were initially sent to the ICU quicker, but as time went on and resources became more limited, clinicians began treating COVID-19 patients on general medicine floors for longer periods of time before escalating to the ICU. Future studies are needed to confirm or refute the hypothesis that the addition of zinc sulphate to a zinc ionophore such as hydroxychloroquine may reduce the need for ICU care in patients with COVID-19.

This study has several limitations. First, this was an observational retrospective analysis that could be impacted by confounding variables. This is well demonstrated by the analyses adjusting for the difference in timing between the patients who did not receive zinc and those who did. In addition, we do not know whether the observed added benefit of zinc sulphate to hydroxychloroquine and azithromycin on mortality would have been seen in patients who took zinc sulphate alone or in combination with just one of those medications since few patients at our hospitals received zinc sulphate as stand-alone therapy. The optimal dose and formulation of zinc supplementation necessary to inhibit RNA-dependent RNA polymerase activity of coronaviruses also remains unknown. Early reports suggested higher doses may be necessary, ranging from 50 to 150 mg elemental zinc/day, and such doses have been proved to be safe for short periods of time when used for other viruses or in improving immune reconstitution [20–23]. In addition, although other formulations of zinc supplementation exist, in the form of acetate or gluconate, our hospital formulary had sulphate, which generally has a higher elemental amount of zinc per tablet. Therefore, further investigation is required to determine whether sulphate is the preferred formulation when used to treat coronaviruses, or if another formulation may be better tolerated. Given the recent concern regarding the potential for side effects associated with hydroxychloroquine, future studies should examine whether zinc sulphate would provide benefit as a stand-alone therapy or in combination with another zinc ionophore. In addition, as zinc is hypothesized to inhibit viral RNA polymerase, future studies are needed to determine if zinc synergistically acts with other antiviral medications. We also do not have data on the time at which the patients included in the study initiated therapy with hydroxychloroquine, azithromycin and zinc. Those drugs would have been started at the same time as a combination therapy, but the point in clinical disease at which patients received those medications could have differed between our two groups. Finally, the cohorts were identified based on medications ordered rather than confirmed administration, which may bias findings towards favouring equipoise between the two groups.

CONCLUSION

Zinc sulphate added to hydroxychloroquine and azithromycin associates with a decrease in mortality or transfer to hospice among patients who do not require ICU level of care and an increased likelihood to be discharged directly home from the hospital. In light of study limitations, this study alone is not sufficient to guide clinical practice. Rather, these findings suggest a potential role for zinc sulphate in COVID-19 patients and support the initiation of future randomized clinical trials investigating zinc sulphate against COVID-19.

ABSTRACT

Background: Ivermectin inhibits the replication of SARS-CoV-2 in vitro at concentrations not readily achievable with currently approved doses. There is limited evidence to support its clinical use in COVID-19 patients. We conducted a Pilot, randomized, double-blind, placebo-controlled trial to evaluate the efficacy of a single dose of ivermectin reduce the transmission of SARS-CoV-2 when administered early after disease onset.

Methods: Consecutive patients with non-severe COVID-19 and no risk factors for complicated disease attending the emergency room of the Clínica Universidad de Navarra between July 31, 2020 and September 11, 2020 were enrolled. All enrollments occurred within 72 h of onset of fever or cough. Patients were randomized 1:1 to receive ivermectin, 400 mcg/kg, single dose (n = 12) or placebo (n = 12). The primary outcome measure was the proportion of patients with detectable SARS-CoV-2 RNA by PCR from nasopharyngeal swab at day 7 post-treatment. The primary outcome was supported by determination of the viral load and infectivity of each sample. The differences between ivermectin and placebo were calculated using Fisher's exact test and presented as a relative risk ratio. This study is registered at ClinicalTrials.gov: NCT04390022.

Findings: All patients recruited completed the trial (median age, 26 [IQR 19–36 in the ivermectin and 21–44 in the controls] years; 12 [50%] women; 100% had symptoms at recruitment, 70% reported headache, 62% reported fever, 50% reported general malaise and 25% reported cough). At day 7, there was no difference in the proportion of PCR positive patients (RR 0·92, 95% CI: 0·77–1·09, p = 1·0). The ivermectin group had non-statistically significant lower viral loads at day 4 (p = 0·24 for gene E; p = 0·18 for gene N) and day 7 (p = 0·16 for gene E; p = 0·18 for gene N) post treatment as well as lower IgG titers at day 21 post treatment (p = 0·24). Patients in the ivermectin group recovered earlier from hyposmia/anosmia (76 vs 158 patient-days; $p < 0.001$).

Interpretation: Among patients with non-severe COVID-19 and no risk factors for severe disease receiving a single 400 mcg/kg dose of ivermectin within 72 h of fever or cough onset there was no difference in the

proportion of PCR positives. There was however a marked reduction of self-reported anosmia/hyposmia, a reduction of cough and a tendency to lower viral loads and lower IgG titers which warrants assessment in larger trials.

Research in context

Evidence before this study

Ivermectin is a broad spectrum antiparasitic drug with known antiviral properties. On April 3, 2020, Caly et al. published evidence from in vitro experiments showing that ivermectin can inhibit the replication of SARS-CoV-2 at micromolar concentrations. This has torn the scientific community into two opposing views, one group calling for avoiding investment and effort in a drug likely to fail clinical trials, and another group calling for rapid scale-up even in the absence of proven safety and efficacy for the potential COVID-19 indication. Since April 2020, there has been an abundance of observational trials, case series and ecological analyses suggesting a potential efficacy of ivermectin against COVID-19. Yet very few reports of rigorously conducted randomized controlled clinical trials. Emerging evidence from studies conducted in Bangladesh and Argentina points towards a potential clinical use.

Added value of this study

This pilot, randomized, placebo-controlled, double blind trial failed to show a reduction in the proportion of PCR-positive patients seven days after ivermectin treatment; yet it shows a reduction in the self-reported anosmia/hyposmia and a (non-statistically significant) tendency to lower viral loads and lower IgG titers which presumably reflect milder disease.

Implications of all the available evidence

The positive signal found in this pilot together with emerging evidence from animal models and other clinical trials warrants the conduction of larger trials using ivermectin for the early treatment of COVID-19.

1. Introduction

As of December 21, 2020, there have been over 70 million cases and 1·6 million COVID-19 deaths worldwide [1]. Although the threshold is difficult to predict accurately [2], the spread of SARS-CoV-2 is unlikely to stop before at least 50% of the population has gained immunity, either by vaccination or recovering from a naturally-acquired infection [3]. There are now promising vaccines candidates advancing to emergency regulatory approval [4], but there is a projected delay in global access to the level required for population impact on the trajectory of the pandemic. While efforts are ongoing to develop treatment options, relatively less attention has been devoted to evaluating drug-based transmission blocking or transmission reduction strategies. These strategies would consist in administering a drug with the aim of reducing onward transmission by those infected and could serve to reduce the burden on health system and gain time until vaccines are fully tested and scaled-up.

Ivermectin is a widely used antiparasitic drug with known partial efficacy against several single-strain RNA viruses [5-7]. Caly et al. reported in vitro inhibition of SARS-CoV-2 replication using micromolar concentrations of ivermectin [8]. These findings, together with early observational evidence and ecological evidence, prompted several Latin-American countries to include ivermectin as part of the national policy for COVID-19 treatment [9].

As of December 21, 2020, there are 45 studies evaluating the efficacy of ivermectin to treat or prevent COVID-19 registered in clinicaltrials.gov, and 74 trials registered in WHO's International Clinical Trials Registry Platform (https://apps.who.int/trialsearch/) of which at least 14 are already completed. Although some observational and case control studies as well as emerging small randomized clinical trials suggest a potential utility [10-13]. Yet, there is still a dearth of robust, randomized controlled trials to appropriately inform policy decisions.

This trial was designed as a pilot to evaluate whether the maximum approved dose of ivermectin in Europe could have an impact on the transmission of SARS-CoV-2 when administered early after disease onset.

2. Methods

This was a pilot, double-blind, placebo-controlled, single-center, parallel-arm, superiority, randomized clinical trial that compared a single dose of ivermectin with placebo in patients with non-severe COVID-19 and no risk factors. The trial protocol was published [14], the last version of the protocol and statistical analysis plan are available as supplementary files. The protocol was approved by the Spanish national ethics committee for drug research (Hospital Puerta de Hierro Majadahonda) and by the Spanish Agency of Medicines and Medical Devices. All procedures were conducted in compliance with the latest revision of the Helsinki Declaration and Good Clinical Practice. All patients provided verbal informed consent at enrollment followed by written consent once their isolation was lifted in accordance to the EMA recommendations: "Guidance on the Management of Clinical Trials during the COVID-19 (Coronavirus) pandemic Version 2 (27/03/2020)" [15]. This study is registered at ClinicalTrials.gov: NCT04390022. This study was funded by ISGlobal and the Clínica Universidad de Navarra. The funding sources had no role on the design, analysis or decision to publish the results of this study.

2.1. Patients

Consecutive outpatients attending the Emergency Room of the Clínica Universidad de Navarra (Pamplona, Spain) with symptoms compatible with COVID-19, no more than 72 h of fever or cough and a positive PCR for SARS-CoV-2 were enrolled. Patients with positive IgG against SARS-CoV-2, comorbidities considered risk factors for severe disease or COVID-19 pneumonia at baseline were excluded (detailed eligibility criteria are provided in the protocol -Supplementary file-).

2.2. Study design and oversight

The trial was conducted in the Pamplona metropolitan area (Navarra, Spain). Patients were enrolled between July 31, 2020 and September 11, 2020 and randomized in a 1:1 ratio to ivermectin (400 mcg/kg) single oral dose or placebo. The randomization sequence was computer-generated by the trial statistician using blocks of four

to ensure balance. Allocation was made by the attending investigator using opaque envelopes. The placebo tablets did not match ivermectin in appearance, therefore, in order for the clinical trial team to remain blinded, treatment was administered under direct supervision by a non-participant nurse that picked up the opaque bottles directly from the pharmacy and administered the content behind closed doors. The clinical trial team had no contact with the investigational products. There was slow recruitment due to a sharp reduction in local transmission for 10 weeks after the lockdown of March-April 2020, the protocol was amended on September 2nd to extend the inclusion criteria from 48 to a maximum of 72 h of cough or fever.

The main objective was to determine the efficacy of a single dose of ivermectin, administered to low risk, non-severe COVID-19 patients in the first 72 h after fever or cough onset to reduce onward transmission.

2.3. Clinical, laboratory and virological monitoring

Assessments on enrollment and at days 4, 7, 14, 21 and 28 post treatment included: general symptoms report, physical examination (including respiratory rate, blood oxygen saturation and chest auscultation) and adverse events. All patients were asked to complete a daily online diary of symptoms from day 1 to 28 post treatment. On enrollment, as well as on days 7 and 14 blood samples were obtained to assess full blood count, C reactive protein, procalcitonin, ferritin, creatinine phosphokinase, lactic dehydrogenase, troponin T, D dimer, IL-6, and renal function.

A nasopharyngeal swab for SARS-CoV-2 PCR was taken at enrollment and on days 4, 7, 14 and 21 post treatment. For consistency, these samples were collected by three clinicians using the same technique. All samples were processed by PCR for genes N and E of SARS-CoV-2 (Real Time PCR SARS-CoV-2, Vircell SLU, Granada, Spain). For every sample, the viral load was calculated using standard reference curve (EDX Sars-Cov-2, Exact Diagnostics LLC, Fort Worth Texas). Additionally, all samples from day 4 post treatment were cultured in Vero cells for 7 days, after which the cytopathic effect was assessed and PCR conducted on the harvested cell-free supernatant. If the PCR from the supernatant was positive at day 4, the procedure was repeated on the samples of that patient for day 7. A semi-quantitative serology for IgG against SARS-CoV-2 (COVID-19 VIRCLIA IgG monotest, Vircell SLU, Granada, Spain) was done on samples from all patients on day 21 post-treatment.

2.4. Outcome measures

The primary outcome measure was the proportion of patients with detectable SARS-CoV-2 RNA by PCR from nasopharyngeal swab at day 7 post-treatment.

Relevant pre-specified secondary outcomes included viral load at days 4, 7, 14 and 21 post treatment; proportion of patients with symptoms (particularly fever and cough) at days 4, 7, 14 and 21 post-treatment as well as proportion of patients progressing to severe disease or death during the trial; proportion of patients with seroconversion at day 21 post-treatment and proportion of drug-related adverse events.

2.5. Sample size justification

In COVID-19, viral load peaks right before or at symptom onset [16,17] and most secondary cases occur prior to day five after symptoms [18]. This pilot was designed to assess the use of ivermectin to reduce transmission. With the objective to reduce onward transmission, a robust effect size in the proportion of PCR positives at day seven after treatment would be needed to have a public health impact. A reduction of at least 50% in the proportion of positives was considered of potential value.

The sample size was based in the comparison of two proportions and calculated to have 80% power at a 5% significance level to detect a 50% reduction (100 vs 50%) in the proportion of participants with positive PCR at day 7 post-treatment. The 100% PCR positivity figure at day 7 is based on the experience with COVID-19 outpatients at the Clínica Universidad de Navarra during the first wave of March-May 2020. The infectivity outcome was supported by assessing changes in viral load and infectivity in cell cultures.

2.6. Statistical analysis

Descriptive analyses used frequency and percentage (based on the non-missing sample size) for qualitative variables and median, interquartile range and n (non-missing sample size) for quantitative variables.

For the primary objective, the proportion of participants with positive PCR at day seven post treatment was calculated. Proportions were compared between study arms using Fisher's exact test and presented as a relative risk ratio (RR) with their corresponding 95% confidence interval (CI). In the analysis of the symptoms reported by patients (symptom diary), missing data was carried over from the last data available. Significance was set at 0.05. The analysis was carried out using Stata (StataCorp. 2019. Stata Statistical Software: Release 16. College Station, TX: StataCorp LLC).

Boxplots and bar plots were produced for the description of quantitative and qualitative variables, respectively. For figure readability, viral load values were log-transformed. Graphs were produced in R version 4.0.2 (R Core Team, R: A Language and Environment for Statistical Computing, Vienna, Austria: R Foundation for Statistical Computing, 2020) with the package ggplot2 (H. Wickham, ggplot2: Elegant Graphics for Data Analysis, Springer-Verlag New York, 2016.).

Viral load data were synchronized prior to analysis by accounting for days since onset of any symptoms and, since the day of infection was not known, an average incubation time of 5 days was assumed [19]. Peak viral load (Cmax) and time to peak viral load (Tmax) were determined directly from the profiles. Area under the viral load curve was calculated using the trapezoidal rule from assumed time of infection to last sample (AUCobs). Duration of time above a cycle threshold (Ct) of 35 was derived directly from profiles or linearly extrapolated profiles if the last recorded Ct value was not below the threshold.

2.7. Post hoc analyses

The median viral load at all sampling times and median IgG titers between study groups were compared using a Wilcoxon rank-sum test.

The effect of study arm on the presence of symptoms was estimated using mixed effect logistic regression models with subject as a random intercept. These models are adjusted by day of follow up (as symptoms are expected to disappear over time) and duration of symptoms before enrolment (as a proxy of disease onset). To assess the potential effect of study arm on symptom progression, the interaction between study arm and day of follow up was also included in the models. Three models were studied for those outcomes for which differences between treatments were observed: any symptom, anosmia or hyposmia, and cough. Additionally, the observed effect of ivermectin on anosmia/hyposmia was assessed in a sub-analysis by sex.

The adipose weight of participants in the ivermectin group was calculated with the method described by Gomez-Ambrosi et al. [20]. This information was used to estimate the ivermectin dose per

adipose-weight received and plotted against the last day of reported anosmia/hyposmia.

3. Results

3.1. Patient characteristics

Of 94 patients assessed, 50 did not meet eligibility criteria, 20 declined to participate and 24 were randomized. All randomized patients received the corresponding study product and completed 28 days of follow-up (Fig. 1). The baseline characteristics of patients in both groups are presented in Table 1.

There was a higher proportion of females in the placebo group (58 vs 42%). Demographics and baseline disease characteristics of participants in both groups are presented in Table 1. Overall, 66% of the patients presented with perceived or objective fever, 25% presented with cough, 70% presented with headache and 58% presented with myalgia or general malaise with no remarkable differences between groups. The median earliest start of any symptom before treatment was 24 h for the ivermectin group (interquartile range, 24–48 h) and 48 h for the placebo group (interquartile range, 36–48 h). At baseline, there were no differences in vital signs, inflammatory markers or full blood count between the groups (Table 1).

3.2. Primary endpoint

There was no difference in the proportion of PCR positive patients at day 7 post treatment, 12/12 (100%) patients had a positive PCR for gene N in both groups. For gene E, 11/12 (91%) in the ivermectin and 12/12 (100%) in the placebo group had a positive PCR (RR 0·92, 95% CI: 0·77–1 0·09, $p = 1·0$).

3.3. Viral load

Genes E and N had comparable results at all time points. Patients in both study groups had similar viral load before treatment with median and interquartile range for genes E and N in the same orders of magnitude (Fig. 2 and Table S1). Although there was a consistent overlap in interquartile ranges and full ranges at all points, the median viral load for both genes was lower at days 4 and 7 post

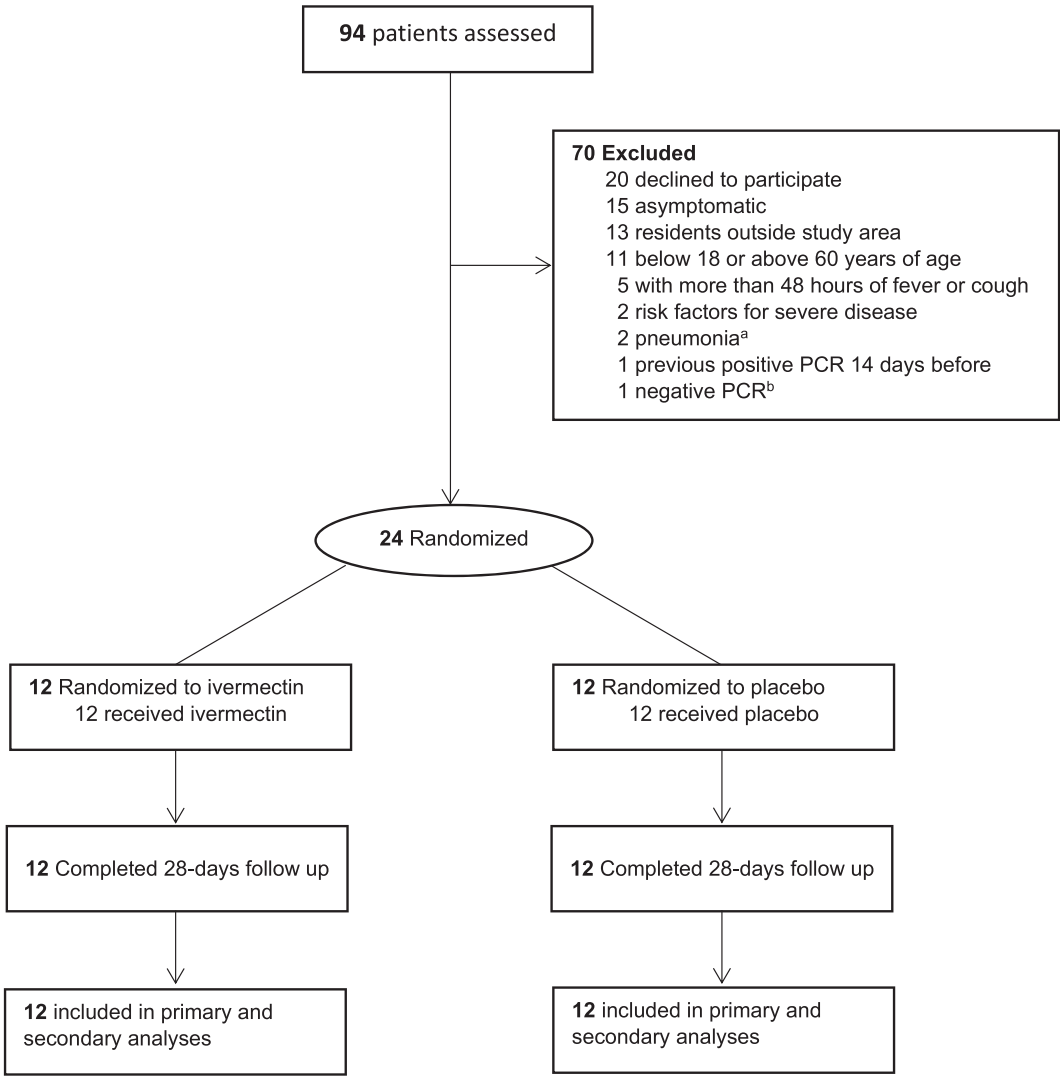

Fig. 1. Enrollment and patient flow. [a] One presented with pneumonia in the ER and one had a compatible X-ray during screening. [b] Formally screened based on epidemiological and clinical suspicion but had a negative PCR.

Platelets, median (IQR), 10^9/L	194 (167–216)	205 (179–247)
White blood cells, median (IQR), 10^9/L	4·7 (4·3–6·3)	4·4 (3·7–5·9)
Neutrophils, median (IQR),%	52·4 (45·6–65·1)	53·4 (43·9–62·2)
Lymphocytes, median (IQR),%	29·5 (18·5- 7·9)	28·7 (20·8–39·9)

[a] Hours before dosing
[b] The slightly higher median systolic blood pressure in the placebo group at baseline was not seen in subsequent study visits and was judged as non-clinically significant, see table S3 for the evolution of all vital signs throughout the study, *Reported or measured fever. IQR: interquartile range

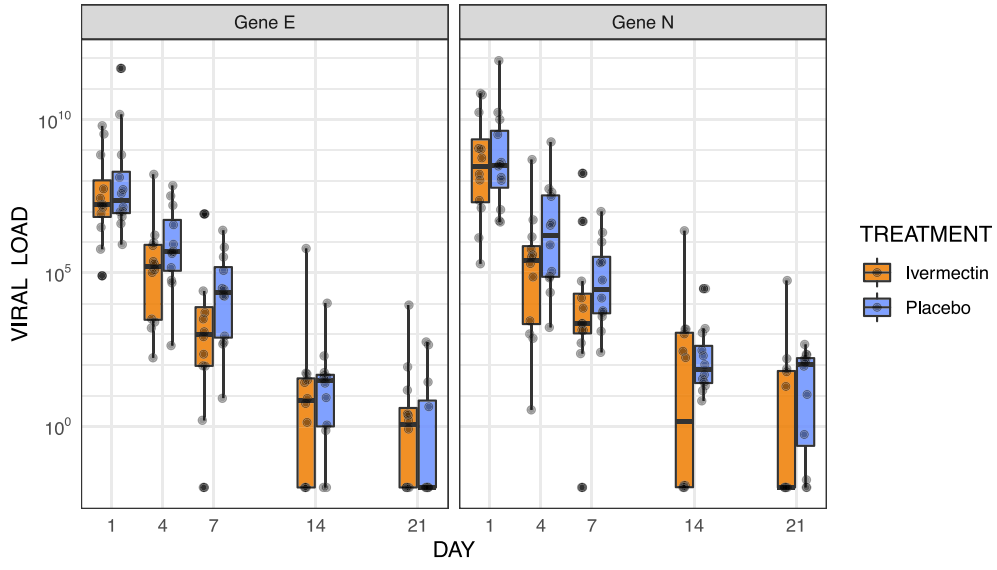

Fig. 2. Viral load evolution by study arm. Viral load values were log-transformed. The boxes show the interquartile range. Dots represent each individual value.

treatment in the ivermectin group with differences increasing from 3-fold lower at day 4 (p = 0·24 for gene E; p = 0·18 for gene N) to around 18-fold lower at day 7 (p = 0·16 for gene E; p = 0·18 for gene N) (Fig. 2 and Table S1). A similar tendency remained for the viral load at days 14 and 21, with values from patients in the ivermectin group consistently lower for at least one of the genes, the difference was not statistically significant at any single point (Fig. 2 and Table S1). The values of cycle thresholds had a very similar behavior (Figure S1). Summary statistics for viral kinetics are provided in Table S2.

Chaccour et al., The effect of early treatment with ivermectin on viral load, symptoms and humoral response in patients with non-severe COVID-19: A pilot, double-blind, placebo-controlled, randomized clinical trial, EClinicalMedicine (2021), https://doi.org/10.1016/j.eclinm.2020.100720

3.4. Viral culture

At day 4 post-treatment, 7/12 samples in the ivermectin and 5/12 samples in the placebo group effectively replicated Vero cell culture; the median Ct values of replicating samples were 23·3 and 23·8 for genes N and E respectively, while the median Ct values of non-replicating samples were 27·6 and 27·9 for genes N and E respectively. By day 7 post treatment only 1/6 in the ivermectin (one previously positive sample was lost) and 1/5 in the placebo group replicated in the cell culture; the median Ct values of replicating samples were 25·1 and 26·0 for genes N and E respectively, while the median Ct values of non-replicating samples were 30·8 and 32·0 for genes N and E respectively.

3.5. Symptoms

There was good compliance with the daily online questionnaire with 282 patient-days reports (84%) and 295 patient-days reports (88%) in the ivermectin and placebo group respectively (Fig. S2).

Patients in the ivermectin group reported fewer patient-days of any symptoms than those in the placebo group (171 vs 255 patient-days). This difference is mostly driven by two symptoms, anosmia/hyposmia and cough. Patients in the ivermectin group reported 50% less anosmia/hyposmia than those in the placebo group (76 vs 158 patient-days of anosmia/hyposmia). The ivermectin group also reported 30% less cough (68 vs 97 patient-days of cough) (Fig. 3).

There were no major differences between ivermectin and placebo in the reported patient-days of fever (12 vs 12), general malaise (51 vs 61), headache (34 vs 38), or nasal congestion (91 vs 97). With much lower magnitudes, the ivermectin group reported 3.5-fold more patient-days of gastrointestinal symptoms (21 vs 6) and 5-fold less shortness of breath (3 vs 15) (Fig. S3).

No patient from either group progressed to severe disease.

3.6. Serology

All patients in both groups seroconverted by day 21 post treatment. Patients in the ivermectin group had a lower median of IgG titers (Index 4·7, interquartile range [3·5–8·9]) than those in the placebo group (Index 7·5, interquartile range [4·2–9·3]) (p = 0·24 by Wilcoxon rank-sum test) (Fig. 4).

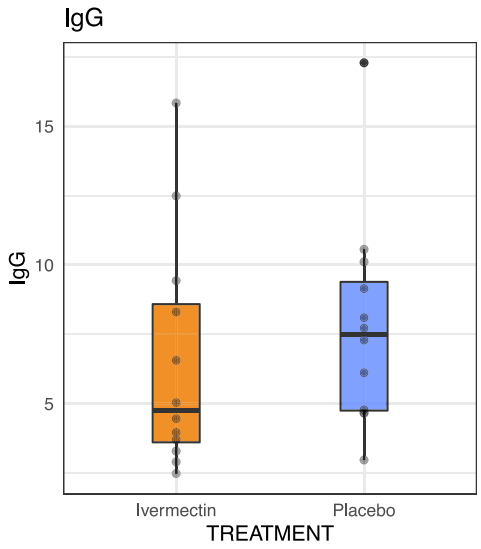

Fig. 4. IgG titers by study arm. The boxes show the interquartile range. Dots represent each individual value (p = 0·24, Wilcoxon rank-sum test).

3.7. Safety

All patients completed the follow up period of 28 days. There were 15 adverse events (7 in the ivermectin and 8 in the placebo group) experienced by 10 patients (5 in the ivermectin and 5 in the placebo group). There were no severe adverse events.

The online diary of symptoms included questions about ivermectin-specific adverse events. There were no differences in the reported patient-days between the ivermectin and the placebo group for confusion (1 vs 0), drowsiness (0 vs 0), or pruritus (0 vs 3). Patients in the ivermectin group reported more patient-days of dizziness (7 vs 1) and blurred vision (24 vs 1), with this last value driven by a single patient in the ivermectin group reporting blurred vision on days 2—28, further evaluation suggested previously undiagnosed presbyopia (Fig. S4).

There were no major differences in the evolution of vital signs (Table S3), inflammatory markers (C reactive protein, procalcitonin, ferritin and IL-6) and rest of laboratory parameters of patients in each group (Table S4).

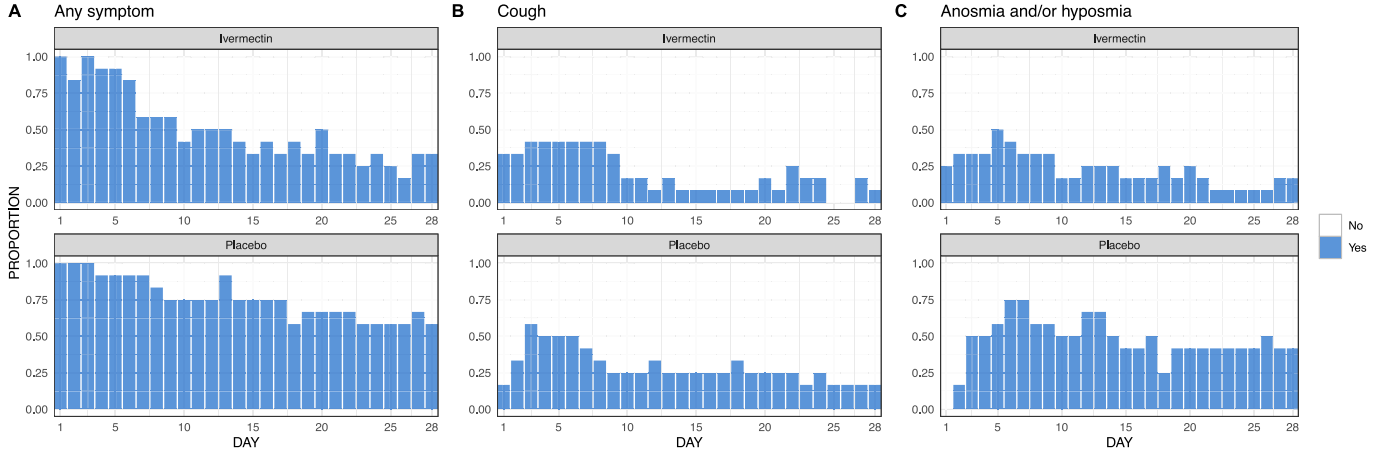

Fig. 3. Daily proportion of any self-reported symptoms, self-reported cough and self-reported anosmia/hyposmia by study arm. Each graph represents the daily proportion of individuals (n/N) who suffered from each symptom in the corresponding study arm for a 28 day follow up. Missing answers were replaced by the value in the immediately preceding day.

Please cite this article as: C. Chaccour et al., The effect of early treatment with ivermectin on viral load, symptoms and humoral response in patients with non-severe COVID-19: A pilot, double-blind, placebo-controlled, randomized clinical trial, EClinicalMedicine (2021), https://doi.org/10.1016/j.eclinm.2020.100720

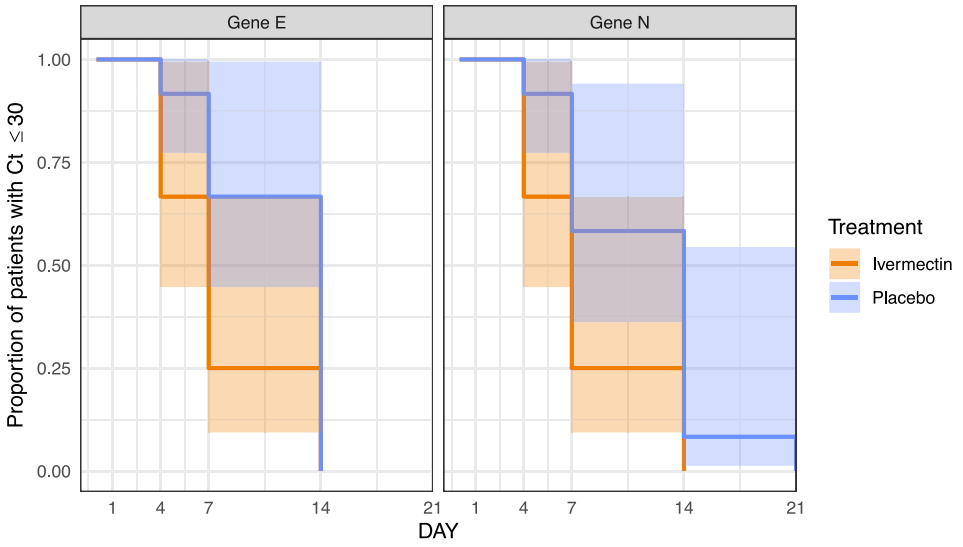

Fig. 5. Kaplan-Meier curves for viral load. A survival threshold of Ct ≥ 30 was used. Log-Rank test yielded significance for the difference in gene E (p = 0·0358) and borderline significance for the difference in gene N (p = 0·0550).

3.8. Post hoc analyses

Given that the main objective of the trial was to explore a reduction in onward transmission of the virus and that the viral cultures of samples from day 7 showed replicative virus only in samples with Ct values below 30, Kaplan-Meier curves were drawn and survival analysis conducted with log-rank test using a survival threshold of Ct ≥ 30. This analysis shows a statistically-significant difference for gene E (p = 0·035, Log-rank test) and borderline significance for gene N (p = 0·055, Log-rank test). The curves are presented in Fig. 5.

In the logistic regression model, a lower chance of presenting any symptoms was observed in the ivermectin arm (OR: 0·04 [95% CI: 0·00, 0·75] p = 0·032). In both arms, presence of any symptoms tended to diminish over time (OR (95% CI): 0·80 (0·74, 0·86) and 0·81 (0·77, 0·85), for placebo and ivermectin respectively). This downward trend was similar in both study groups (p = 0·687). With regards to the presence of cough, we did not find differences between study groups (p = 0·575) nor in the existing trend to diminish over time (p = 0·373). However, differences were observed for the presence of anosmia/hyposmia: for patients in the placebo group, there was no trend in time in the presence of anosmia (OR (95%CI): 0·99 (0·95, 1·02) p = 0·459). Conversely, patients in the ivermectin group showed a significant decrease (OR (95%CI): 0·90 (0·85, 0 0·94) p < 0·001) (Fig. S5).

The overall effect of ivermectin on anosmia/hyposmia was mainly driven by male patients (20 vs 76 patient-days of anosmia/hyposmia in the ivermectin and placebo groups respectively) in sharp contrast with female patients (56 vs 81 patient-days of anosmia/hyposmia in the ivermectin and placebo groups respectively) (Fig. S6). A sensitivity analysis to assess if sex had any impact on the logistic regression models was performed. Adding this variable to the models did not change the coefficients presented above.

The participants had an adipose weight ranging from 14% to 39% of their body weight. This resulted in ivermectin doses per adipose kilo ranging from 1028 mcg/adipose-kg to 2963 mcg/adipose-kg, even if the actual doses per full body weight were achieved in the relative narrow range of 399–427 mcg/kg (Table 2). The ivermectin doses per adipose-kg were plotted against the duration of anosmia/hyposmia and the last day of reported anosmia/hyposmia with no evident pattern, a regression was not attempted given the scarcity of data (Fig. S7).

4. Discussion

In spite of its partial antiviral properties, ivermectin received limited early attention in Europe or the US as a potential drug to be repurposed against COVID-19. This was largely based on one pharmacokinetic model stressing the inability of currently approved oral doses to reach lung tissue levels at the antiviral concentrations

Table 2
Body composition and dose of ivermectin-treated participants.

Participant ID	Age years	Sex M/F	Weight kg	Height m	BMI kg/m^2	Adipose weigh %	Adipose weight* kg	3-mg tablets received tablets	Total dose mg	Dose/kg mcg/kg	Dose adipose/kg mcg/kg

Please cite this article as: C. Chaccour et al., The effect of early treatment with ivermectin on viral load, symptoms and humoral response in patients with non-severe COVID-19: A pilot, double-blind, placebo-controlled, randomized clinical trial, EClinicalMedicine (2021), https://doi.org/10.1016/j.eclinm.2020.100720

described by Caly et al., [21] even if other, peer-reviewed models predict up to 10-fold accumulation of ivermectin in target tissue [22]. There are additional reasons to avoid direct inferences from the results of in vitro experiments or pharmacokinetic models, these include the potential role of ivermectin metabolites, the potential immunomodulatory role of the drug, and questions about the virus/cell ratios and appropriateness of the Vero cellular lines used in the cultures [23].

This pilot study was designed to assess the question of whether further investments in the potential repurposing of ivermectin were warranted. As such, we aimed at generating evidence on viral kinetics, antibody response and clinical efficacy in a cohort of patients at low risk of severe disease. Without a clearly defined mechanism of action, a sole signal in any of said parameters would not suffice to justify further efforts. This pilot shows a tendency to lower viral loads in the ivermectin group, a tendency to lower IgG titers that may reflect milder disease and clinical benefit in cardinal symptoms of COVID-19 associated with tissue damage: anosmia/hyposmia and cough. These results are in line with emerging evidence from trials in Bangladesh [10,11] and Argentina [12] showing a faster viral clearance in treated participants, as well as with recent data from a SARS-CoV-2 hamster model from Institute Pasteur which also showed a marked sex dichotomy in the effect of ivermectin on anosmia/hyposmia [24].

Pending confirmation of these results, this pilot sheds some light on the potential mechanism of action of ivermectin against COVID-19. Note the trial was not powered to detect modest differences in viral load, yet a small effect is suggested when viral load was ascertained directly by PCR and indirectly using IgG titers as markers of disease severity [25,26]. Also, in this pilot ivermectin has not shortened the duration of symptoms associated with systemic inflammation such as fever or malaise, nor has it had a measurable impact on systemic inflammatory markers.

Given these findings, consideration could be given to alternative mechanisms of action different from a direct antiviral effect. One alternative explanation might be a positive allosteric modulation of the nicotinic acetylcholine receptor caused by ivermectin and leading to a downregulation of the ACE-2 receptor and viral entry into the cells of the respiratory epithelium and olfactory bulb [27].

Another mechanism through which ivermectin might influence the reversal of anosmia is by inhibiting the activation of pro-inflammatory pathways in the olfactory epithelium. Inflammation of the olfactory mucosa is thought to play a key role in the development of anosmia in SARS-CoV-2 infection [28].

Ivermectin is known to downregulate the expression of several pro-inflammatory genes, including those of IL-8, TNF-α, and cathelicidin LL-37 [29]. This effect is thought to partially explain the efficacy of ivermectin in the treatment of rosacea [29,30]. The effect on LL-37 might be particularly important, as this molecule directly influences several pro and anti-inflammatory pathways, including the stimulation of IL-18 and IL-1β production, and has a chemotactic effect for neutrophils and eosinophils [31]. This effect might be mediated by inhibiting the entrance of the vitamin D receptor (VDR) into the nucleus [32]. Ivermectin inhibits importins of the α/β family, which play a key role in the ligand-independent transportation of the VDR, a crucial step in the vitamin D-mediated expression of the hCAMP18 gene, which encodes the LL-37 precursor [33-35]. It is possible that the inhibition of importins may thus contribute to the immune regulatory effect of ivermectin, and its influence on other vitamin D-mediated pathways, supporting further studies in this area.

Albeit requiring confirmation, these results raise several important questions. If the mechanism of action of ivermectin against COVID-19 is related to a nicotinic effect, then inhibitory concentrations for this receptor (which are in the nanomolar range) could be achievable in the lung tissue for a short period of time with oral dosing and for considerably longer periods with nebulized therapy [36]. If the mechanism is immunomodulatory, then the appropriate dose and regimen should be tailored accordingly. Before considering higher or multiple dose schemes, there is also need to better understand the potential role of ivermectin's metabolites in any observed effect. Finally, given the tendency to lower IgG titers in the ivermectin group, there is need to evaluate the potential relationship between ivermectin treatment, disease severity, inflammation, viral dynamics and antibody titers; [37,38] particular attention should be paid to the long-term humoral and cellular immune responses against SARS-CoV-2 in ivermectin treated patients.

This pilot points towards a potential use of ivermectin in COVID-19 which warrants further exploration under larger trials, with clinical outcomes in patients with risk factors or more severe disease. This is of particular importance for settings with limited resources given ivermectin's low price, broad availability and scalability of manufacturing processes.

This pilot has several key limitations that warrant careful interpretation of the results. Firstly, it was designed to explore a potential signal for the use of ivermectin in COVID-19, not to provide definitive evidence on the subject, hence its small sample size. Second this pilot was restricted to subjects with non-severe disease and no risk factors in whom the treatment was provided in the first 48 h of fever or cough, this should be taken into consideration for the design of any confirmatory studies to be conducted. Additionally, the quantification of the viral load presented is intrinsically limited by heterogeneity in the samples, even if all were obtained by the same clinicians, standardization against a human epithelial cell gene would be required to ensure the viral loads are truly comparable [39].

The positive signal found in this pilot warrants the conduction of larger trials using ivermectin for the early treatment of COVID-19. Such trials should include patients with risk factors for severe disease as well as patients with pneumonia. The potential for a mechanism of action different to direct antiviral effect also opens the door for pre-exposure prophylaxis in high-risk groups.

Author contributions

Carlos Chaccour and Aina Casellas had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

Conceptualization: CCh, NRR, MFA
Data curation: CCh, AC, JB
Formal analysis: AC, CCh, FH, VS
Funding acquisition: CCh, NRR
Investigation: CCh, AB, IP, AFM, PRC, MAR, MRM, CJI, FC, MG, EL, JCG, JRY, JLD, GR, BS, MFA
Methodology: CCh, AC, FC, CD, GM, FH, GR, BS, MFA
Supervision: CCh, BS, GR, MFA
Writing - original draft: CCh, AC
Writing - review & editing: all authors contributed, reviewed and approved the last draft.

Funding

Idipharma SL (Noain, Spain) contributed with in kind placebo tablets. This study was supported by ISGlobal and the University of Navarra. CCh, PRC, MAR, FH and NRR received salary support from Unitaid through the BOHEMIA grant to ISGlobal. ISGlobal acknowledges support from the Spanish Ministry of Science and Innovation through the "Centro de Excelencia Severo Ochoa 2019–2023"; Program (CEX2018–000,806-S), and support from the Generalitat de Catalunya through the CERCA Program.

Data availability

Upon publication, all data supporting the results will be archived in a public repository accessible at http://diposit.ub.edu/dspace/handle/2445/101776

Declaration of Competing Interest

JLDP reports speaker fees from Pfizer and MSD as well as research grants from Novartis, outside the scope of the submitted work. No other competing interests were disclosed

Acknowledgments

We thank the patients who participated in this study and the nursing staff of the emergency room and technicians of the microbiology lab of the Clínica and the Biobank, Universidad de Navarra for their dedication to this study.

Ivermectin to reduce malaria transmission I. Pharmacokinetic and pharmacodynamic considerations regarding efficacy and safety

Carlos Chaccour[1,2,3*], Felix Hammann[4] and N. Regina Rabinovich[1,5]

Abstract

Ivermectin is an endectocide that has been used broadly in single dose community campaigns for the control of onchocerciasis and lymphatic filariasis for more than 30 years. There is now interest in the potential use of ivermectin regimens to reduce malaria transmission, envisaged as community-wide campaigns tailored to transmission patterns and as complement of the local vector control programme. The development of new ivermectin regimens or other novel endectocides will require integrated development of the drug in the context of traditional entomological tools and endpoints. This document examines the main pharmacokinetic and pharmacodynamic parameters of the medicine and their potential influence on its vector control efficacy and safety at population level. This information could be valuable for trial design and clinical development into regulatory and policy pathways.

Keywords: Ivermectin, Endectocide, Pharmacokinetics, *Anopheles*

Background

Vector control has been a fundamental pillar for the remarkable achievements in malaria control 2000–2015 [1]. Residual transmission [2, 3] and insecticide resistance [4] are some of the challenges faced for sustaining the gains of vector control. Innovation is required to reach the ambitious goals proposed by the Global Technical Strategy for Malaria 2016–2030 [5].

Ivermectin is a mixture of two semi-synthetic analogs of the fermentation products of *Sterptomyces avermitilis*. It belongs to the macrocyclic lactone complex; its chemical structure has been reviewed elsewhere [6]. Ivermectin is an anti-parasitic medicine approved for the treatment and control of human onchocerciasis, lymphatic filariasis (LF), strongyloidiasis [7] and scabies [8]. It is also an endectocide, a drug capable of killing arthropods that feed on a treated individual, including *Anopheles* mosquitoes. This property makes mass drug administration (MDA) with ivermectin a potential tool to reduce malaria transmission [9, 10]. Such an intervention has the potential to reach malaria vectors that feed on the temporal and spatial gaps left by core vector control interventions (long-lasting insecticidal nets (LLINs) and indoor residual spraying (IRS).

This paper reviews the pharmacokinetic and pharmacodynamic properties of ivermectin that can affect the efficacy and safety of MDA campaigns for malaria transmission reduction.

Essential pharmacology

Mechanism of action

Ivermectin blocks synaptic transmission in invertebrates by binding to glutamate-gated chlorine channels in nerve and muscle, leading to hyperpolarization, paralysis and death of the invertebrate, including mosquitoes. These channels are part of the Cys-loop family of ligand-gated ion channels and ivermectin has consequently been shown to have additional effects on other members, for

instance the gamma-aminobutyric acid (GABA), histamine, and pH-sensitive chloride channels [7, 11].

In mammals, ivermectin acts as an allosteric agonist of $GABA_A$ receptor, another member of the Cys-loop family of ligand-gated ion channels. These receptors are located on neurons in many central nervous system regions (incl. the cerebral cortex, the limbic system, and thalamus) and increase chloride conductance, resulting in hyperpolarization and less formation of action potentials [12]. In vertebrates, GABA is a major inhibitory transmitter. The net effect of $GABA_A$ receptor stimulation is central nervous depression, which defines the syndrome of ivermectin toxicity in vertebrates.

The glutamate-gated chlorine channel in *Anopheles gambiae*

The glutamate-gated chlorine channel (GluCl) from *Anopheles gambiae* has recently been characterized [11]. These channels are predominantly expressed in some of the organs involved in motor and sensory systems, which explains the paralytic and other effects of the drug on mosquitoes, even at sub-lethal concentrations.

In *An. gambiae*, the gene for the GluCl can be expressed in four isoforms, but only one is insensitive to ivermectin. Little is known about the expression of these channels in wild mosquito populations. Mosquito resistance to ivermectin has not been reported, but theoretically selective over-expression of the ivermectin-insensitive isoform could develop as a resistance mechanism. However, the reduced fertility seen in mosquitoes taking sub-lethal doses of the drug [13, 14] could help delay this possibility.

Pharmacokinetics

The following discussion refers to pharmacokinetics of ivermectin in humans. Veterinary references are explicitly mentioned as such.

Absorption

Ivermectin is readily absorbed after oral administration. The absorption half-life ranges from 0.5 to 2.5 h [15, 16]. There are appreciable differences in systemic bioavailability (F) depending on mode of administration and disease state; ethanol based liquid formulations have up to twice the availability of solid formulations (AUC ratio 1.08–2.29) [15]. Infestations with worms such as *Strongyloides* can lead to paralytic ileus and severely impaired absorption of ivermectin. This has led to several patients requiring treatment with parenteral veterinary formulations [17, 18]. Time since last meal does not seem to influence ivermectin's bioavailability, although this is still subject to debate [19, 20].

Ivermectin is subject to presystemic metabolism and efflux in the gut. Intestinal cytochrome P_{450} 3A4 (CYP 3A4) can degrade ivermectin [21], and the active efflux pump P-glycoprotein (P-gp, MDR1, ABCB1), located luminally on intestinal enterocytes, transports absorbed ivermectin from the enterocyte back into the lumen [22]. Drugs or xenobiotics can induce or inhibit the activity of these mechanisms [23], as can pharmacogenetics differences, most notably in P-gp expression [24, 25].

As a lipophilic and comparatively heavy compound, ivermectin is thought to be subject to enterohepatic circulation (EHC) [16]. This is further supported by ivermectin being a substrate for important biliary efflux pumps (P-gp, and Breast cancer resistance protein (BCRP, ABCG2) [26]. Presence of EHC can increase the total exposure of a compound in that it can be absorbed multiple times, with high peak after initial administration and subsequent peaks after the compound has been excreted into bile and then reabsorbed again in the small intestine. At low doses, the peak concentration (Cmax) is proportional to the dose, but this proportionality is lost with doses equal or higher than 150 mcg/kg [27]. After a single oral dose of 150 mcg/kg, the peak is around 40 ng/ml [7, 15, 28]. The reported time needed to reach Cmax (Tmax) varies but is generally accepted to be approximately 4 h [28].

Figure 1 represents the PK curve observed by Elkassabi [28] in Sudanese patients. The relationship between plasma concentration and the mortality of mosquitoes feeding on treated individuals is reviewed in the efficacy section below.

Distribution

Ivermectin is highly lipophilic, shows a great degree of protein binding (>90%), and distributes widely in the body with a volume of distribution (V_d) of 3.1–3.5 l/kg. Owing to its lipophilicity, ivermectin partitions to adipose tissue, which increases V_d and leads to accumulation with prolonged elimination, as drug distributes back to plasma from fatty tissue [16, 29]. This can explain the different pharmacokinetic pattern seen in women and volunteers with higher body mass index. Protein binding becomes important in populations with high prevalence of malnutrition: there, lower plasma protein levels (especially hypoalbuminemia) will result in higher free concentrations of ivermectin and, subsequently, more drug effect and toxicity.

Distribution to the brain is hindered by the blood–brain-barrier. Specifically, this is mediated by ivermectin's size, which is not conducive to passive diffusion, and the presence of efflux pumps, for which ivermectin is a substrate. The primary efflux pump is the P-gp (of which ivermectin is also an inhibitor), although BCRP can also transport ivermectin [22, 26]. The blood–brain-barrier therefore restricts ivermectin's access to its toxicity target

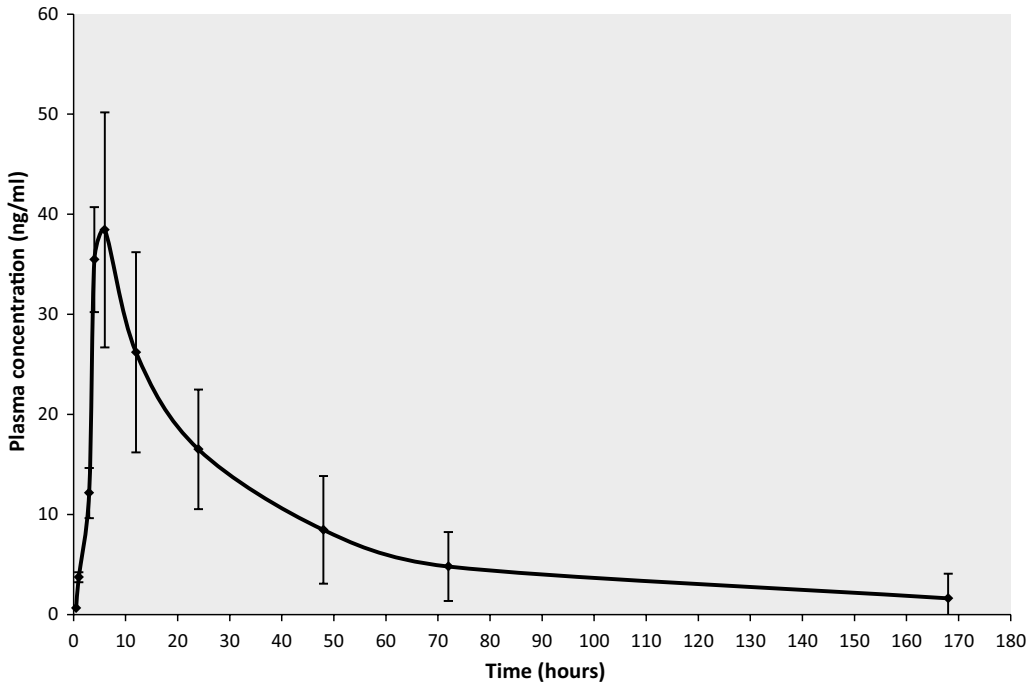

Fig. 1 The PK curve of ivermectin. Plasma concentration of ivermectin in 10 Sudanese patients infected with onchocerciasis after a single oral 150 mcg/kg dose (Data from Elkassabi [28])

in mammals, the central nervous $GABA_A$-receptor and forms the basis for ivermectin's good tolerability. P-gp expression at birth is quite low and reaches adult levels only after 6 months. This plays a large role in the susceptibility to central nervous effects from opioids [30] and possibly also for other P-gp substrates such as ivermectin. No controlled trials of ivermectin pharmacokinetics and safety have been performed in neonates and infants. In rats, however, ivermectin significantly increased postnatal mortality, presumably through exposure from maternal milk [31].

Metabolism and elimination

The plasma half-life is approximately 18 h [7]. Ivermectin is metabolized by the CYP3A4 in gut and liver [32]. The hepatic cytochrome P_{450} system at birth has 30–50% of the activity of adults [33, 34]. By consequence, failure to adjust to weight but also for decreased hepatic clearance could theoretically lead to higher than expected ivermectin exposure and toxicity in neonates and infants. Less than 1% of ivermectin is excreted unchanged in the urine (i.e. renal insufficiency will have little impact on pharmacokinetics), with most of the drug being eliminated through bile and faeces.

Ivermectin's metabolites are present at very low concentration, which makes isolation and structural characterization challenging. Authors have resorted to first identify metabolites in vitro by means of liver microsomes before attempting an in vivo characterization [27, 35]. The correlation of both systems is good in several species tested. Following this methodology, three polar metabolites: 24-hydroxymethyl-H_2B_{1a}, 24-hydroxymethyl-H_2B_{1a}-Monosaccharide and 24-hydroxymethyl-H_2B_{1b} account for up to 50% of all metabolites in liver tissue of cattle, rat and sheep in the first 14 days after dosing [27, 35]. In swine, more than two-thirds of liver residues are composed of 3″-*O*-desmethyl-H_2B_{1a} and 3″-*O*-desmethyl- H_2B_{1b} [27, 35].

In humans, studies with radio-labelled ivermectin show that peak plasma concentration of metabolites is about twice that of the parent drug and occurs later, at 7 h (vs four for parent drug) [36]. Plasma metabolites are less polar than the parent drug and could be fatty acid ester conjugates of the monosaccharides or aglycone of the parent drug [36]. The major metabolites excreted are 3″-*O*-desmethyl-H_2B_{1a} and 3″-*O*-desmethyl-H_2B_{1a}-Monosaccharide in urine and faeces respectively [36]. The plasma half-life of metabolites is about 72 h, fourfold that of the parent drug. If these metabolites have mosquitocidal activity, this could explain recent findings of a "post-ivermectin" effect in which mosquitoes feeding on treated volunteers long after the parent drug is no more identifiable in plasma still show an increased mortality [37, 38].

FOI 26-3132 - Document 5

Ivermectin is metabolized by CYP3A4 [32] but in vitro studies suggest it does not significantly inhibit its metabolizing activity or that of CYP2D6, CYP2C9, CYP1A2, and CYP2E1, all involved in its metabolism to a lower extent [7]. There is, however, a theoretical possibility of interaction with CYP3A4 inhibitors (such as protease inhibitors) or inducers such as rifampicin.

Ivermectin is both a substrate and a potent inducer of the P-gp. P-gp plays a role in the transportation of ivermectin to the intestinal lumen and in preventing its crossing of the blood-brain barrier [39]. P-gp inhibitors (such as antifungal azoles) can increase ivermectin plasma levels in animals [40, 41]. Post-marketing reports of increased International Normalized Ratio (INR) have been rarely reported when ivermectin was co-administered with warfarin [7].

The drug–drug interactions of ivermectin with artemisinin-based combination therapy (ACT) have not been well explored. Co-administration with artemether–lumefantrine was well tolerated in a small study in Burkina Faso [42], data on its safety in combination with dihydroartemisinin-piperaquine will be available from 141 participants in the IVERMAL trial [43] and further evidence on its safety in combination with dihydroartemisinin-piperaquine and primaquine will be available from the IMSEA trial [37].

Assessing the efficacy of ivermectin to kill mosquitoes

Efficacy is defined as the killing effect of ingestion of ivermectin by mosquitoes via blood (either through a direct-skin blood meal or through in vitro/membrane feeding methods). The evidence supporting this lethal effect has been reviewed extensively [9, 10, 44] and will not be re-visited here (see Additional file 1 for all studies). However, studies to assess the efficacy of ivermectin in reducing the survival of mosquitoes are not standardized. A typical approach is to allow a sample of vectors to feed on blood containing the drug or on a treated subject. Resulting mortality is assessed at intervals and reported in different formats.

The concept of lethal concentration 50 (LC_{50})

The LC_{50} is a commonly seen metric of ivermectin killing effect on mosquitoes [45, 46]; it is the concentration of ivermectin in the imbibed solution or blood meal that kills 50% of the mosquitoes during a defined period of observation. It is a measure of efficacy similar to the minimum inhibitory concentration used in bacteriology and it should not be misconstrued that the goal is to kill only 50% of the feeding mosquitoes. The LC_{50} will vary according to the time point chosen for the mortality assessment. At a given drug concentration and mosquito species, the 3-day LC_{50} will be higher than the 9-day LC_{50}, i.e. less drug is needed to kill 50% of the mosquitoes in 9 days, due to the addition of naturally occurring deaths. An alternative approach would be to determine the time to median mortality at any given concentration, but this has not been commonly used.

The feeding method used to determine the LC_{50} could also influence the measurement outcome. Ivermectin is highly lipophilic, it is found in higher concentrations in dermal and adipose tissue than venous plasma [29]. It is hypothesized that the resulting concentration gradient between the adipose tissue and the capillary blood may increase the drug concentration in the capillaries when compared to venous blood. This may be relevant as mosquitoes imbibe blood from subdermal capillaries and thus may ingest higher concentrations of ivermectin than would be predicted from the drug concentration in venous samples, i.e. mosquitoes feeding directly on the skin of a volunteer may have higher mortality than mosquitoes feeding on the blood of the same volunteer in a membrane-feeding device. Evidence is being generated with aim to clarify confounding of mortality measures by route of administration to mosquitoes, and perhaps other factors.

Pharmacokinetic considerations regarding efficacy

The efficacy of ivermectin to reduce transmission is expected to be a function mainly of its lethality to the vector population. Additional benefit will be obtained from a change in the age structure of the mosquito population: in areas of ivermectin MDA, there is increasing mortality of older biting females, this skews the mosquito population towards younger (less infectious) ages and reduces transmission beyond the initially seen lethality for up to 3 weeks [10, 47]. Additionally, older mosquitoes seem to be more susceptible to ivermectin that their younger counterparts [48].

Along these lines, the sublethal effects of the drug on mosquito fertility and flying capacity [13, 14, 45] will contribute to the overall effect (see "Other effects of ivermectin" below). Both lethality and sublethal effects will be closely related to drug concentration in reached in the blood of treated individuals *and* to the time this blood concentration is sustained.

All the concepts defined here refer to the mortality of mosquitoes feeding on a single treated person.

The mortality of mosquitoes caused by ivermectin has a dose–response gradient and is limited by the theoretical LC_{100}

The higher the concentration, the higher the mortality of mosquitoes feeding on those individuals at that time will be [42], this finding has been supported by modelling [49]. This increase in lethality will be limited by the

theoretical LC_{100} (the concentration killing 100% of biting mosquitoes, this is a theoretical concentration difficult to reach in nature). Any blood concentration above this threshold will not contribute to additional mortality (one cannot kill more than 100% of the biting mosquitoes). Figure 2 illustrates this concept.

Ivermectin's impact on mosquito mortality is directly related to the time there is a lethal concentration in the blood

The longer the drug remains in the blood, the more mosquitoes it will kill or disable. Any increase in duration of mosquitocidal concentrations is expected to contribute to additional mortality. Modelling shows that the time the drug remains in blood above mosquito-killing levels is the parameter that drives impact on transmission [50].

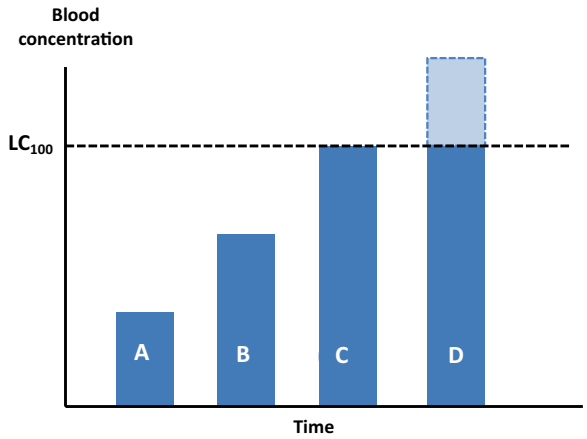

Fig. 2 The effect of increasing concentrations of ivermectin on its efficacy. *Columns A*, *B* and *C* are expected to have increasing efficacy. The area above the LC_{100} in *column D* will not contribute to further mosquito mortality. In the absence of a long elimination tail, the efficacy of the dose of *column C* and that of *column D* will be equal. *Columns* are used for illustration. LC_{100}: lethal concentration 100

The lethal effect is heterogenic

The lethality observed in any mosquito population feeding on a treated individual after a single oral dose will not be uniform. It will vary according to the plasma levels at the time of biting in close relationship with the PK of the drug. Figure 3 illustrates this concept. The total effect will be the sum of the proportions dying at different time points.

The lethal effect could be a function of the area under the curve

The blood concentration and the time the drug remains in the blood can be represented by the area under the curve (AUC). Because the blood concentration above the theoretical LC_{100} cannot add to lethality, the efficacy can be expected to be a function of the AUC that is below the LC_{100}. The AUC below LC_{100} will vary according to the magnitude of the single dose given, the number of doses, the administration route, the absorption and distribution rates of the drug as well as its metabolism and elimination. Secondary release from adipose tissue after accumulation could also play a role.

Conceptually, the ideal ivermectin dose would maximize the time drug level is near the LC100 without wasting drug going beyond the level at which most mosquitoes are killed

Given the heterogeneity of mosquito lethality in time, in the (theoretical) presence of a constant biting rate, a "peaked"

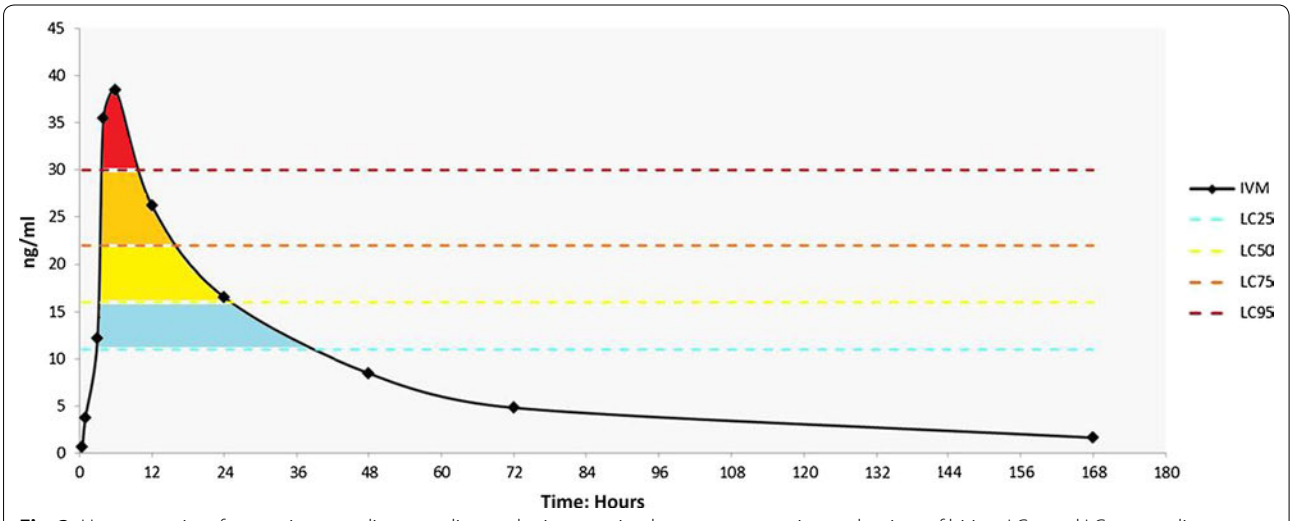

Fig. 3 Heterogeneity of mosquito mortality according to the ivermectin plasma concentration at the time of biting. LC_{50} and LC_{25} according to Kobylinski et al. [46]. The LC_{95} and LC_{75} shown have not been determined and are shown for illustration purposes. *LC* lethal concentration

curve with a Cmax close to the LC100, but with a narrow base, can have the same efficacy of a wider curve, even if the Cmax is lower. Figure 4a illustrates this concept. Ivermectin MDA could be however tailored to make the Cmax coincide with the peak biting activity of the local vectors [11].

Following this rationale and considering the point illustrated in Fig. 2, a large dose yielding a "peaked" curve with Cmax high above the LC_{100} could be less efficacious than a dosing scheme yielding the same area under the curve without surpassing the LC_{100}. This is because the AUC above the LC_{100} will not directly contribute to the efficacy. This is illustrated in Fig. 4b.

Time above lethality target

Modelling can help generate a robust hypothesis on the mosquito lethality target at a population level. This will be a function of the individual dose per body weight. The time above lethality target is related to the area under the curve but takes into consideration the susceptibility of the local mosquitoes. It can be expressed in time as a "mosquitocidal window". Figure 5 illustrates how the susceptibility of the local vector can influence this variable.

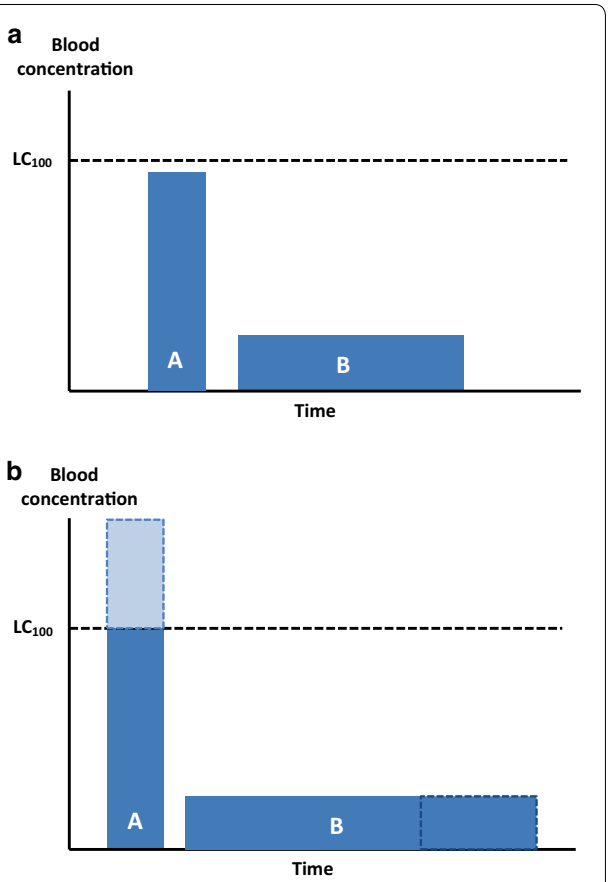

Fig. 4 AUC of different dosing schemes and their potential relationship with efficacy. **a** The area of both *columns* is the same ($A = B$), hence, in the presence of constant biting rate, the total number of mosquitoes killed by A and B might me similar, even if B does not reach the same Cmax. **b** If the theoretical LC_{100} is surpassed (*light blue area*), the drug consumed to reach such plasma levels is partly wasted because it does not contribute to efficacy and may in turn increase the possibility of side effects. *Columns* are used only for illustration. LC_{100} lethal concentration 100

Dose–response curves

The slope of the curve will represent the logarithmic increase in the AUC below LC_{100} needed to kill a higher proportion of mosquitoes. Although recent data suggests the relationship between plasma concentration and mosquito mortality is linear at the individual level [42], at the population level the relationship AUC-efficacy is unlikely to be so. Figure 6 illustrates this concept.

Options to increase the efficacy of ivermectin

Higher doses per body weight, multiple dose regimens, or slow-release formulations are all theoretical ways to increase the AUC and hence the efficacy. The duration of sublethal concentrations can play an important role in general efficacy as vectors imbibing sublethal concentrations can have a higher mortality rate due to impaired motility or temporary paralysis (knock-down). Epidemiological and PK modelling can be used to plan the doses and regimens to be tested in field trials, but care must be taken to reflect the potential importance of this additional effects.

Higher doses (increasing the Cmax)

Using higher doses per body weight will result in larger AUC driven by a higher Cmax (Fig. 7). This will result in longer time above lethal concentrations because the slope of elimination will remain the same. This is the most straight-forward method because it could be implemented using the current oral formulation at a single encounter. The main challenges with this approach include the safety of a higher Cmax that could increase toxicity while and partial drug waste due to a portion of the AUC above the theoretical LC_{100}. Acceptability in areas where previous lower ivermectin doses have been used must be part of integrated community engagement, also needed for the understanding of direct and indirect benefits that can be expected from this approach.

Multi-dose regimens

A multiple-dose regimen would result in a series of peak concentrations that could have cumulative effect depending on the frequency of the doses (Fig. 8). The effect of every dose would also be limited by the theoretical LC_{100} plateau. The main limitations of this approach are compliance and the logistics of multiple rounds of MDA. Additionally, the valleys caused by the intermittent dosing may result in "vulnerable windows" because levels

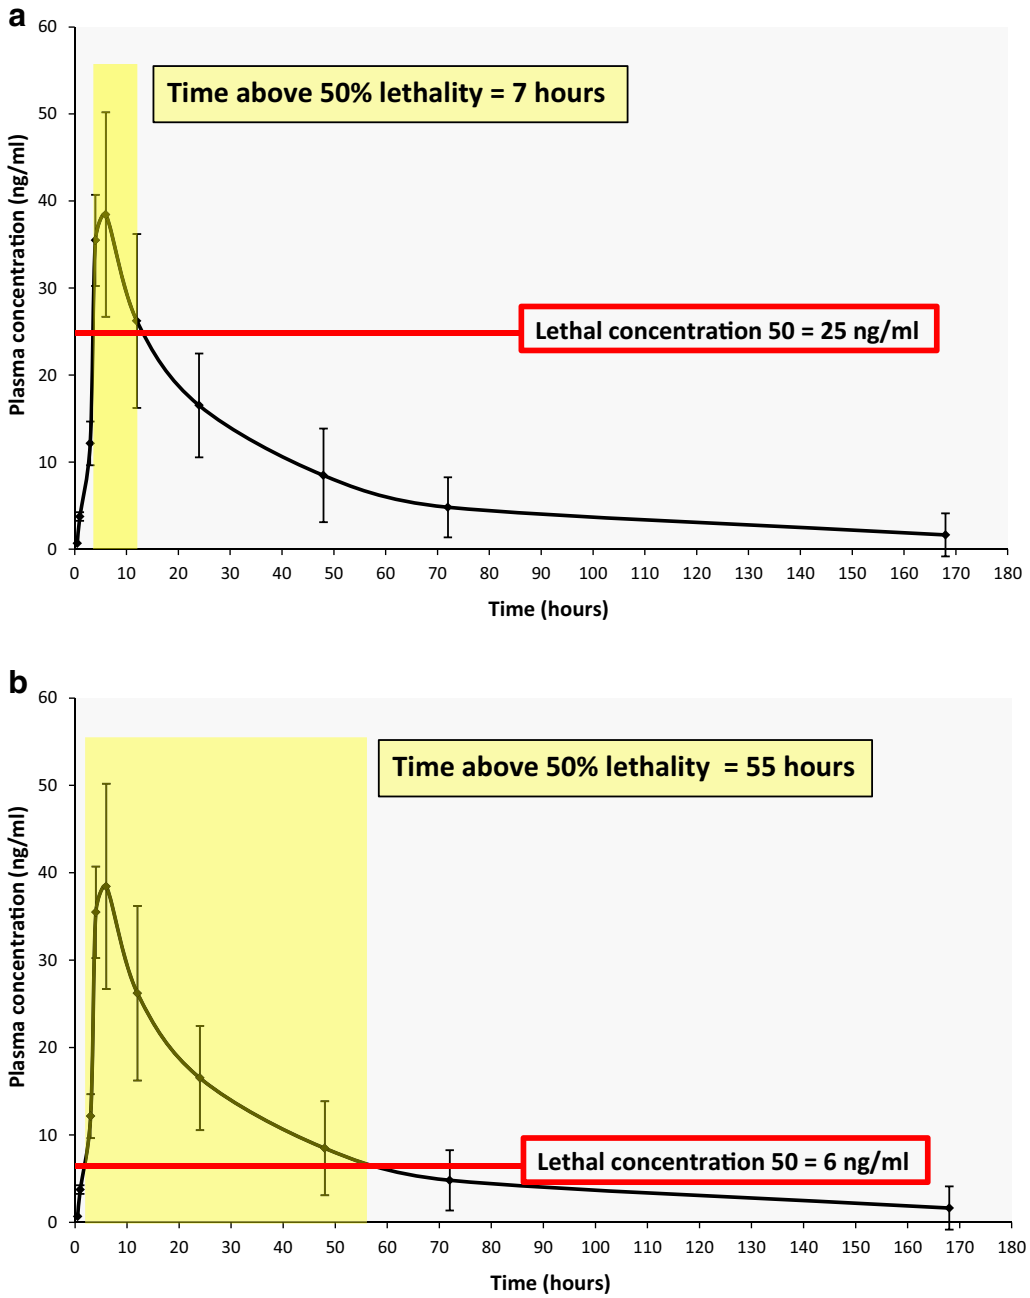

Fig. 5 The time above lethality and the "mosquitocidal window". An illustration of how the lethality target selected and the susceptibility of the local vectors can affect the efficacy of ivermectin to reduce malaria transmission. The *curves* represent the PK of ivermectin after a single oral 150 mcg/kg dose according to Elkassaby [28]. In both *panels*, the lethality target is the LC_{50}. The vectors of **a** are less susceptible and higher concentrations are required to kill 50% of them, the time above lethality target is 7 h. The vectors of **b** are much more susceptible, this increases the time above lethality eightfold. *LC* lethal concentration

might be in the insufficient dose range, decreasing efficacy. Preliminary data from a recent cluster-randomized trial showed a 20% reduction in clinical incidence of malaria in children under five by active case detection in areas where a 200 mcg/kg dose was given to all eligible population every 3 weeks for six doses [51].

Slow-release formulations

A long-lasting, slow-release formulation [52, 53] would have effect on the Cmax depending on the release rate, which, if controlled, could theoretically improve the efficacy/safety ratio (Fig. 9). The main issue with this approach is investment in R&D and the need to reassess

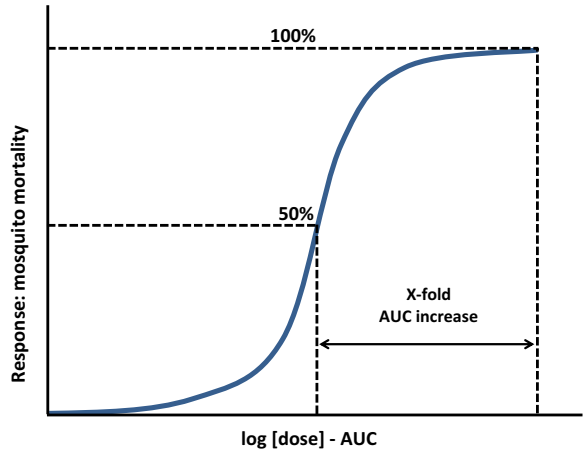

Fig. 6 Logarithmic ivermectin dose–response curve as mosquitocidal. In the case of ivermectin, the dose will be a function of the AUC and the response a function of the total mosquito mortality plus the sublethal effects. *AUC* area under the curve

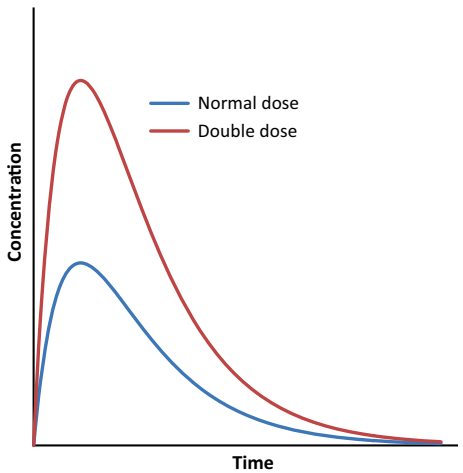

Fig. 7 Increasing efficacy using higher doses. Using a higher dose-per-body weight in a single encounter increases the AUC by increasing the Cmax. *AUC* area under the curve

the efficacy of the new formulation on the treatment of neglected tropical diseases.

Other options

One alternative to increase the AUC is to prolong the half-life of the drug (alter the elimination slope), which could theoretically be achieved with CYP3A4 and/or P-gp inhibitors. Doing so, however, may unreasonably increase the risk of toxicities and drug interactions, especially with antiretrovirals. The addition of a rather specific CYP3A4 inhibitor with no P-gp inhibition, such as voriconazole [54], would be an interesting approach as this would increase bioavailability of ivermectin while not impairing P-gp's vital function at the blood–brain barrier.

Other effects of ivermectin

In addition to the direct killing effect of ivermectin, there several sub-lethal effects that can increase the net impact of the drug on malaria transmission:

Effect on vector fertility

Several studies report diminished fertility of *Anopheles* mosquitoes after an ivermectin-loaded blood meal containing sub-lethal concentrations [13, 14]. Reduced hatching of the laid eggs has also been observed. Of note, this effect may delay but not completely avoid the appearance of ivermectin-resistant mosquitoes.

Effects on vector behaviour

Knock down, lesser flight performance and reduced tendency to bite have all been reported after taking sublethal ivermectin concentrations in a blood meal [45, 55]. These effects measured in the laboratory might contribute to greater mosquito mortality in the field.

Effects on the parasite

In the mosquito, ivermectin might inhibit plasmodium sporogony [46, 56] and could have an effect on liver schizonts as seen in vitro [57, 58] and confirmed in mouse model [57], these findings require further evaluation.

Key knowledge gaps regarding efficacy

Methods

- Lack of standardized protocols for the assessment of ivermectin's efficacy.
- Lack of correlation between the mortality observed in mosquitoes taking ivermectin through membrane vs those taking it via skin-feeding. Validating membrane feeds as a reliable, predictive assay compared to direct skin-feeding would facilitate evaluation of different approaches.

LC_{50}

The main gap is dearth of data on The LC_{50} determined via human direct skin-feeding. Results should be obtained for different species and strains in different sites, especially for known outdoor-biting species or main vectors of areas targeted for elimination.

Time above lethality

Determine the blood concentration that should be achieved with an ivermectin-based tool and how long should it be sustained in order to have a measurable impact on transmission.

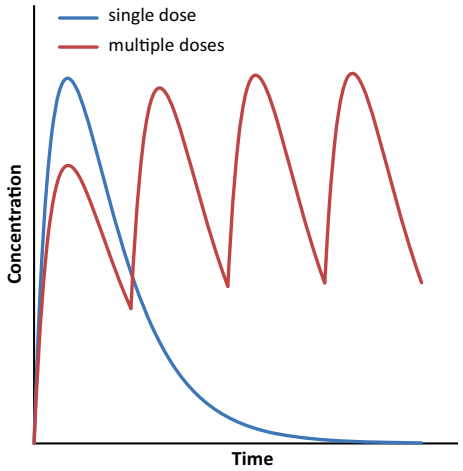

Fig. 8 Increasing efficacy by means of multiple dosing. Using a series of multiple doses can increase the AUC while avoiding reaching plasma concentrations where the efficacy/safety ratio is lower

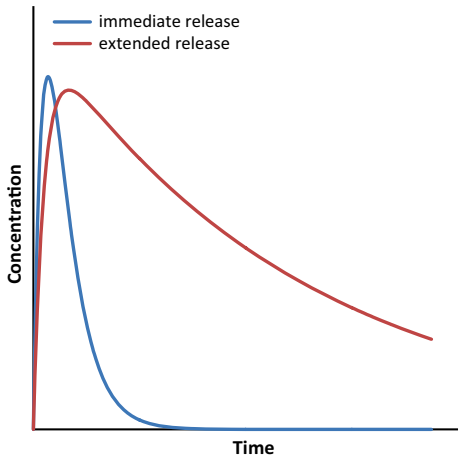

Fig. 9 Increasing efficacy with a slow-release formulation. A long lasting formulation would increase AUC by prolonging time above lethality, without significant increase in the Cmax and theoretically improving the efficacy/safety ratio. *AUC* area under the curve

Other effects

Assess whether ivermectin, by having a mechanism of action different from all public health insecticides available today, could help reduce the risk of insecticide resistance that is not CYP-mediated. Also the influence of ivermectin´s effects on mosquito fertility in potentially delaying the appearance of ivermectin-resistant mosquitoes.

PK considerations regarding safety

Ivermectin has been licensed for human use for almost 30 years, and its safety has been assessed in over 70 trials. More than 2.7 billion 150–200 mcg/kg single doses have been distributed by the Mectizan Donation programme [59]. Since community use of ivermectin implies that drug will be given to at risk and infected individuals, all for indirect benefit of lowering malaria disease rates, the safety profile and the risk–benefit assessment will be critical. For use as a vector control measure, it is the combination of the blood levels and the duration of these levels that will need to have an acceptable safety profile. Both parameters are directly related to drug dosage and regimen required to reach impact. Regarding safety, the adverse effect rate is also expected to be a function of the cumulative dose. Host factors such as illnesses and co-administered drugs must also be taken into account.

Therapeutic index

Drugs developed for elimination endeavours and MDA administration must have a high therapeutic index [60]. The therapeutic index is a measure of the range of doses that elicit a therapeutic response without unacceptable adverse effects [61]. Using ivermectin for vector control, this relationship will be between the mosquito mortality (as a proxy for efficacy) and the AUC (as a proxy for dose per body weight and number of doses). Figure 10 illustrates this concept.

As an example, Guzzo et al. administered 1.404–2.000 mcg/kg in a single dose to 16 healthy volunteers in the US (>tenfold the usual 150-200 mcg/kg single dose for onchocerciasis) and did not report a greater adverse effect rate than in controls [62]. These findings suggest the therapeutic index of ivermectin for onchocerciasis control is at least higher than 10. For malaria control the therapeutic index will be lower as the dose needed will be higher. The findings of Guzzo et al. provide a good safety reference at 3.200 mcg/kg in a week (see Table 1). The Centers for Disease Control and Prevention recommends doses of up to 1.400 mcg/kg within a month for the treatment of severe crusted scabies [63].

The efficacy/safety ratio

A particular AUC will elicit a specific efficacy/adverse effects ratio. This ratio is expected to increase exponentially with the AUC; in theory, once the LC_{100} has been reached, this ratio can only increase at the expense of the time above lethality. Using the therapeutic index concept described above, after a certain cumulative dose, toxicity will start to increase and the efficacy/adverse effects ratio will be reduced (Fig. 11). Increasing the dose per body weight given in a single encounter is a possible strategy to increase the efficacy. This strategy, however, must be carefully evaluated since the AUC above the LC_{100} will minimally contribute to efficacy and may in turn increase the risk of toxicity.

Safety profile of ivermectin in community campaigns–implications for malaria

Since the creation of the Mectizan Donation Programme in 1988, more than 2.7 billion doses of ivermectin have been distributed for the control of onchocerciasis and lymphatic filariasis in Africa, Latin America, and Asia [59]. Exclusion criteria are: children under 15 kg, pregnant women, nursing mothers in the 1st week after delivery, the severely ill and those with known hypersensitivity to the drug [64]. Coverage target is normally between 65 and 80% of the whole population [65].

Safety of ivermectin in onchocerciasis MDA campaigns

In onchocerciasis-infected patients, adverse events (AE) to ivermectin are usually mild, transient, associated with intensity of microfilarial infection and primarily characterized as mild Mazzoti-type reactions to dying microfilaria [66]. These effects wane in subsequent administrations [67]. No significant association has been found between ivermectin plasma levels and AE recorded [68]. A recent Cochrane review of ivermectin for river blindness shows that side effects are rarely reported [69]. Outside *Loa loa* endemic areas (see below), the drug is remarkably safe.

Loa-associated encephalopathy

Loa loa is a parasitic infection that is broadly present in geographies overlapping the onchocerciasis/LF programmes. While causing limited direct disease, administration of ivermectin to individuals infested with *Loa loa* can result in encephalopathy in 0.01–0.11% of the treated population [70], if the *Loa loa* burden is high (>30.000 parasites/ml), the odds ratio can be above 1000 [70]. The syndrome includes confusion, lethargy and coma. The pathophysiology behind this syndrome is not clear, but rapid killing of *Loa* microfilariae or even defects in transmembrane efflux pumps may play a role [70, 71]. At a population level, high levels of microfilaraemia are seen in 1% of the population in areas with an overall *Loa loa* prevalence greater than 20%. This threshold was used by the Mectizan Expert Committee and the Technical Consultative Committee to define the preventive strategies recommended for ivermectin distribution in *Onchocerca* and *Loa* co-endemic areas [72]. Nonetheless, the risk of this severe adverse event excludes parts of *Loa*-endemic central Africa from ivermectin MDA campaigns for the elimination of onchocerciasis; this includes areas of Angola, Cameroon, Central African Republic, Chad, Congo, Democratic Republic of the Congo, Equatorial Guinea, Ethiopia, Gabon, Nigeria and South Sudan [73].

Several tools and strategies are emerging in response to the limitations caused by *Loa* which creates a near term window of opportunity for malaria: New diagnostic tools (loascope) allow for quantitative population screening in real time [74] and novel biomarkers could also predict burden at individual level [75]. This test and (not) treat strategy may offer a programmatic approach to addressing the *Loa* barrier to ivermectin treatment. This strategy could reduce the *Loa* burden at population level, lowering the risk of parasite-burden-related adverse reactions. Finally, single-administration of drug combos [76] can offer a rapid pathway to LF elimination, this treatment also reduces *Loa loa* burden and thus risks from ivermectin for any indication (including malaria).

Safety of ivermectin at doses higher or more frequent than approved for NTDs

A single ivermectin dose of 150–200 mcg/kg results in a too short-lasting mosquito-killing effect to be applicable for malaria impact. Therefore, for this indication, higher doses and/or multi-dose regimens than those currently used for onchocerciasis will be needed. A range of dosages are already recommended for different indications. The FDA-approved ivermectin dose for strongyloidiasis MDA is 150 mcg/kg (every 12 months), although the possibility of quarterly use in individual patients is also included in the label [7]. The French authorities recommend up to 400 mcg/kg for the control of lymphatic filariasis in selected areas [77]. For severe crusted scabies, up to seven 200 mcg/kg doses within a month in combination with topical treatment and keratolytics are recommended in the US [63] and Australia [78]. The possibility of using more than 3 doses for the treatment of moderate to severe crusted scabies cases is included in the Australian label [8].

Very few studies, at varying doses and frequencies, have evaluated the safety of ivermectin regimens at doses

Table 1 The safety of ivermectin at doses higher or more frequent than current approval

Reference	Population	Highest single dose	Maximum frequency	Maximum number of doses	Maximum total dose (period)	Adverse events
Awadzi et al. [100]	75 males with moderate to heavy *Onchocerca* infection	800 mcg/kg	Single	Single	800 mcg/kg (once)	No difference with controls taking the 150 mcg/kg dose
Awadzi et al. [101]	100 adult males infected with *Onchocerca*	800 mcg/kg	Days 1 and 4	2	1.600 mcg/kg (4 days)	No difference with controls taking the 150 mcg/kg dose
Guzzo et al. [62]	68 male and female healthy, adult volunteers	2.000 mcg/kg	Days 1, 4 and 7	3	3.273 mcg/kg (1 week)	No difference with controls
Kamgno et al. [67]	657 adult males infected with *Onchocerca*	800 mcg/kg	3-monthly	13	8.950 mcg/kg (3 years)	The high dose group reported a statistically higher rate of transitory mild and subjective visual side effects (No structural explanation). For all other AE comparable rates reported in all groups
Smit et al. [43]	141 adults with uncomplicated malaria	600 mcg/kg	Days 1, 2 and 3	3	1.800 mcg/kg (3 days)	Pending publication of results

The maximum total dose is the cumulative dose received by a participant during a given period which is given in brackets

AE adverse events

FOI 26-3132 - Document 5

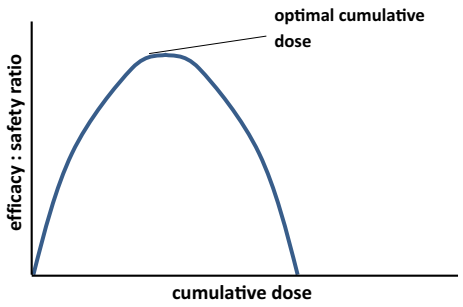

Fig. 11 The efficacy/safety ratio. The relationship between the efficacy: adverse effect ratio and the cumulative dose

above 400 mcg/kg for control of NTDs (Table 1). Pharmacokinetic modelling suggests that a regime consisting of a daily dose of 600 mcg/kg for 3 days has the potential to sustain ivermectin concentrations lethal to *Anopheles* mosquitoes for at least 1 week [43]. This is the basis of the recently finished IVERMAL trial in Kenya [43].

The skewing of the age structure of the mosquito population for around 3 weeks after a single round of MDA for onchocerciasis (150 mcg/kg) could also support reduction in transmission of malaria. This has been used as the basis for the RIMDAMAL trial [79] which consisted on six rounds of ivermectin MDA 3 weeks apart each. Preliminary data from this cluster-randomized trial shows no significant adverse events with this those [51].

Safety of ivermectin during pregnancy and lactation

Pre-clinical studies in pregnant mice, rats and rabbits show teratogenicity at doses toxic to the mother (400 mcg/kg, 5.000 mcg/kg and 3.000 mcg/kg during pregnancy days 6–18 respectively) [7, 80]. Ivermectin can produce delayed development and increase pup mortality in rats at maternal doses of 1600 mcg/kg [80]. It is estimated that in *Onchocerca*-endemic areas, up to 50% of pregnant women in the first trimester are systematically inadvertently treated with ivermectin during MDA campaigns [81].

Five studies have specifically evaluated the effects of inadvertent ivermectin treatment during pregnancy (four case–control studies and one clinical trial). The results are presented in Table 2. The studies encompass a total of 839 women treated during pregnancy, including 442 women treated in the first trimester. No difference with controls is reported regarding pregnancy outcome, newborn health status or early child development. There is however no systematic database of inadvertent exposure during pregnancy to date. Based on these results, the proscription of ivermectin treatment during pregnancy was lifted for areas where women are *at high risk of blindness*. The decision to include pregnant women, however, is left at the discretion of the program directors [82].

Low ivermectin levels are found in human breast milk after a single oral dose of 150–250 mcg/kg in healthy women with a peak at 1 h post-ingestion of 18.5 ng/ml [80, 83]. It remains detectable in human milk at very low levels (<1 ng/ml) for up to 14 days after a single dose [80]. Only nursing mothers in the 1st week after delivery are systematically excluded during MDA campaigns [64, 82].

A systematic review of the evidence regarding safety in pregnancy is needed. This is important because at population level the effectiveness of any ivermectin-based strategy will be determined by the population coverage achieved [84]. If the safety of the expected higher or more frequent doses needed for malaria is not established in pregnancy, excluding women in reproductive age is

Table 2 Five studies assessing the safety of ivermectin during pregnancy compared with community based controls

Reference	Country	Number of pregnant women	Number inadvertently treated	In the first trimester	Pregnancy outcome	Child mortality	Child development

FOI 26-3132 - Document 5

likely to reduce the efficacy of the intervention to reduce malaria transmission.

Safety of ivermectin in infants and children

Ivermectin is licensed for the treatment of children weighing more than 15 kg [7, 8]. In MDA campaigns a height of 90 cm is used as a proxy for 15 kg. A preclinical toxicology study in 24 neonatal (7–13 days old) rhesus monkeys showed no adverse reaction after 2 weeks of daily doses of up to 100 mcg/kg [80]. An additional study in eight immature rhesus monkeys (13–21 months old), receiving doses of up to 1.200 mcg/kg for 14–16 days showed no treatment related findings; three animals presented increased serum transaminases which was attributed to an infectious origin. In humans, there are only anecdotal case reports [85, 86] and small case series [87] of its use off-label in infants less than 15 kg.

Similarly to pregnancy, the importance of a clear guidance regarding use in children weighing less than 15 kg is directly related to ivermectin MDA efficacy. At population level, coverage will be directly proportional to efficacy [84]. Importantly, the impact of including small children on the overall efficacy of ivermectin MDA for malaria will be related to the mosquito biting rate as well as risk of transmission in this particular population.

In areas of high transmission, where most of disease burden occurs in children under 5 years, this age group is expected to receive the largest proportional benefit of ivermectin MDA to reduce malaria transmission. In the context of the RIMDAMAL trial, the main outcome measure was malaria incidence in children under 5 years of age, where most of these children did not receive ivermectin [51]. Conducting dose-ranging studies in children will allow for increased population coverage of an ivermectin-based vector control intervention.

Safety of ivermectin in high-risk groups

There is no renal or hepatic ivermectin dose defined [7]. Renal dose adjustments would not appear necessary for a drug for which less than 1% is excreted unchanged in urine. It is conceivable that active metabolites exist that are eliminated renally. There is little information available on the safety of ivermectin in patients over 65 years of age. A report of excess deaths (several causes) among 47 residents of a nursing home following ivermectin MDA for scabies (single dose 150–200 mcg/kg) [88] raised heated debate [89–92]. Ivermectin was licensed in Australia for the treatment of scabies in 2013 [93]. The elderly tend to have less adipose tissue and thus lower volumes of distribution for lipophilic drugs, such as ivermectin, which will result in higher plasma concentrations. They are also more prone to hypoalbuminaemia due to malnutrition, potentially yielding higher free concentrations of ivermectin. Lastly, hepatic function (and with that: capacity for detoxification) decreases with age.

There is no evident biological basis for concern on potential cardio-toxicity. Dukuly et al. [94] prospectively followed 32 men (mean age 61 years), including 20 with baseline EKG abnormalities and found no significant changes after ivermectin treatment.

HIV-infected individuals are not excluded from treatment based on their serological status [64]. Potential drug–drug interactions with anti retrovirals or TB drugs must be particularly taken into account when treating this special population (see drug interactions below).

Concerns about the theoretical risk of using ivermectin in patients with epilepsy have been resolved [82, 95].

Environmental concerns about ivermectin

There are three ways in which ivermectin can enter the environment: excretion from treated humans or animals, from disposal of pharmaceutical waste, or from emissions from manufacturing sites [80]. Haley et al. showed ivermectin undergoes rapid degradation in light and soil [80, 96]. This, combined with tight binding to soil and sediment prevents environmental accumulation and minimizes its potential impact on non-target organisms [80, 96]. Veterinary ivermectin formulations affect the dung fauna and there was initial concern that it may delay dung degradation [97]. More recent studies have suggest this is not the case [98].

Key knowledge gaps regarding safety

- The safety profile of ivermectin when used at higher doses, or with longer exposure treatment schemes.
- The safety of the proposed dose/schemes in populations likely to affect coverage if excluded i.e. potentially pregnant women and children under 15 kg.
- New strategies to assess and prevent the *Loa*-related adverse effects.
- The safety of ivermectin in combination with anti-malarials and other drugs commonly used in endemic areas such as antiretrovirals, TB drugs and other antihelmintics.

Conclusions

Ivermectin MDA has the potential to reduce malaria transmission by increasing the mortality of malaria vectors biting treated individuals, particularly those only partially affected by LLINs and IRS due to behavioural or physiological resistance. A thorough understanding of the pharmacological properties of ivermectin is pivotal to design studies aiming at providing evidence for a policy recommendation.

Ivermectin is safe in MDA campaigns at the current dose approved for onchocerciasis and LF 150–200 mcg/

FOI 26-3132 - Document 5

kg administered not more than four times a year. If used for malaria control, the dose and administration scheme will change. The efficacy of an ivermectin-based tool will be directly related to coverage; hence all population groups should be represented in the safety data collections, including women in reproductive age, children and the elderly. Additional preclinical safety studies might be needed to include these groups in clinical trials. The appropriate best time to include susceptible groups would be after the dose, formulation and administration scheme have been defined.

Effectiveness of Ivermectin in SARS-CoV-2/COVID-19 Patients

Aijaz Zeeshan Khan Chachar, Khurshid Ahmed Khan, Mohsin Asif, Khushbakht, Arous Khaqan, Rabia Basri

Abstract: Background:The first case of Infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) were diagnosed in Wuhan, China in 2019. In the first half of 2020 this disease has already converted into a global pandemic. Objectives: To assess the efficacy of Ivermectin in mild cases of COVID-19 patients on the basis of predefined assessment criteria. Study Settings: Fatima Memorial Hospital, Lahore Study Design: Open label randomized control trial. Duration of Study: From 1st May, 2020 to 30th June, 2020.Patients & Methods: Sample size and technique: Sample size was 50 patients; 25 patients were kept in control group and 25 patients were kept in experimental group. Results: There were total 50 patients, divided into two groups case and control group.The mean age of the participants was 40.60 ± 17 and out of those 31 (62%) were male and 19 (38%) were females. Cough was observed more in case group (p= 0.049). Fever, myalgias and dyspnea were the commonest symptoms in both the groups (p= 1.000). Diarrhea and vomiting were more common in control group (p=0.0001, p= 0.042 respectively). On follow up at day 7, patients were stratified as asymptomatic and symptomatic. Amongst the case group, out of 25 patients, 16(64%) patients were asymptomatic and rest of the 9(36%) patients was asymptomatic. In control group, out of 25 patients, 15(60%) patients were asymptomatic and rest of the 10(40%) patients was asymptomatic. p-value (0.500). Statistically there was no significant difference between case group who were given ivermectin along with symptomatic treatment and control group who were only given symptomatic treatment without ivermectin, being asymptomatic on day 7 at follow up. p-value (0.500)

Keywords: Corona Virus, Covid-19, SARS-COv-2, Antiviral, Ivermectin, Pandemic

Introduction:

The first case of Infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) were diagnosed in Wuhan, China in 2019. In the first half of 2020 this disease has already converted into a global pandemic, having different forms of presentation in different patients.

Exponential rise in its cases along with associated mortality has shaken the world.[1]

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a single-stranded ribonucleic acid (RNA) virus that causes a severe acute respiratory syndrome. The virus was originally called SARS-CoV-2 named officially by World Health Organization as COVID-19 and a global health emergency. The first known case of infection was recorded in early December 2019 and subsequently spread to various continents, including Europe and the United States[2, 3]Generally, 75 percent of patients recover without any notable complication however 25 percent can experience associated complications leading to intensive care unit transfer and even mortality.[4]

Ivermectin has different effects to treat variety of diseases and it has proven antimicrobial, antiviral, and anti-cancer properties and considered as a wonder drug. It is highly effective against many microorganisms including some viruses.[5] Many studies revealed its antiviral effects on RNA viruses such as Zika, dengue, yellow fever, West Nile, Hendra, Newcastle, Venezuelan equine encephalitis, chikungunya, Semliki Forest, Sindbis, Avian influenza A, Porcine Reproductive and Respiratory Syndrome, Human immunodeficiency virus(HIV) type 1, and severe acute respiratory syndrome coronavirus SARS-CoV-2. Fon other hand there are few studies showing antiviral effects of ivermectin against DNA viruses such as Equine herpes type 1, BK polyomavirus, pseudorabies, porcine circovirus 2, and bovine herpesvirus 1.[5] Ivermectin plays a vital role in several biological mechanisms, therefore it could emerge as a potential candidate in the treatment of a wide range of viruses including COVID-19 as well as other types of positive-sense single-stranded RNA viruses. In vivo studies of animal models revealed a broad range of antiviral effects of ivermectin, however, more clinical trials are necessary as it's the need of the hour to do so, as we can validate the potential efficacy of ivermectin in clinical settings.

The recent report by Caly et al.[6] describing the antiviral potential of ivermectin against the severe

acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in vitro arrive to the agenda of potential candidates for COVID-19 treatment.[6]

Currently, there is not any Food and drug administration (FDA) approved specific effective antiviral treatment available for COVID-19.Although most of the COVID-19 patients have mild or moderate courses, up to 5%–10% can have severe, potentially life threatening course, there is an urgent need for development of effective & safe drugs to deal with this novel virus. Optimized supportive care remains the mainstay of therapy. There are more than 300 clinical trials going on, various antiviral and immunomodulating agents are in different stages of evaluation for COVID-19 in those trials and results/ primary end points of few trials will be published in the next couple of months. Despite the urgent need to find an effective and safe antiviral treatment for COVID-19 through randomized controlled studies, certain agents are being used all over the world based on either in-vitro or conclusive evidence or observational studies.[7]

The clinical efficacy and utility of ivermectin in SARS-CoV-2-infected patients is unpredictable at this stage, as we are dealing with a completely novel virus.

There is an urgent need for investigation of the mortality causes and development of novel therapeutic options for severe COVID-19.

Operational definition:
COVID-19 infection:
Patients were labeled to have mild disease due to acute respiratory syndrome coronavirus 2 (SARS-CoV-2; previously named as 2019-nCoV) proven via RT-real time COVID-19 polymerase chain reaction (PCR) test.

Methodology:
Study Design:
It was a open label randomized control trial where participants were allocated using predefined protocol who met the inclusion criteria of study after signing a written & informed consent either by the patient or the person legally authorized to sign.

Study Settings:
Study was conducted in Fatima Memorial Hospital, Lahore among patients reporting to COVID-19 clinics and medical outpatient department OPD.

Sample size and technique:
our sample size was 50 patients; 25 patients were kept in control group and 25 patients were in experimental group. Patients were allocated randomly to the groups by computer generated number. Sampling technique was convenient sampling as per the inclusion and exclusion criteria. It was an open label randomized control trial which was done on COVID-19 patients proven by RT- PCR fulfilling the criteria (mild severity).

Duration of study: Starting after IRB approval, 1st May, 2020 to 30th June 2020

Inclusion Criteria:
- All patients diagnosed with COVID-19 infection with positive reverse transcriptase RT-PCR test, who were willing to participate in this study
- Patients having age of 18-75 years
- Patients of both genders male and female
- Patients who had mild symptoms of Corona virus disease and RT- PCR positive for SARS-Cov-2
- Ability to take oral medication and were willing to adhere to the drug intake regimen

Exclusion Criteria:
- Known severe allergic reactions to Ivermectin
- Pregnancy or breastfeeding
- Severe symptoms likely attributed to Cytokine Release Storm
- Malignant diseases
- Chronic kidney disease

Data Collection and analysis Procedure: All patients having COVID-19 proven by RT-PCR reporting to outpatient department OPD and clinics at Fatima memorial Hospital were studied. Patients were allocated randomly to the groups by computer generated number. Data regarding Epidemiological, demographic, clinical, and treatment was collected and analyzed. Outcomes were noted. All the data entered on a structured Performa (Annex-I)

Response of the patients after Ivermectin prescription and response of the patients without Ivermectin prescription was recorded. Response was recorded on the basis of clinical parameters (Fever, Cough, sore throat, Headache, Shortness of breath, lethargy, and fatigue. Any side effects noted after prescription of Ivermectin was recorded.

Ivermectin Prescribing protocol:
Patients were prescribed Ivermectin 12mg stat and then 12 mg after 12 hours and 12mg after 24 hours and we looked at the response at day 7 on follow up in terms of improvement of symptoms like (Fever, Cough, sore throat, Headache, Shortness of breath, lethargy, and fatigue.

Data was entered and analyzed using SPSS 25.0. Frequency and percentages were calculated for the qualitative variables like gender, comorbidity, symptoms, response to treatment. Quantitative variables of the study like age were expressed as Mean ± SD

Ethical Considerations:
Patients were included in the study after written and informed consent. Institutional review board IRB approval was taken from the ethical committee.

Results:
Total of fifty patients were included in our study, the mean age of the participants was 40.60 ± 17 and out of those 31 (62%) were male and 19 (38%) were females. Patients were divided in two groups, case and control. Case group was offered the symptomatic treatment along with Ivermectin and control group was given only symptomatic treatment without Ivermectin. Control group particpants' were older than the case group statistically but there is no difference between the average ages of both groups (p= 0.582). There was no association between the gender and case group (p= 0.561). Cough was observed more in case group (p= 0.049). Fever, myalgias and dyspnea were the commonest symptoms in both the groups (p= 1.000). Diarrhea and vomiting were more common in control group (p=0.0001, p= 0.042 respectively). Regarding loss of taste and and anosmia, were more seen in case group (p=0.0009) Table-1

Table: 1 -Age & Gender distribution of the participants & Comparative analysis of groups at presentation

Variables	Group		Total	p-value
	Case	**Control**		
Age	40.60 ±17	43.08 ± 14.8	41.84±15.695	0.582
Gender Male	17 (34%)	14(28%)	31(62%)	0.561
Female	8 (16%)	11(22%)	19 (38%)	
Cough	24 (48%)	18(36%)	42(84%)	0.049
Fever	25 (50 %)	24 (48 %)	49(98%)	1.000
Sore throat	20 (40%)	14(28%)	34(68%)	0.128
Headache	20(40%)	13(26%)	33(66%)	0.072
Dyspnea	25(50%)	25(50%)	50(100 %)	------
Nausea	6(12%)	10 (20%)	26(32%)	0.364
Vomiting	6(12%)	14(28 %)	20(40%)	0.042
Diarrhea	4(8%)	17(34 %)	21(42%)	0.000
Myalgia	23(46 %)	24(48%)	47(94%)	1.000
Loss of taste	15(30%)	5(10%)	20(40%)	0.009
Anosmia	15(30%)	5(10%)	20(40%)	0.009
Hypotension	2(4 %)	6(12 %)	8(16 %)	0.247

Age is presented as Mean±SDand for comparison independent sample t test is applied
All the categorical variables are presented in N (%) and Fisher's Exact Test is applied

On follow up at day 7, patients were stratified as asymptomatic and symptomatic. Amongst the case group, out of 25 patients, 16(64%) patients were asymptomatic and rest of the 9(36%) patients was asymptomatic. In control group, out of 25 patients, 15(60%) patients were asymptomatic and rest of the 10(40%) patients was asymptomatic. p-value (0.500) statistically there is no significant difference between case group who were given ivermectin along with symptomatic treatment and control group who were only given symptomatic treatment without ivermectin, being asymptomatic on day 7 at follow up. p-value (0.500) Table-2

In case group, adverse reaction of ivermectin like heartburn was seen in 8(32%) patients and reported as well.

Table-2: Comparative analysis of groups on Follow up at day 7

Group	**follow up @Day 7**		
	Asymptomatic	Symptomatic	Total
Case	16 (64%)	9(36%)	25
Control	15(60%)	10(40%)	25
Total	31 (62%)	19(38%)	50(100%)

Discussing about the comorbidities, out of all these 50 patients, there were 20(40%) patients who had diabetes mellitus, 11(22%) in case group and 9(18%) in control group. Hypertension was seen in 13(26%) patients, 7(14%) in case group and 6(12%) in control group. There were 6(12%) obese patients, 2(%4) in case group and in 4 (8%) in control group. Cardiovascular disease was observed in 4 (8%) patients and each group had 2(4%) patients. There were 15(30%) patients who were active smokers, 9 (18%) in case group and 6(12%) in control group. There was no patient with chronic lung disease in our study (Table-3)

Table: 3.Frequency of comorbidities

Comorbidity	*Total*	*Case group*	*Control group*
DM*	20 (40%)	11(22%)	9 (18%)
HTN+	13(26%)	7(14%)	6(12%)
Obesity	6(12%)	2(4%)	4(8%)
CVD$	4(8%)	2(4%)	2(4%)
Smoking	15(30%)	9(18%)	6(12%)

DM* Diabetes mellitus, HTN+ Hypertension, CVD$ Cardiovascular disease

Discussion:

In this study, Effectiveness of Iveremectin was assessed among the participants by looking at the symptoms on day 7 at follow up. To best of our knowledge, very few studies of this kind had been conducted in our region. We report that patients on presentation had fever, myalgias being the commonest symptoms found in both groups' patients presenting to our hospital.

Regarding recovery at Day 7 on follow up, case group vs control group, 16 (64%) Vs 15 (60%) and a study conducted in Bangladesh[8] revealed recovery in terms of being symptom free was seen in 55% patients which is comparable with our study results, however the study conducted in Bangladesh was a comparative study between two groups receiving two different treatment regimens, one group received ivermectin with doxycycline and other group received azithromycin with hydroxychloroquine.

A study conducted by Patel A[9] on 169 critically sick patients in early days of Covid-19 showed survival benefit in 18.3% of patients, however this study took all the critical patients of Covid-19 and in contrast to our study which was only conducted on mild cases of COVID-19 and our study revealed that after giving Ivermectin, on day 7, 64% patients were symptom free (recovery). A huge difference in recovery between our study and the study conducted by Patel A[9] can be attributed to the patients' selection in both the studies. We selected only mild disease patients with Covid-19 whereas study by Patel A[9] selected all the critically sick patients including mechanically ventilated patients.

A huge multicentre study named as ICON (Ivermectin in Coronavirus disease nineteen) conducted in Covid-19 patients in South Florida[10,11] enrolled 280 admitted patients and mean age of the participants was 59.6 ±17.9 years and our study participants mean age was 42±17 years which is comparable to some extent as we only took out patients and study by Rajter JC[10] only enrolled all the admitted patients, so elder patients got admitted more.

In the study conducted by Rajter JC[10] there were two groups, one treated with ivermectin and other group was given conventional treatment other than Ivermectin, there was statistically significant difference between two groups' mortality 15% vs 25% and also mortality was also lower in 75 patients having severe pulmonary disease treated who were given ivermectin (38.8% vs 80.7%). Ivermectin group showed less mortality during treatment of COVID-19, especially in patients who were on higher inspired oxygen or ventilatory support. In contrast our study was first of its kind in our country conducted on outpatients having mild disease, showed recovery in 64% patients.

COVID-19 pandemic has affected over 200 countries in a span of less than 4 months burdening on the entire health care systems of many countries with no FDA approved drug which can stop the viral transmission or infectivity. Most of the drugs which are being used to treat this novel virus are not so effective and the development of vaccines is under preparation and may be available on trial basis in future, therefore, there is urgent need of the day to develop and use drugs cautiously. Ivermectin which is famous and used frequently as antiparasitic drug but in recent past studies have shown that Ivermectin has antiviral activity. It is easily available in our country and highly affordable as well. Ivermectin is officially approved for use in SARS-cov patients in few countries like Peru and Bolivia.[12]

COVID-19 has hit the whole world resulting in a significant mortality as well as leaving a huge impact on every country's economy. Various treatment options are still under study. Recently ivermectin's activity against SARS-CoV-2 gives ray of hope, but off-label and compassionate use requires careful risk–benefit considerations, especially in critically ill patients. A path to consider is evaluation first of impacts on virologic outcomes in uncomplicated, low-risk patients early in the course of the disease. Well-conducted clinical trials informed by robust pharmacokinetic models should be considered to validate the impact before the use of ivermectin to treat SARS-CoV-2 is implemented.

Conclusion:

Our study didn't show statistically any significant difference between case and control group. In Ivermectin's (case group) recovery was almost equal to control group who received only conventional symptomatic treatment, so this is the need of the day that we need to conduct more randomized controlled trials across our country involving major tertiary care health care facilities with larger sample size to assess its efficacy for validating the use of Ivermectin against SARS-CoV-2. Nearly 40 clinical trials are ongoing world over for measuring the outcome of COVID-19 treatment with Ivermectin.

Comparative efficacy and safety of pharmacological interventions for severe COVID-19 patients

An updated network meta-analysis of 48 randomized controlled trials

Qinglin Cheng, PhD[a,b,*], Gang Zhao, PhD[a], Junfang Chen, BS[a], Qingjun Jia, MD[a], Zijian Fang, MD[a]

Abstract

Background: To date, there has been little agreement on what drug is the "best" drug for treating severe COVID-19 patients. This study aimed to assess the efficacy and safety of different medications available at present for severe COVID-19.

Methods: We searched databases for randomized controlled trials (RCTs) published up to February 28, 2022, with no language restrictions, of medications recommended for patients (aged 16 years or older) with severe COVID-19 infection. We extracted data on trials and patient characteristics, and the following primary outcomes: all-cause mortality (ACM), and treatment-emergent adverse events (TEAEs).

Results: We identified 4021 abstracts and of these included 48 RCTs comprising 9147 participants through database searches and other sources. For decrease in ACM, we found that ivermectin/doxycycline, C-IVIG (i.e., a hyperimmune anti-COVID-19 intravenous immunoglobulin), methylprednisolone, interferon-beta/standard-of-care (SOC), interferon-beta-1b, convalescent plasma, remdesivir, lopinavir/ritonavir, immunoglobulin gamma, high dosage sarilumab (HS), auxora, and imatinib were effective when compared with placebo or SOC group. We found that colchicine and interferon-beta/SOC were only associated with the TEAEs of severe COVID-19 patients.

Conclusion: This study suggested that ivermectin/doxycycline, C-IVIG, methylprednisolone, interferon-beta/SOC, interferon-beta-1b, convalescent plasma (CP), remdesivir, lopinavir/ritonavir, immunoglobulin gamma, HS, auxora, and imatinib were efficacious for treating severe COVID-19 patients. We found that most medications were safe in treating severe COVID-19. More large-scale RCTs are still needed to confirm the results of this study.

Abbreviations: ACM = all-cause mortality, CI = confidence interval, C-IVIG = hyperimmune anti-COVID-19 intravenous immunoglobulin, COVID-19 = coronavirus disease 2019, CP = convalescent plasma, CQ = chloroquine, DS = duration of study, HCQ = hydroxychloroquine, HS = high dosage sarilumab, IFN-β = interferon beta, IG = immunoglobulin gamma, LPV/r = lopinavir/ritonavir, LS = low dosage sarilumab, NMA = network metaanalysis, OR = odds ratio, RCTs = randomized controlled trials, RRB = risk of reported bias, SOC = standard of care, SS = sample size, SUCRA = surface under the cumulative ranking area, TEAEs = treatment-emergent adverse events, WHO = World Health Organization.

Keywords: efficacy, network meta-analysis, randomized controlled trials, safety, severe COVID-19

1. Introduction

To date, the World Health Organization has confirmed over 480 million cases.[1] The mortality in patients with COVID-19 was estimated at 1.28%.[1] For the current analyses, COVID-19 infection is the leading cause of the global burden of disease and public health, which has increased significantly since 2019, driven mainly by high morbidity, high impact, and mortality.[2]

Analysis of the data showed many pharmacologic interventions have been used to treat COVID-19 patients, which have been effective against COVID-19 infection.[3–5] However, there were many compounds that differ in efficacy and safety, and it was not clear which drug was the "best" drug for treating severe COVID-19 patients. Due to the small sample size and time-updated lagged in previous meta-analyses and studies, there has been debate about the effectiveness and safety of

The authors have no conflicts of interest to disclose.

The datasets generated during and/or analyzed during the current study are publicly available.

Received: 25 May 2022 / Received in final form: 1 September 2022 / Accepted: 6 September 2022

http://dx.doi.org/10.1097/MD.0000000000030998

drugs, with some findings contradicting each other for COVID-19 infection.[6,7]

Of primary concern was the medications on COVID-19 with all infection levels (i.e., mild, moderate and severe infection) in prior studies.[8] Here, we had a critical shortage that we lacked an analysis stratified by different infection levels in medications of COVID-19. It is well known that the disease varies in infection, which could lead to individual treatment of different infection subgroups in patients.[9]

Though the network metaanalysis (NMA) has been performed in prior reports,[7] there was little published data on the network study for the therapy of severe COVID-19 patients. Additionally, we found that there have been further randomized controlled trials (RCTs) of some other drugs for the treatment of COVID-19 through the literature search.[10] Some large-scale RCTs have been completed in the treatment of COVID-19 infection. We urgently need an updated assessment of the available evidence to support clinical decision-making.

How do we select pharmacological interventions for severe COVID-19 patients in clinical practice? In order to fill this gap, we did an updated NMA of RCTs for drug interventions of severe COVID-19 infection. The purpose of this study is to evaluate the efficacy and safety of medications based on RCTs of the available evidence for severe COVID-19 infection.

2. Materials and Methods

2.1. Protocol and registration

We performed the present NMA in accordance with the guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement.[11] This study was a review article and did not involve a research protocol requiring approval by a relevant institutional review board or ethics committee. Informed consent was also not applicable. We registered the protocol in the International Prospective Register of Systematic Reviews (PROSPERO) (CRD42021293879).

2.2. Search strategy and selection criteria

We conducted a systematic literature search in 8 electronic databases (PubMed, Elsevier Science Direct, Cochrane Library, Google Scholar, Springer Link, MedRxiv, China National Knowledge Infrastructure, and Wanfangdata) for RCTs published, with no language restrictions from their inception to February 28, 2022. We included the RCTs on the treatment of severe COVID-19 patients (aged 16 years or older). The appendix had full search strategies listed (Supplemental Appendix 1, http://links.lww.com/MD/H533). We extracted data on RCTs, patient and medications characteristics (Table 1).

To determine their eligibility, we reviewed the abstracts and full-texts of potentially relevant articles. We selected articles for the evaluation based on the criterion: at least one statistical analysis of the association between severe COVID-19 and medications was presented and described as an assessment for efficacy or safety.

All RCTs that measured the efficacy or safety between drug interventions and severe COVID-19 infection were considered for inclusion. We listed full inclusion and exclusion criteria in the appendix (Supplemental Appendix 2, http://links.lww.com/MD/H534). During the selection of qualified studies, we resolved any ambiguity through mutual discussion and consensus.

2.3. Data extraction

At least 2 independent investigators (JQJ, CJF, and FZJ) extracted and entered onto all data through a standardized data extraction form. The main data extracted was the assessments of efficacy and safety. We collected the following information: basic characteristics, including author name, publication year, country/countries of origin, study design, method of COVID-19 testing, patient population, age, gender, sample size, interventions, treatment medication dose, controls, control medication dose, follow-up time, and primary outcomes; Primary outcomes, including all-cause mortality (ACM) and rate of treatment-emergent adverse events (TEAEs). We also contacted the authors if they did not report the above data information in the published article. One independent investigator undertook a preliminary extraction of studies, and another investigator reviewed the extraction. Differences were discussed, and a third researcher participated (CQL) if they reached no agreement.

2.4. Quality assessment

At least 2 investigators (ZG, CQL, JQJ, CJF, and FZJ) evaluated the risk of bias for all studies. We estimated the risk of bias with the Cochrane Risk-of-Bias Tool.[12] We assessed the certainty of evidence by using the Grading of Recommendations Assessment, Development, and Evaluation approach for the NMA.[13]

2.5. Outcome measures and definitions

The severe COVID-19 infection represented patients with fever or suspected respiratory infection, plus one of the following: respiratory rate > 30 breaths/min, severe respiratory distress, or SpO2 ≤ 93% on room air.[14,15] The primary outcomes were the ACM and TEAEs for severe COVID-19 patients, from the beginning of treatment to the end of follow-up. The definitions of ACM, TEAEs, and severe COVID-19 patients can refer to our previous study.[14]

2.6. Data analysis

2.6.1. Assessment of the transitivity assumption. Transitivity is the fundamental assumption of indirect comparisons and NMA. We investigated the distribution of potential effect modifiers to assess the transitivity assumption. Potential effect modifiers included multicenter study, duration of study (DS), blinding, crossover design, sample size (SS), industry sponsorship, and risk of reported bias (RRB).

2.6.2. Network meta-analysis. We used STATA statistical software (Version 15, Stata Corporation, and College Station, Texas, USA) to conduct NMAs. We analyzed binary variables (ACM and TEAEs) using odds ratio (OR) with 95% confidence interval (CI). The appendix reported additional details (Supplemental Appendix 3, http://links.lww.com/MD/H535). We defined statistical significance as the P value < .05.

We merged simultaneously the direct evidence and indirect evidence or different indirect evidence through an NMA. In NMA, we analyzed the effect of intervention using group-level data. A fixed-effect model (i.e., $I^2 \leq 50\%$) or a random-effect model (i.e., $I^2 > 50\%$) was used to summarize the effect sizes of NMA. We ranked the therapeutic effect for each outcome using the surface under the cumulative ranking area (SUCRA) curve and mean ranks.[16] In addition, the endpoints which lower was better would show rank 1 was the best and rank N was the worst based on figures and vice versa.

2.6.3. Assessment of heterogeneity and inconsistency. We used the node splitting method (i.e., split evidence on a specific comparison into direct and indirect evidence) to estimate the inconsistency of NMAs.[17] There was no significant inconsistency in outcomes if $P > .05$.

Table 1

Characteristics of randomized controlled trials of pharmacological interventions in severe patients with COVID-19.

Author name (reference)	Publication yr	Country/ Countries of origin	Study design	Method of COVID-19 testing	Numbers of participants	Gender*	Age (yrs)	Interventions	Treatment medication dose	Controls	Control medication dose	Follow-up time (d)	Primary outcomes
Absalón-Aguilar A et al [18]	2021	Mexico	TRPCTs	RT-PCR	116	Males (n = 76); Females (n = 40)	≥ 18	Colchicine (n = 56)	Patients received 1.5 mg of colchicine at baseline, which corresponded to the day of the patient's recruitment in the study, and, then, 0.5 mg PO BID for 10 days	Placebo (n = 60)	Patients received placebo PO at baseline, which corresponded to the day of the patient's recruitment in the study, and, then, 0.5 mg PO BID for 10 days	10	ACM; ratio of TEAEs
Ader F et al [19]	2022	Europe	MDRCTs	RT-PCR	328	Not specified	≥ 18	Remdesivir/SOC (n = 161)	Remdesivir was administered intravenously at a loading dose of 200 mg on day 1 followed by a 100 mg, 1-h infusion once-daily for a total duration of 10 days	SOC (n = 167)	Lopinavir–ritonavir (LPV/R), LPV/R and interferon beta-1a, or hydroxychloroquine	29	ACM
Ali S et al [20]	2021	Pakistan	RCTs	RT-PCR	50	Males (n = 35); Females (n = 15)	≥ 18	Hyperimmune anti-COVID-19 Intravenous Immunoglobulin (C-IVIG) (n = 40)	5% C-IVIG dosage arms (0.15, 0.20, 0.25, 0.30 g/kg)	SOC (n = 10)	Not specified	28	ACM; ratio of TEAEs
AlQahtani Met al.[21]	2021	Bahrain	RCTs	RT-PCR	40	Males (n = 32); Females (n = 8)	≥ 21	Convalescent plasma (n = 20)	The dosage of CP was 400 mL, given as 200 mL over 2 h over 2 successive days	SOC (n = 20)	Possible therapy including antiviral medications, tocilizumab and anti-bacterial medication	28	ACM; ratio of TEAEs
AlShehry Net al. [22]	2021	Saudi Arabia	RCTs	RT-PCR	164	Males (n = 137); Females (n = 27)	≥ 18	Convalescent plasma/SOC (n = 40)	300 mL (200–400 mL/treatment dose) convalescent plasma at least once, and if required, daily for up to 5 sessions	SOC (n = 124)	Not specified	30	ACM
Aman Jet al. [10]	2021	Netherlands	DRPCTs	RT-PCR	385	Males (n = 264); Females (n = 121)	≥ 18	Imatinib (n = 197)	800 mg on day 0 followed by 400 mg daily on d 1–9	Placebo (n = 188)	Not specified	28	ACM
Avendano Sola C et al [23]	2020	Spain	MRCTs	RT-PCR	81	Males (n = 44); Females (n = 37)	≥ 18	Convalescent plasma (n = 38)	Receive 1 dose (250-300 mL) of convalescent plasma	SOC (n = 43)	Not specified	97	ACM; ratio of TEAEs
Beltran-Gonzalez JLet al. [24]	2021	Mexico	DRPCTs	RT-PCR	106	Males (n = 66); Females (n = 40)	53 ± 16.9	Hydroxychloroquine (n = 33)	Hydroxychloroquine 400 mg every 12 h on the first day and subsequently, 200 mg every 12 h for 4 days	Placebo (n = 37)	Not specified	30	ACM
Beltran-Gonzalez JL et al [24]	2021	Mexico	DRPCTs	RT-PCR	106	Males (n = 66); Females (n = 40)	53 ± 16.9	Ivermectin (n = 36)	Ivermectin, 12 mg or 18 mg	Placebo (n = 37)	Not specified	30	ACM

*If the total number of gender is not equal to the number of participants, it is due to loss to follow-up from participants.

FOI 26-3132 - Document 6

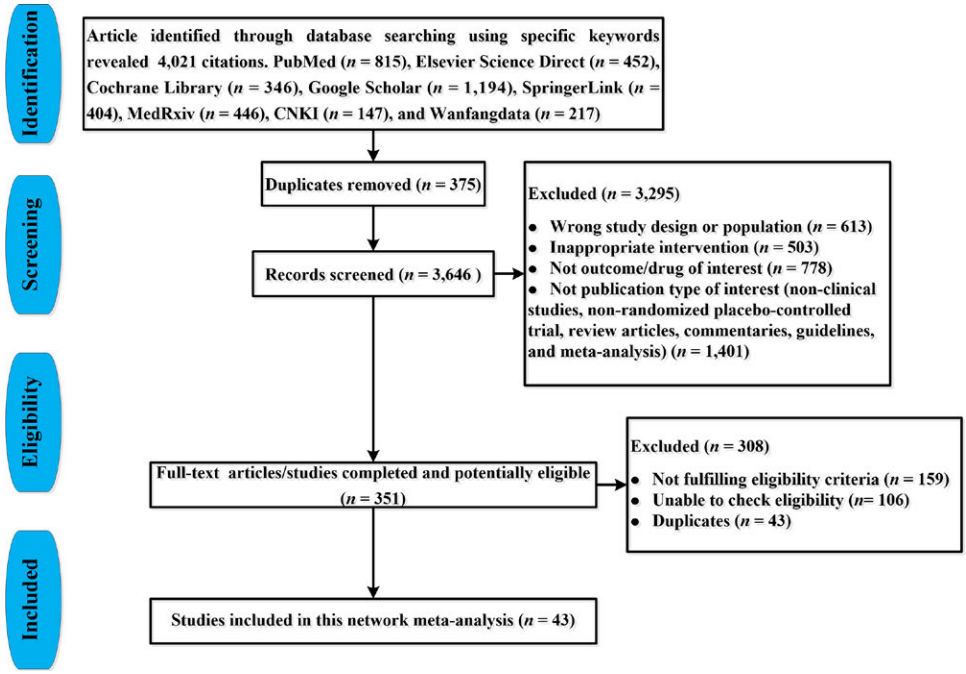

Figure 1. PRISMA flow-chart for study selection.

2.6.4. Assessment of the risk of bias. We assessed the risk of bias of included studies using the Cochrane Collaboration's Tool for Assessing Risk of Bias,[12] classifying the risk of bias as high, unclear, or low. We evaluated the small-study effect using comparisonadjusted funnel plots.[17]

2.6.5. Sensitivity analysis. The inclusion of various study designs and populations might contribute to heterogeneity and inconsistency. We used sensitivity analysis to evaluate the effect of our conclusions. We analyzed the data using the following restrictions: multicenter study, DS, blinding, crossover design, SS, industry sponsorship, and RRB.

We used the "netmeta" package in R (version 4.0.5) to duplicate the NMAs of primary outcomes.

3. Results

3.1. Description of included studies

The search identified 4021 citations, out of which 3670 were excluded for duplications, wrong study design or population (i.e., non-severe COVID-19 infection), inappropriate intervention, not outcome/drug of interest, non-clinical studies, non-RCTs, review articles, commentaries, guidelines, and meta-analysis by checking titles and abstracts. The full texts of 351 articles were obtained to check eligibility, in which we excluded 308 articles for non- fulfilling eligibility criteria, unable to check eligibility and duplications. Finally, 43 studies[10,18–59] were included in our NMA. Figure 1 shows the selection process for the included studies.

Forty-eight RCTs, including 9147 patients, were included (Fig. 1) and described in Table 1. This analysis had a mean sample size of 106 [interquartile range 58–238]. The age of subjects was greater than or equal to 16 years. The median duration of follow-up treatment was 28 days (interquartile range 27–30).

3.2. Quality appraisal

The included RCTs were of good quality (Fig. 2). Figure 2 also showed the risk of bias summary.

3.3. Network of evidence

In the network of connected RCTs (Fig. 3), the width of the lines corresponded to the number of trials included each treatment comparison. From Figure 3, we could see that the result was well connected. As shown in Figure 3A, the standard of care (SOC) was the most well-connected treatment, with chloroquine (CQ), hydroxychloroquine (HCQ), CQ/HCQ, convalescent plasma (CP), CP/SOC, remdesivir, remdesivir/SOC, lopinavir/ritonavir (LPV/r), interferon-beta-1b (IFN-β-1b), C-IVIG (i.e., a hyperimmune anti-COVID-19 intravenous immunoglobulin), ivermectin/doxycycline, IFN-β/SOC, tocilizumab, ruxolitinib/SOC, methylprednisolone, azithromycin/SOC, and auxora directly connected to it. Sarilumab such as high dosage sarilumab (HS) and low dosage sarilumab (LS), CQ/HCQ, ivermectin, canakinumab, colchicine, baricitinib, immunoglobulin gamma (IG), α-Lipoic acid, imatinib, mavrilimumab, lenzilumab, mycobacterium-w, otilimab, N-acetylcysteine, tocilizumab, high-dose intravenous vitamin C, hydrocortisone, and CP were directly connected to placebo in this network plot. Several sources of indirect evidence were available to inform comparisons between ivermectin, tocilizumab, HCQ, CP, auxora, placebo, and SOC (Fig. 3A). In Figure 3B, there was also a direct connection between SOC and C-IVIG, CP, LPV/r, ruxolitinib/SOC, ivermectin, IFN-β/SOC, and tocilizumab, or between placebo and HS, LS, mycobacterium-w, mavrilimumab, colchicine, canakinumab, baricitinib, human umbilical cord-derived mesenchymal stem cells, HCQ, lenzilumab, CP or tocilizumab. Several indirect connections were available between SOC and CP, tocilizumab, placebo (Fig. 3B).

3.4. Efficacy outcomes

Forty-one studies[10,18–38,40–51,53–59] reported ACM as outcome measurement (Supplemental Table S1, http://links.lww.com/MD/H536). We found that C-IVIG (OR 0.22, 95% CI 0.05-0.95), methylprednisolone (OR 0.27, 95% CI 0.09-0.77), IFN-β/SOC (OR 0.30, 95% CI 0.11-0.83), CP (OR 0.49, 95% CI 0.26-0.94), remdesivir (OR 0.58, 95% CI 0.37-0.93), and HS (OR 0.45, 95% CI 0.20-0.99) were associated with the decrease of ACM when compared with the SOC group (Fig. 4). Unfortunately, there was

FOI 26-3132 - Document 5

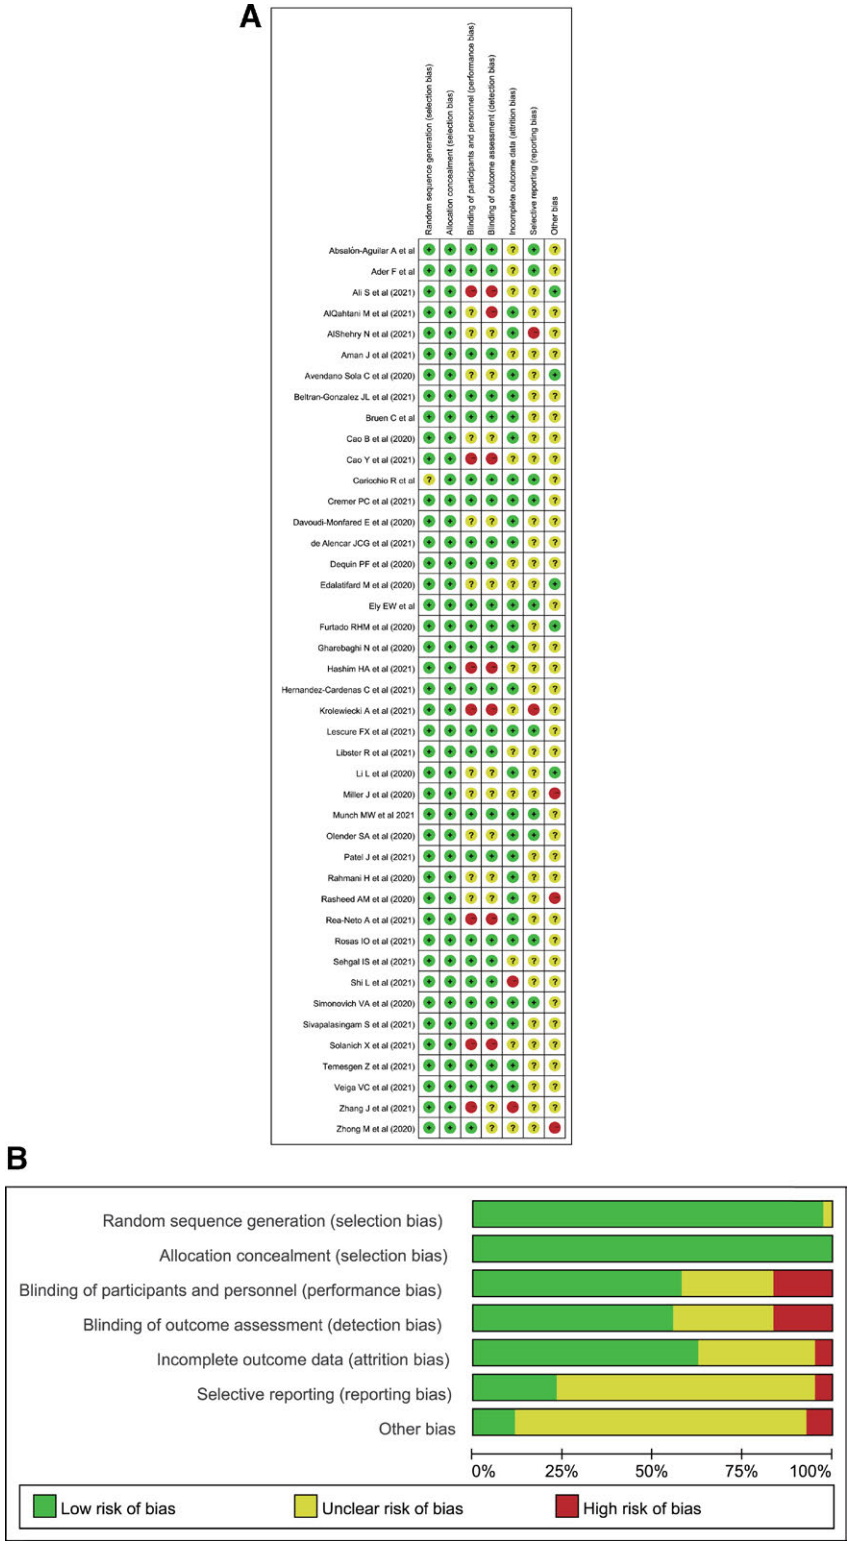

Figure 2. The quality of the included randomized controlled trials. (A) Risk of bias summary (Note: The yellow circle with question mark represents "unclear risk of bias", the red one with minus sign represents "high risk of bias" and the green one with plus sign represents "low risk of bias"). (B) Risk of bias graph.

no significant difference in other 27 medications (e.g., ivermectin/doxycycline, IFN-β-1b, LPV/r, IG, LPV/r, and imatinib) or placebo for ACM when compared with SOC.

For a decrease in ACM, ivermectin/doxycycline (OR 0.06, 95% CI 0.00-0.88), C-IVIG (OR 0.12, 95% CI 0.02-0.61), methylprednisolone (OR 0.15, 95% CI 0.04-0.52), IG (OR 0.27, 95% CI 0.08-0.85), IFN-β/SOC (OR 0.17, 95% CI 0.05-0.56), IFN-β-1b (OR 0.16, 95% CI 0.03-0.98), auxora (OR 0.37, 95% CI 0.18-0.78), imatinib (OR 0.49, 95% CI 0.25-0.96), CP (OR 0.27, 95% CI 0.11-0.64), remdesivir (OR 0.32, 95% CI 0.14-0.74), and LPV/r (OR 0.32, 95% CI 0.12-0.85) were effective when compared with the placebo group (Fig. 4). We did not identify that there was a difference between placebo and other 22 medications (e.g., ruxolitinib/SOC, ivermectin, tocilizumab,

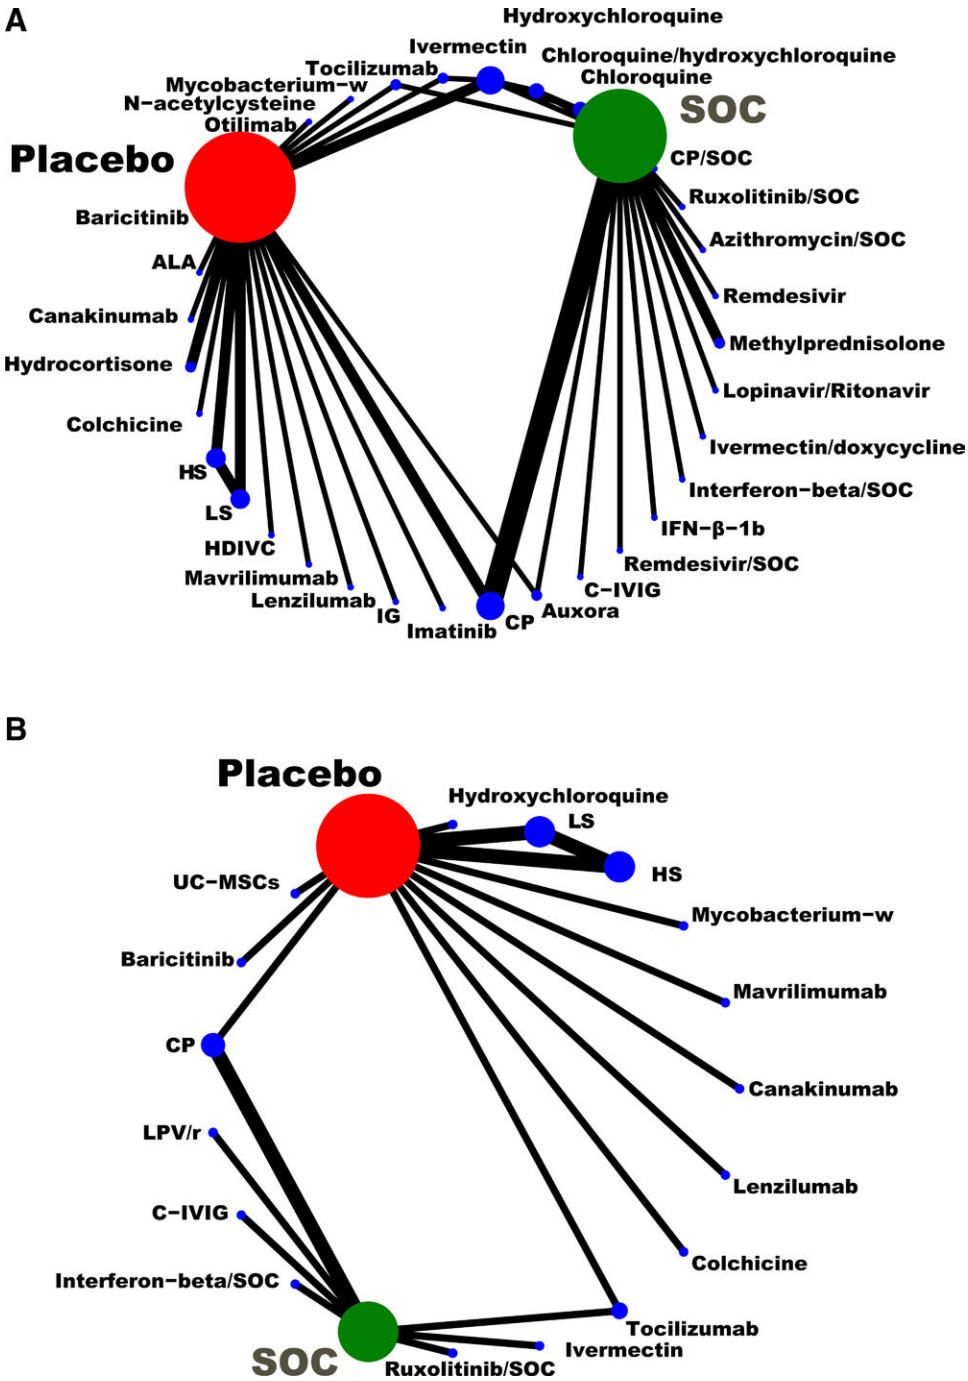

Figure 3. Network plot of eligible comparisons for all-cause mortality (A), and the ratio of treatment-emergent adverse events (B) for medications in patients with severe COVID-19. ALA= α-Lipoic acid, C-IVIG = hyperimmune anti-COVID-19 intravenous immunoglobulin, COVID-19 = coronavirus disease 2019, CP = convalescent plasma, IFN-β= interferon-beta, IG = immunoglobulin gamma, HDIVC = high-dose intravenous vitamin C, HS = high dosage sarilumab, LS = low dosage sarilumab, SOC = standard-of-care, UC-MSCs = human umbilical cord-derived mesenchymal stem cells.

HS, and mavrilimumab) or SOC for the ACM of severe COVID-19 infection (Fig. 4).

The Supplemental Figure S1, http://links.lww.com/MD/H538 presented the ranking for the ACM of medications in severe COVID-19 patients based on cumulative probability plots and SUCRA.

3.5. Safety outcomes

In the safety outcome, data from 19 studies[18,20,21,23,26–29,34,38–40,48,50–54,56]were merged for analysis (Supplemental Table S2, http://links.lww.com/MD/H537). We found that colchicine (OR 2.77, 95% CI 1.03-7.42) and IFN-β/SOC (OR 18.98, 95% CI 1.70-211.84) seemed to increase the risk of TEAEs when compared with the SOC group. Moreover, IFN-β/SOC (OR 19.00, 95% CI 2.36-153.10) were associated with the increase of TEAEs when compared with placebo. We found no significant difference in TEAEs in other 15 medications for severe COVID-19 patients when compared with SOC or placebo (Fig. 5).

The figure of SUCRA showed that baricitinib had the highest cumulative probability (SUCRA: 88.3%) becoming the best intervention in TEAEs, followed by LPV/r (SUCRA: 78.8%), SOC (SUCRA: 76.0%), lenzilumab (SUCRA: 72.6%),

C-IVIG (SUCRA: 68.5%), tocilizumab (SUCRA: 63.6%), placebo (SUCRA: 53.1%), ivermectin (SUCRA: 52.3%), canakinumab (SUCRA: 51.9%), mycobacterium-w (SUCRA: 50.1%), LS (SUCRA: 49.3%), mavrilimumab (SUCRA: 47.1%), ruxolitinib/SOC (SUCRA: 46.8%), CP (SUCRA: 44.5%), HS (SUCRA: 31.0%), HCQ (SUCRA: 29.5%), human umbilical cord-derived mesenchymal stem cells (SUCRA: 29.1%), colchicine (SUCRA: 14.2%), and IFN-β/SOC (SUCRA: 3.2%) (Supplemental Figure S2, http://links.lww.com/MD/H539).

3.6. Evaluation of inconsistency

According to the inconsistency test (Table 2), no significant inconsistency or qualitative difference was available for the ACM and TEAEs. Thus, the consistency hypothesis was accepted in this NMA.

Table 2

The evaluation of inconsistency for the efficacy and safety of medications among severe COVID-19 patients.

Network meta-analysis	Number of dimensions	Chi² value	*P* value
All-cause mortality	34	2.37	.668
The ratio of treatment-emergent adverse events	18	0.69	.407

COVID-19 = coronavirus disease 2019.

FOI 26-3132 - Document 5

3.7. Sensitivity analysis and publication bias

We analyzed the potential sources of heterogeneity or inconsistency by using subgroup and meta-regression analyses. Univariable meta-regression and subgroup analyses indicated that there were heterogeneous sources (such as DS, blinding and RRB) for the ACM ($P < .05$) (Fig. 6A). Whilst the SS and RRB were the heterogeneity source of TEAEs based on the sensitivity analysis ($P < .05$) (Fig. 6B).

None of the funnel plots of outcomes (ACM and TEAEs) indicated a significant asymmetry (Supplemental Figure S3, http://links.lww.com/MD/H540).

4. Discussion

This study was based on 48 RCTs, which included 9147 severe patients randomly assigned to 35 medications or SOC or placebo. Our NMA indicated that 12 medications (i.e., ivermectin/doxycycline, C-IVIG, methylprednisolone, IFN-β/SOC, IFN-β-1b, CP, remdesivir, LPV/r, HS, IG, auxora, and imatinib) were efficacious for the therapy of severe COVID-19 infection based on the controls of SOC or placebo. For a decrease in ACM, on the one hand, C-IVIG, methylprednisolone, IFN-β/SOC, HS, remdesivir, and CP were more efficacious than SOC; on the other hand, the efficacy of ivermectin/doxycycline, C-IVIG, methylprednisolone, IFN-β/SOC, IFN-β-1b, CP, remdesivir, LPV/r, IG, auxora, and imatinib were superior to placebo in all 35 drug interventions. From this, we can infer that there is a difference in the findings of medications for severe COVID-19 patients from different control conditions in RCTs.

Curiously, our findings differed from our earlier pilot studies,[14,60] which have only indicated 2 effective medications (i.e., IG and methylprednisolone) in the decreased ACM for severe COVID-19 patients. In addition, the CP group showed lower TEAEs than the placebo for severe COVID-19 infection in our earlier NMAs.[14,60] These inconsistencies may be due to an increase in sample size in the updated NMA. The study extended the previous work that provided a reference for selecting the medication for patients with severe COVID-19 infection.[61] The present study raises the possibility that we cannot completely discount the efficacy of other medications for severe COVID-19 infection in clinic. So far, maybe it's because there was inadequate evidence of a benefit in ACM for them. In either case, it is noteworthy that we must fully consider its efficacy and safety when the medications are used in treating severe COVID-19 patients. Some medications (e.g., tocilizumab, otilimab, and mavrilimumab) might be a selection of combination treatment for COVID-19 infection.[62,63]

It is particularly worth mentioning that host factors, including age, prior-medical history, demographics, and medical facility, may be key determinants of disease severity and progression.[64] Similarly, the above factors are associated with the drug treatment effect of COVID-19 infection. Several studies have reported that aging and prior-medical history (such as cancer or chronic kidney/liver/lung diseases) might be 2 prominent impact factors for medical therapy from COVID-19.[65,66] Kopel *et* al suggested that some demographics factors (such as gender, ethnic group and socioeconomic status) were associated with the therapy of COVID-19 infection.[67,68] In another study in India, Sarkar et al[69] reported that different strains of SARS-CoV-2 were associated with the efficacy of antiviral drugs. It has also been suggested that medical facilities may be an impact factor for the COVID-19 treatment.[70] We have considered these impact factors in the overall therapy for COVID-19 patients during this NMA design. To reduce the impact of age, we included all of studies based on patient age greater than or equal to 16 years. As is well known, the design principles of RCTs are randomization, control, blinding, and repetition.[71] According to the 48 RCTs data analysis of this NMA, we confirmed that age, prior-medical history, gender and racial ratios for participants were balanced between experimental and control groups ($P > .05$). In view of this, we suggest that the effects of age, prior-medical history, gender and racial ratios in the findings are small in this NMA study. This might present one of the main strengthens of this NMA. Unfortunately, the description of most studies was insufficient in the gender-specific, different strains and medical facilities for COVID-19 therapy in previous RCTs. We could not explore the efficacy of drugs treatment from the gender-specific or different strains as well as the impact from medical facilities for COVID-19 therapy.

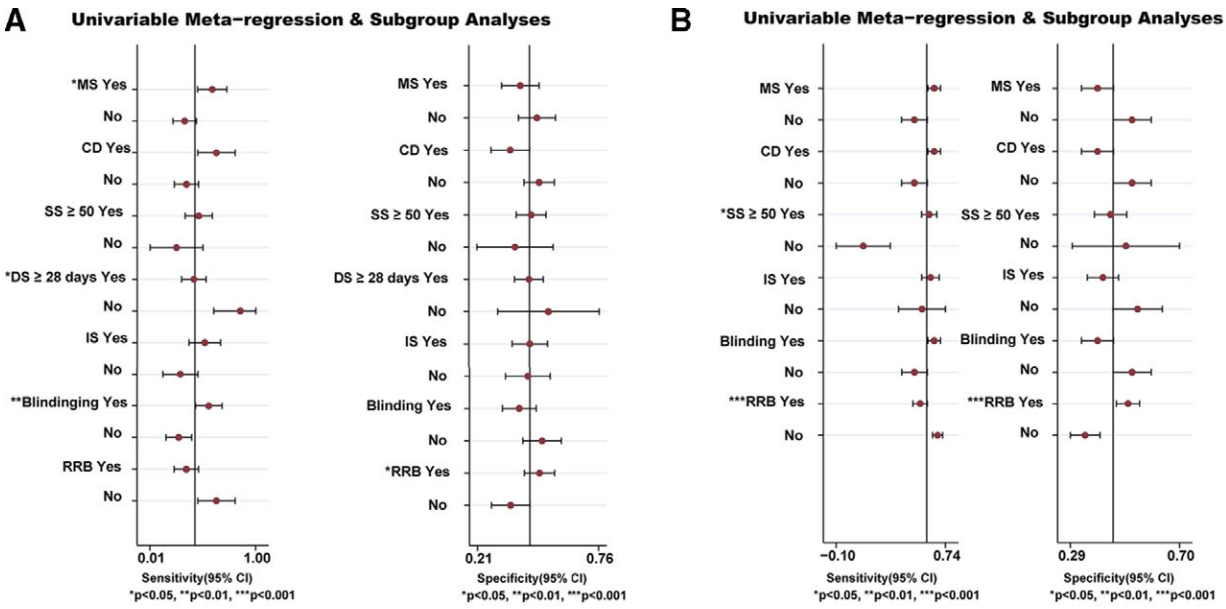

Figure 6. Meta-regression and sensitivity analyses for the efficacy and safety of medications in patients with severe COVID-19 infection. (A) all-cause mortality. (B) the ratio of treatment-emergent adverse events. CD = crossover design, COVID-19 = coronavirus disease 2019, DS = duration of study, IS = industry sponsorship, MS = multicenter study, RRB = risk of reported bias, SS = sample size.

4.1. Efficacy of current medications

This study supported evidence from previous observations.[72,73] As we know, intravenous immunoglobulin has already been validated as an effective antiviral drug for treating COVID-19, SARS and Middle East respiratory syndrome.[20,74,75] This is consistent with our results (i.e., C-IVIG, HS, and IG). Recent evidence suggested that anti-cytokine effects, inhibition of complement activation, and down-regulation of B and T cells' functions by C-IVIG can prevent organ failure and subsequent mortality in severe COVID-19 patients.[20] Our findings also confirmed that sarilumab could prevent patients with COVID-19 from progressing to death. Sarilumab is a fully human antibody against the interleukin (IL)-6 receptor, which can rapidly lower C-reactive protein and mediate COVID-19 clearance.[76] Prolonged glucocorticoid treatment is associated with improved outcomes of acute respiratory distress syndrome.[77] Several reports have also shown that treatment with methylprednisolone could significantly reduce the risk of death among patients with acute respiratory distress syndrome.[78] This also accords with our observations, which suggested that methylprednisolone was associated with decreased ACM in severe COVID-19 patients.

The SUCRA indicated that ivermectin/doxycycline was the highest ranked intervention with a SUCRA of 0.821. Previous studies showed that ivermectin or doxycycline is effective in treating COVID-19 patients.[79,80] We attribute this to a couple of reasons. First, ivermectin or doxycycline might possess antiviral as well as immunomodulatory activity.[79,80] Second, they might have anti-inflammatory and immunomodulatory agents and can curb over-reacting innate and cellular immune responses.[81] One possible implication may be that the ivermectin/doxycycline is an excellent selection for treating severe COVID-19 patients. Of note, based on the result of meta-regression analysis on the heterogeneity (such as DS, blinding, and RRB), the present result may need further verification. Thus, statistical indications of clinical superiority in this network analysis required careful interpretation.

Interestingly, we found that small-molecule protein kinase inhibitors (i.e., auxora and imatinib) were efficacious for the therapy of severe COVID-19 infection. Recent research has established that a calcium release-activated calcium channel inhibitor, such as auxora, can reduce the occurrence of COVID-19 death due to blocking the release of multiple pro-inflammatory cytokines, including IL-6. Additionally, evidence showed that imatinib might play its potentially antiviral and beneficial immunomodulatory role in severe COVID-19 patients.[82] These results further support those of previous studies.[25,83] Collectively, the present findings indicate that the small-molecule protein kinase inhibitors provide a new, and perhaps superior, avenue for the severe COVID-19 treatment. In addition, our results may provide a robust strategy for clinical combination therapy among severe COVID-19 patients.

We have demonstrated that IFN-β/SOC, IFN-β-1b, remdesivir, LPV/r and CP were associated with a reduction of ACM in severe COVID-19 infection. Several lines of evidence suggested that IFN deficiency was a hallmark of severe COVID-19.[84] IFN might treat severe COVID-19 infection through adapted anti-inflammatory therapies that target IL-6 or TNF-β.[84,85] Data from prior studies suggested that remdesivir was a broad-spectrum antiviral activity against RNA viruses, which could improve the survival of COVID-19 infection due to inhibiting viral replication.[86] Recent studies reported that LPV/r displayed inhibitory activities against SARS-CoV-2 main protease and inhibited SARS-CoV-2 replication in Vero E6 cells.[87] Similarly to other antibodies therapy, CP can prevent the death of severe COVID-19 patients because of alleviating the inflammation and overreaction of the immune system through antibodies.[88] These findings further support the idea of our NMA study.

Conversely, no significant difference was found in other 21 medications (e.g., HCQ, α-Lipoic acid, hydrocortisone, otilimab, and mavrilimumab) for the ACM of severe COVID-19 infection when compared with SOC or placebo. This finding was contrary to previous studies which have suggested that some antiviral drugs (hydrocortisone, mavrilimumab, etc) were associated with decreased ACM in patients with COVID-19.[29,32,89,90] It is difficult to explain this result, but it might be related to the difference of participants' selection in differential studies. For instance, the findings of this NMA were based on a larger sample size (i.e., more participants were included). Correspondingly, most of the previous studies presented a smaller sample size.[29,32] The present study differed from earlier studies,[90,91] which selected subjects with all infection levels (i.e., mild, moderate and severe infections). Furthermore, prior studies were inadequate for the analyses stratified by different infection levels (i.e., non-severe and severe infection) in medications of COVID-19.[29,32,89,90] Prior studies suggested that COVID-19 patients at different infection levels often led to different outcomes of treatment.[92] Another possible explanation for this was that we compared the efficacy and safety of SOC, which existed the bias due to the differential SOC of every country (i.e., the SOC is not standardized) except for the reasons given above.[21,23,45] The present study raised the possibility that our findings might be beneficial to guiding the selection of drug interventions for clinicians in severe COVID-19 patients.

4.2. Safety of current medications

In terms of safety, we summarized the TEAEs. We found that colchicine and IFN-β/SOC were only associated with the TEAEs of severe COVID-19 patients in this study. Recent meta-analysis studies and large-scale RCTs[45,46,92] seemed to be consistent with our findings, which identified most pharmacological treatments had a good safety in treating severe COVID-19. However, as mentioned in the present study, colchicine and IFN-β/SOC should be chosen cautiously in treating severe COVID-19 patients based on safety. Colchicine might increase the TEAEs in treating patients with severe COVID-19 infection. It is difficult to explain this result, but it might be related to the toxicity (e.g., gastrointestinal mucosal damage) in the case of colchicine treatment.[93] In addition, it is possible that the use of IFN-β in combination with SOC was associated with increased TEAEs in treating severe COVID-19, which should be weighed in all future IFN-β studies.[94]

In summary, clinicians might need to select treatment regimens based on the ranks of efficacy and safety (i.e., SUCRA) when medications are used in treating severe COVID-19 patients. Additionally, it should be reminded that further studies, which reduce the effects of SS and RRB, will need to be undertaken based on the result of sensitivity analysis.

Some limitations constrained this study. Firstly, included studies might be small in this NMA, which should be considered when interpreting the findings. Secondly, the published data we extracted included only 2 types of outcomes, some important outcomes such as discharge ratio, clinical improvement ratio, and the ratio of virological cure, were not analyzed. Thirdly, although we did our best to include all available RCTs, we cannot eliminate the possibility of missing data. Fourthly, some nodes in our network included only a few trials. The sample size of actual head-to-head trials was very small. Hence, comparative efficacy and safety between interventions was frequently based on indirect comparisons. Finally, the sensitivity analysis showed that there were several heterogeneity sources, which may conceal or exaggerate the effect size of this network analysis. Further large-scale RCTs, which control these confounding factors, will need to be undertaken to verify our findings. Though there are still many shortcomings in our research, it is certain that the prevention

FOI 26-3132 - Document 5

and therapy of COVID-19 is set to change for the better in the future.

5. Conclusions

In conclusion, this NMA demonstrated that ivermectin/doxycycline, C-IVIG, methylprednisolone, IFN-β/SOC, IFN-β-1b, CP, remdesivir, LPV/r, IG, HS, auxora, and imatinib were effective for treating severe COVID-19 patients. There may be a difference in the findings of medications for severe COVID-19 patients from different control conditions (i.e., placebo and SOC) in RCTs. We found that most medications were safe in treating severe COVID-19. The present NMA reported uncertain estimates on the efficacy and safety of medications in the severe COVID-19 treatment. Maybe it's because there was inadequate evidence of a reduction in ACM and the absence of TEAEs. However, this study had 2 strengths. One was that a comprehensive meta-analysis strategy was used to reduce the risk of publication bias. The other was that the SUCRA was used to assess possibly the best intervention.

Despite these limitations, to date, the present findings might represent the most comprehensive meta-analysis of the available evidence for severe COVID-19 infection. Future guidelines and decision-making treatment plan should consider these results for the severe COVID-19 treatment. Importantly, the government, academia and researchers should collaborate to develop more large-scale RCTs studies and further estimate the efficacy and safety of treatment interventions on mortality, virological and clinical outcomes for different levels of infection with COVID-19.

Abstract

Objectives: We investigated the outcomes of Ivermectin-Doxycycline vs. Hydroxychloroquine-Azithromycin combination therapy in mild to moderate COVID19 patients.

Methods: Patients were divided randomly into two groups: Ivermectin 200µgm/kg single dose + Doxycycline 100mg BID for ten days in group A, and Hydroxychloroquine 400mg for the first day, then 200mg BID for nine days + Azithromycin 500mg daily for five days in group B (Control group). RT-PCR for SARS-CoV-2 infection was repeated in all symptomatic patients on the second day onward without symptoms. Repeat PCR was done every two days onward if the result found positive. Time to the negative PCR and symptomatic recovery was measured for each group.

Results: All subjects in Group A reached a negative PCR, at a mean of 8.93 days, and reached symptomatic recovery, at a mean of 5.93 days, with 55.10% symptom-free by the fifth day. In group B, 96.36% reached a negative PCR at a mean of 9.33 days and were symptoms-free at 6.99 days. In group A 31.67% of patients expressed symptoms caused by medication, this was 46.43% in group B.

Conclusion: The combination therapy of Ivermectin-Doxycycline showed a trend towards superiority to the combination of Hydroxychloroquine-Azithromycin for mild to moderate COVID19 disease.

Keywords: Azithromycin, Bangladesh, COVID-19, Doxycycline, Hydroxychloroquine, Ivermectin, randomized controlled trial (RCT)

Coronavirus disease 2019 (COVID-19) is a global pandemic declared by the world health organization (WHO). Over ninety million people have already been infected by severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2), and billions have been affected by the socioeconomic squeal. As SARS-CoV-2 is a novel virus, there are no proven treatment options yet. Early treatment before the disease becomes severe would be optimal. The

treatment's current considerations include lopinavir/ritonavir, favipiravir, and remdesivir. These are currently in use in moderate to severe COVID-19 patients. Treatments for patients in the early stage of the disease with mild to moderate symptoms have not been well established. Studies have shown that Chloroquine and Hydroxychloroquine (HCQ) are not beneficial in moderate to severe COVID19 disease. However, they have become the current standard for mild to moderate and early disease states. Chloroquine has been shown as a potential suppressor of SARS-CoV-2 in an in vitro study.[1] Though many trials have established a good outcome in mild to moderate cases, unfortunately, chloroquine toxicity is a paramount concern.[2] HCQ, a less toxic derivative, has also been found to be effective.[3] Recently, an anti-parasitic drug Ivermectin has been described as highly effective in an in vitro study against SARS-CoV-2.[4] HCQ-Azithromycin combination therapy has also been shown to be a possibly effective combination therapy in the treatment of SARS-CoV-2.[5, 6] These two studies reported 100% and 83% recovery in the sixth and seventh day with a reduced hospital stay. Alam MT et al.[31] recently described an encouraging result in a case series of COVID19 patients with a combination of Ivermectin and Doxycycline. Till now, there has not been a randomized study of Ivermectin in patients with mild to moderate COVID19. Ivermectin is well-tolerated, less toxic, and has fewer adverse effects than HCQ. HCQ-Azithromycin combination therapy has also been mentioned in the "National guideline for COVID management 4.0" of Bangladesh as an initial therapy against COVID19. Due to drug complications and discouraging statements about HCQ treatment made by WHO, it is crucial to find an effective, economical alternative to HCQ. Therefore, we decided to investigate the efficacy of Ivermectin-Doxycycline combination therapy and compare it to the standard HCQ-Azithromycin treatment according to the "National guideline for COVID management 4.0" among the mild to moderate cases of COVID19 patients.

Methods

Ethical Consideration and Approval, Informed Consent

This study was approved by the Ethical committee of Chakoria Upazilla Health Complex, Chittagong, Bangladesh. UHC/Chakoria/Ethical Approval/2020/01 (15-04-20). The purpose of the research was explained to participants. Once verbal consent was understood and agreed upon, a written form was given. This was done to get informed consent and legal identification. The individuals who gave consent were enrolled in this study.

Study Population and Data Collection

Patients (16 years to 80 years of age) tested positive for SARS-CoV-2 infection by Real-time polymerase chain reaction (RT-PCR) at Chakoria Upazilla Health Complex, Cox's Bazar, Bangladesh, from second may to the fifth June 2020, were initially included in this study, including those with and without the symptoms. The PCR analysis of the collected samples was performed in Cox's Bazar Medical College. All patients received a full evaluation, including a history of current illness, comorbid condition, and associated complaints. Patients with unstable comorbid conditions like bronchial asthma, chronic obstructive pulmonary disease (COPD), ischemic heart disease (IHD), uncontrolled diabetes mellitus (DM), advanced renal and hepatic disease, carcinoma, hospitalized, and immuno-compromised patients were excluded. Patients were examined for oxygen saturation and only those with oxygen saturation of 95% or above who fit the outpatient treatment protocol for COVID19 were included. Patients with respiratory symptoms received chest radiographs. Those with normal or near-normal chest radiographs (up to 10% involvement) were included.

Randomization and Treatment Intervention

Randomization was done using an odd-even methodology and applied to registration numbers, consecutively in a 1:1 ratio, by the hospital registration office. Treatment was given, and the final enrolment was done by the attending physician (investigator). All the patients enrolled in this study were treated as outpatient department (OPD) patients.

For the study, patients were divided into two groups, as follows:

- Group A (n=60): Ivermectin 200µgm/kg single dose + Doxycycline 100mg BID for ten days.
- Group B (n=56): Hydroxychloroquine 400mg for the first day, then 200mg BID for nine days + Azithromycin 500mg daily for five days (considered as the control group).

Ivermectin dosing was determined by the case series performed by Alam MT et al., and HCQ dosing was decided as per "National guideline for COVID management 4.0".

All the subjects were provided with symptomatic treatment such as fever, headache, cough, and myalgia. Drug interactions and contraindications for each individual were considered carefully. The schedule of medication intake was adequately explained to each patient. Group A's instructions included that Ivermectin tablet (200µg/kg) single dose to be taken on an empty stomach an hour before a meal on the first day. Doxycycline 100 mg cap-

sule be taken twice daily after meal for ten days starting from day one. Group B's instructions included Hydroxychloroquine 400mg (two tablets of 200mg each) to be taken on the first day, then 200mg (one tablet) twice daily after meal for nine days. Azithromycin 500mg (one tablet of 500mg) to be taken once daily after meal for five days starting from day one. Patients were advised to self-isolate, take proper nutrition, hydration, and maintain a sanitary environment.

Repeat Nasopharyngeal and Throat Swab PCR

All subjects underwent repeat nasopharyngeal and throat swab PCR for SARS-CoV2 every other day until their PCR was negative. These repeat PCR tests began on the fifth day after taking the medication for subjects who began the study and remained symptom-free. The PCR repeat testing began on the second symptom-free day onward for subjects who began the study with symptoms or developed symptoms. The investigators had telephone contact with all the subjects every three days throughout the study to determine any therapy's adverse effects. A re-evaluation PCR was performed after seven days following the first negative PCR.

Endpoints were a negative PCR and resolution of symptoms. The duration from the first day of drug intake to the negative PCR was counted as the recovery period. The duration from the first day of drug intake to the disappearance of symptoms was counted as the period to symptomatic recovery. "Adverse effects" were determined by the existence of the pharmacological side effects of the particular drug during treatment. A detailed history of adverse effects (other than previous disease symptoms) experienced by each participant was collected during the follow-up sample collection. An asymptomatic participant presented with no symptom of COVID-19 and remained the same until the negative PCR.

Data Analysis and Statistics

Data were presented as mean±standard deviation, and statistical analysis was done by Graph pad Prism software. Column analysis was done to find the mean with the standard deviation in each group. T-test was done to see the significance between the values where needed. $P<0.05$ was considered statistically significant.

Results

This study was completed in a pre-determined period from May second to June fifth, 2020, and 181 patients tested positive for SARS-CoV-2 infection in that period. 42 patients had comorbid conditions (some required hospitalization) that might have affected the recovery time, and 14 patients were unwilling to participate in the study. Nonetheless, 9 patients did not show-up (3 from group A and 6 from group B) for the follow-up sample collection, so these were excluded, and 116 patients were finally included in the analysis (Fig. 3).

Demographic Characteristics of the Study Subjects

As shown in Table 1, the total number of patients was 116; male 84 and female 26, age 16 to 80 years, and mean age (33.94±14.12 years). Group A (Ivermectin + Doxycycline): male 43 (71.67%), female 17 (28.33%), age 35.72±15.1 years; males 37 years and female 32.88 years. Group B (Hydroxychloroquine + Azithromycin): male 47 (83.93%), female 9 (16.07%), age 31.91 years; male 31.35, and female 34.5 years. (Fig. 1 a, b) Among the total, 91 (78.45%) were symptomatic, and 25 (21.55%) were asymptomatic patients with contact history. These were 49 (81.67%) and 11 (18.33%) in group A, 42 (75%) and 14 (25%) in group B.

Recovery Rate and Mean Recovery Duration Between Groups

In group A, recovery to negative PCR rate was 100% (60/60). The mean recovery duration to negative PCR was 8.93 days (8 to 13 days). 41 (63.3%) of patients had no new complaints other than their presenting symptoms. New symptoms that may have been attributed to adverse drug effects included

Table 1. Baseline characteristics of the study group patients.

Parameters	
Number of patients (n)	116
Male	90 (77.58)
Female	26 (22.41)
Group A (n, %)	60
Group A Male (n, %)	43 (71.67)
Group A Female (n, %)	17 (28.33)
Group B (n)	56
Group B Male (n, %)	47 (83.93)
Group A Female (n, %)	9 (16.07)
Age (in years)	33.94±14.12 (8 to 80 Years)

FOI 26-3132 - Document 5

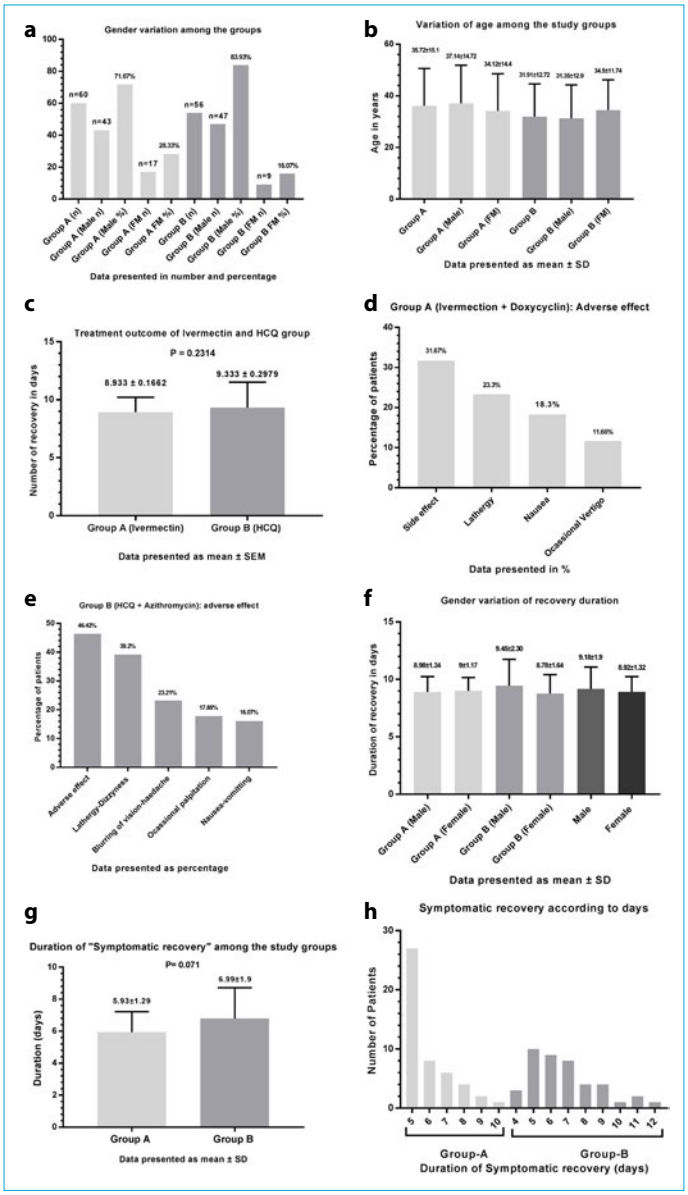

Figure 1. (a) Number of patients according to gender among the groups. **(b)** Gender variation of age among the study groups (data presented as mean±SD). **(c)** Recover duration of Ivermectin-Doxycycline and HCQ-Azithromycin group; note: the difference between the groups' recovery duration is not statistically significant P=0.231. **(d)** Adverse effect expressed by the patients of group A. **(e)** Adverse effect experienced by the patients of group B. **(f)** Variation of the recovery duration according to the gender; note: males in group B and males as gender, in general, have a longer recovery period than the females. **(g)** Duration of the symptomatic recovery (in days) among the groups. The difference between the duration among groups is not significant P=0.071. **(h)** Subgroup analysis of the recovery duration among the groups. Note: group A has a higher number of symptomatic recoveries in the early days; this indicates a better efficacy of Ivermectin-Doxycycline therapy.

lethargy in 14 (23.3%), nausea in 11 (18.3%), and occasional vertigo in 7 (11.66%) of patients (Fig. 1c).

In group B, out of 56 patients, two male patients were referred to a tertiary hospital. They did not recover to a negative PCR as part of the study. Therefore, the recovery rate to negative PCR was 96.36% (54/56). The mean duration of recovery to negative PCR was 9.33 days (5 to 15 days). 30 (53.57%) of the patients had no new complaints other than their presenting symptoms. Fresh symptoms that were recognized as an adverse effect of HCQ included 13(23.21%) with mild blurred vision and headache; 22 (39.2%) with increased lethargy and dizziness, 10 (17.85%) with occasional, mild palpitation, and 9 (16.07%) with nausea and vomiting (Fig. 1e).

Difference in Recovery to Negative PCR between Groups

The difference between group A and group B recovery to negative PCR duration was not statistically significant in unpaired t-test, p=0.2314 (Fig. 1c). Subgroup analysis of the recovery duration: male 9.18±1.90 days and female 8.92±1.32 days, p=0.515; in group A male 8.907±1.342 days and female 9±1.173 days, p=0.44; and in group B male 9.18±1.90 days and female 8.92±1.32 days, p=0.407. The recovery duration of both group males and females were not significant, p=0.18 and 0.69, respectively (Fig. 1f).

The mean duration of symptomatic recovery was 5.93 days (5 to 10 days) in group A and 6.99 days (4 to 12 days) in group B (Fig. 1g). This difference in time to symptomatic recovery between group A and group B is not statistically significant, p=0.071 (Fig. 1g). In group A, over half of the subjects had become symptom-free by five days 27 (55.10%), with the remaining subjects becoming symptom-free on day six (16.32%), day seven (12.24%), day eight (8.16%), day nine (4%), and day ten (2.04%) (Fig. 1h). In group B, recovery was slower with subjects becoming symptoms free on fourth day 3 (7.14%), the fifth day 10 (23.8%), sixth day 9 (21.43%), seventh day 8(19.04%), eighth & ninth day 4 (9.52% each), eleventh day 2 (4.76%), and tenth and twelfth day (2.38% each) (Fig. 1h).

Mean Duration of Time to Negative PCR between Groups

In the secondary analysis of subjects who began the study with symptoms, the mean duration of time to negative PCR was 9.061 days in group A and 9.738 days in group B. This was not statistically significant in the unpaired t-test, p=0.0714. The mean duration of time to becoming negative PCR of patients without symptoms was 8.364 days in group A and 7.917 days in group B, which was not statistically significant in unpaired t-test, p=0.443 (Fig. 2b). Further analysis showed the highest recovery was achieved on the eighth day among group A patients in case of both asymptomatic (n=11) and symptomatic (n=49) patients,

8 (72.72%) and 22 (44.89%), respectively (Fig. 2 c, d). This recovery was relatively slower in group B. On the sixth day 3 (7.5%), seventh day 1 (2.5%), eighth day 9 (22.5%), ninth and tenth day 8 (20%) each, eleventh and twelfth day 4 (10%) each, thirteenth day 1 (2.5%), and fourteenth day 2 (5%) in group B patients with symptoms (n=40). Among asymptomatic patients (n=14), this was 1 (7.5%) on the fifth day, 2 (14.2%) individually on the sixth, seventh, eighth, tenth day, 4 (28.57%) on the ninth day, and 1 (7.1%) on the eleventh day (Fig. 2 c, d). No significant difference in the recovery duration was found in the subgroup analysis of the recovery duration according to the study groups' age. 61 to 70 years in group A had the longest recovery duration, 9.5±2.12, and 71 to 80 years was the shortest 8days. In group B, this was 11.71±2.48 days in the 41 to 50 years and 8.37±2.44 days in the 10 to 20 years age group (Fig. 2 e).

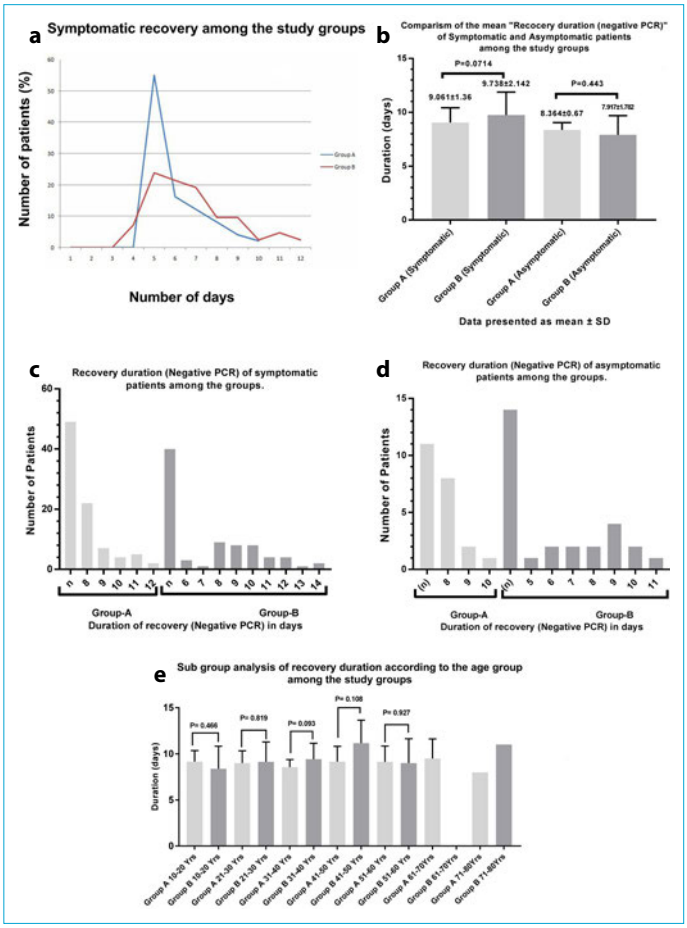

Figure 2. (a) Comparison between the symptomatic recoveries among the study groups. Note: group A (Ivermectin-Doxycycline) showed a pick recovery on the 5th day. In group B (HCQ-Azithromycin), the symptomatic recovery started relatively earlier on the 4th day but had a slow trend. **(b)** The mean duration of recovery (beginning of the treatment to the negative PCR) of the patients with and without symptoms among groups A& B was not statistically significant in the subgroup analysis. **(c)** Subgroup analysis of recovery duration of the symptomatic patients among the study groups. Maximum numbers of negative PCR were achieved on the 8th day in both groups. Group A 22 (44.89%) and group B 9 (22.5%). The recovery rates are faster in group A, though relatively earlier but slow in group B. **(d)** Subgroup analysis of the asymptomatic patients' recovery duration. Most group A patients gained viral clearance on 8th day 8 (72.72%). Not: first PCR was done on the 5th day. In group B, 1(7.1%) was recovered on the 5th day and 2 (14.2%) on the 6th day. The highest recovery was observed on the 9th day 4 (28.57%). **(e)** Subgroup comparison of the recovery duration according to age.

Discussion

The COVID-19 pandemic in Bangladesh is part of the coronavirus worldwide pandemic disease caused by a newly discovered coronavirus. It was initially called novel coronavirus and later named SARS-CoV-2 due to its similar characteristics with SARS-CoV-1.[7-9] The treatment methods for COVID-19 are emerging and rapidly evolving because of ongoing research being done worldwide by a record number of investigators. Due to each medical and research facility's uniqueness, the approach to patient care with COVID-19 varies from institution to institution in Bangladesh. Many patients with mild to moderate disease were treated with HCQ and Azithromycin. New concerns about HCQ has led us to seek alternatives with shorter recovery time and better tolerability. Thus, we have undertaken a comparative therapeutic analysis, comparing these standard drugs with Ivermectin and Doxycycline.

In this randomized treatment study of groups A and B, the presenting symptoms of the COVID19 patients were fever, cough, sore throat, weakness, chest discomfort, breath-

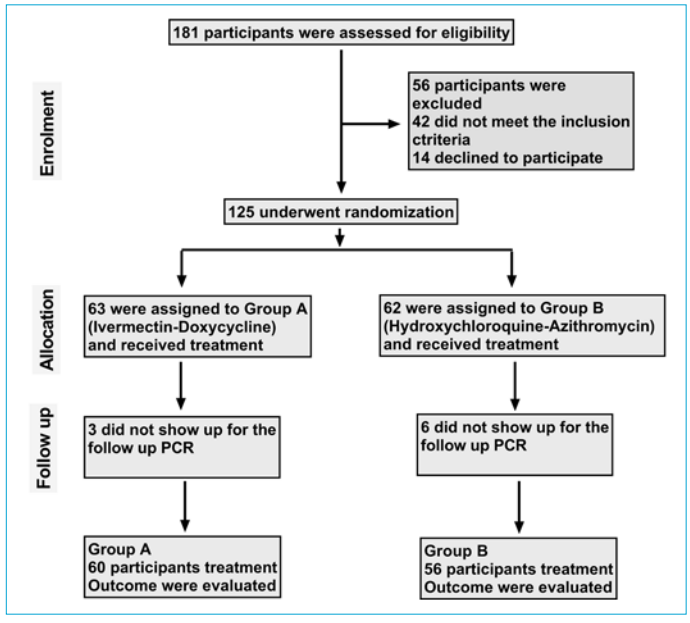

Figure 3. Flow diagram of randomization and treatment assignment of the participants.

ing difficulty, diarrhea, myalgia, and abdominal pain. To avoid the recovery duration's influence, we solely selected the cases devoid of severe comorbidities. The difference in recovery to negative PCR duration was not significant (p=0.231) among the two groups. The mean recovery duration is shorter, 8.933 days in group A than in group B, 9.33 days (Fig. 1 c). Also, group A had a better outcome ratio of 100% (60/60) recovery to negative PCR compared to that of group B 96.36% (54/56).

HCQ has decades of treatment use as an immunomodulator.[10] At present, it has been the topic of discussion concerning its potential use to treat patients with COVID-19.[11] It is thought that the effect of HCQ results in the selective killing of the infected cells. Therefore, it may accelerate viral clearance in COVID-19.[13] Some studies showed that severe deterioration in some patients with COVID-19 had been closely associated with dysregulated and excessive cytokine release termed "cytokine storm."[14, 15] HCQ was found to inhibit SARS-CoV-2 infection in vitro and significantly decrease cytokine production, especially the pro-inflammatory cytokines.[16] Correspondingly, Azithromycin is a macrolide group of antibiotics. It has been studied as part of possible treatment of COVID-19 combined with HCQ and has been reported to add benefit.[17, 18] However, a recent report failed to establish whether it has any antiviral activity or any synergistic activity with HCQ in the treatment of COVID-19.[19] Therefore, a further comparative study can enhance the significance of HCQ- Azithromycincombination therapy.

On the other hand, Ivermectin is a relatively safe and well-tolerated anti-parasitic drug that can inhibit nuclear transport activity.[20] Recently, in-vitro studies have shown its function against SARS-CoV-2.[21, 22] A recent report suggested that Ivermectin reduces mortality rates in hospitalized patients with COVID-19.[23] However, it is unknown if antiviral levels are attainable while using known dosing regimens of Ivermectin therapy in patients with COVID-19.[24, 25] Thus, it is vital to investigate Ivermectin's dose regimens for COVID-19 treatment or to determine if there is appropriate synergism using combination therapy with another drug. Also, Doxycycline is a tetracycline class of antibiotics with a long history of clinical use.[26] The efficacy and tolerability of Ivermectin and Doxycycline were established in combination with an earlier study to treat onchocerciasis.[27] Several recent studies have suggested a therapeutic role of Doxycycline against COVID-19.[28, 29]

In our study, the difference in recovery to become symptom-free was not statistically significant (Fig. 1c). Nevertheless, the Ivermectin group showed better symptomatic recovery than the HCQ group (Fig. 2 a-d). According to the age among study groups, the difference was not statistically significant (Fig. 2 e). Ivermectin-Doxycycline combination expressed an earlier and faster relief of COVID features (Fig. 1 g) and viral clearance than the HCQ-Azithromycin combination. However, the mean recovery duration is not statistically significant (Fig. 1c). In the Ivermectin-Doxycycline group a greater number of patients gained faster symptomatic recovery than that of the HCQ group (Fig. 1h] This suggests Ivermectin-Doxycycline may have better efficacy in reducing the COVID-19 symptoms than HCQ-Azithromycin therapy.

The Ivermectin-Doxycycline group had better patient compliance and fewer adverse effects compared to the HCQ-Azithromycin group (Fig. 1 d, e). The adverse effects of HCQ in our study are similar to others.[30, 31] The sex difference was also examined, but there were no significant differences between males and females in this study (Fig. 1 f). According to this study, the Ivermectin-Doxycycline treatment regimen was well tolerated, and effective treatment for mild to moderate degrees of SARS-CoV-2 infection. Not only concerning the time to become symptom-free and the viral clearance, but also in terms of safety, side-effect profile, and compliance the Ivermectin-Doxycycline combination is superior to HCQ-Azithromycin therapy for mild to moderate degrees of COVID-19 patients. We strongly believe that increasing the dose and the duration of Ivermectin treatment will further benefit in reducing the recovery period of COVID19 infection beyond that which was seen in our study. This will also prevent disease progression and morbidity in COVID-19 patients.

Our study has limitations, and these include relatively small sample size, the dose of Ivermectin, and case selection. The outcome may be biased by factors like disease severity, lack of cooperation of some participants, and unknown comorbidity.

Conclusion

Researchers have suggested different drug combination therapies for COVID19. According to our study, the Ivermectin-Doxycycline combination therapy has better symptomatic relief, shortened recovery duration, fewer adverse effects, and superior patient compliance compared to the Hydroxychloroquine-Azithromycin combination. Based on this study's outcomes, the Ivermectin-Doxycycline combination is a superior choice for treating patients with mild to moderate COVID-19 disease. Despite this study's limitation, we tried to select our study group patients without any major or unstable comorbid condition as far as possible to avoid differences in treatment outcomes among the groups. Further study is required on a larger scale with an increase in Ivermectin treatment duration.

Abstract: In December 2019, a new severe acute respiratory syndrome coronavirus (SARS-CoV-2), causing coronavirus disease 2019 (COVID-19), emerged in Wuhan, China. Despite containment measures, SARS-CoV-2 spread in Asia, Southern Europe, then in America and currently in Africa. Identifying effective antiviral drugs is urgently needed. An efficient approach to drug discovery is to evaluate whether existing approved drugs can be efficient against SARS-CoV-2. Doxycycline, which is a second-generation tetracycline with broad-spectrum antimicrobial, antimalarial and anti-inflammatory activities, showed in vitro activity on Vero E6 cells infected with a clinically isolated SARS-CoV-2 strain (IHUMI-3) with median effective concentration (EC_{50}) of 4.5 ± 2.9 µM, compatible with oral uptake and intravenous administrations. Doxycycline interacted both on SARS-CoV-2 entry and in replication after virus entry. Besides its in vitro antiviral activity against SARS-CoV-2, doxycycline has anti-inflammatory effects by decreasing the expression of various pro-inflammatory cytokines and could prevent co-infections and superinfections due to broad-spectrum antimicrobial activity. Therefore, doxycycline could be a potential partner of COVID-19 therapies. However, these results must be taken with caution regarding the potential use in SARS-CoV-2-infected patients: it is difficult to translate in vitro study results to actual clinical treatment in patients. In vivo evaluation in animal experimental models is required to confirm the antiviral effects of doxycycline on SARS-CoV-2 and more trials of high-risk patients with moderate to severe COVID-19 infections must be initiated.

Keywords: COVID-19; SARS-CoV-2; doxycycline; treatment; prophylaxis; antiviral; anti-inflammatory

1. Introduction

In December 2019, a new severe acute respiratory syndrome coronavirus (SARS-CoV-2), causing coronavirus disease 2019 (COVID-19), emerged in Wuhan, China [1]. Despite containment measures, SARS-CoV-2 spread in Asia, Southern Europe, then in America and in Africa. As of 9 October 2020, according to the treatment guideline of the National Institutes of Health (NIH), there is no Food and

FOI 26-3132 - Document 5

Drug Administration-approved antiviral treatment against SARS-CoV-2 [2]. Several drugs are tested in the context of the DisCoVeRy trial [3] and a controversial early treatment that associates a combination of hydroxychloroquine and azithromycin has been used worldwide with a reduced risk of hospitalization, a reduced risk of death and a shorter duration of viral shedding [4–10]. Conversely, some studies showed that treatment of mild-to-moderate or mild-to-severe COVID-19 with hydroxychloroquine alone or in combination with azithromycin did not improve clinical status or duration of viral shedding in comparison with standard care [11–15]. Identifying effective, low cost antiviral drugs with limited side effects which are affordable immediately, especially for emerging countries, is urgently needed. An efficient approach to drug discovery is drug repurposing that consists of evaluating whether existing approved drugs can be efficient against SARS-CoV-2.

Doxycycline is a second-generation tetracycline with broad-spectrum antimicrobial [16] and anti-inflammatory activities [17]. Additionally, doxycycline was approved as prophylaxis against malaria by the Food and Drug Administration in 1994 and has been used since 2006 at the dose of 100 mg/day by the French military forces deployed in malaria-endemic areas [18].

Doxycycline also shows antiviral activity in vitro. This tetracycline derivative significantly inhibited the replication of the vesicular stomatis virus in vitro [19] and that of the dengue virus by inhibition of NS2B-NS3 serine protease [20–22]. Doxycycline showed inhibition of entry and replication of Chikungunya virus in Vero cell at 11 μM [23]. Using the in-silico method, doxycycline might be a potential inhibitor of Crimean-Congo hemorrhagic fever virus nucleoprotein, an essential protein in virus replication [24]. Additionally, doxycycline inhibited the early-stage replication of the porcine reproductive and respiratory syndrome virus, which causes respiratory disease, with EC_{50} (median effective concentration) of 0.25 μg/mL (about 0.5 μM) [25]. The current study evaluated the antiviral effect of doxycycline against SARS-CoV-2.

Doxycycline could be an attractive option for the treatment of COVID-19 [26]. Therefore, the activity of doxycycline was assessed in vitro against a clinically isolated SARS-CoV-2 strain and was compared with the activity of chloroquine.

2. Results

The cytotoxicity evaluation of doxycycline and chloroquine showed that the CC_{50} values were >100 μM for 48 h. The CC_{50} value of chloroquine is consistent with those previously described [27,28]. The antiviral effects of doxycycline against the clinically isolated SARS-CoV-2 strain (IHUMI-3) were concentration-dependent.

The median effective concentration (EC_{50}) and 90% effective concentration (EC_{90}) for doxycycline were 4.5 ± 2.9 μM and 23.5 ± 16.5 μM, respectively (Figure 1). The EC_{50} and EC_{90} for chloroquine were 3.2 ± 1.8 μM and 13.9 ± 6.4 μM, respectively (Figure 2). The EC_{50} value for chloroquine is consistent with previous results on Vero E6 cells at MOI of 0.2 to 0.25 [27,29].

The ratios C_{max}/EC_{50} and C_{max}/EC_{90} in blood for doxycycline were estimated at 0.75 and 0.07, respectively after an oral administration of doxycycline 100 mg, at 2.21 and 0.41 after an oral administration of doxycycline 200 mg and at 1.14 and 0.21 after intravenous administration of 100 mg of doxycycline.

Our results demonstrated that doxycycline interacted at both entry and post-entry stages of the SARS-CoV-2 infection in Vero E6 cells (Figure 2).

FOI 26-3132 - Document 5

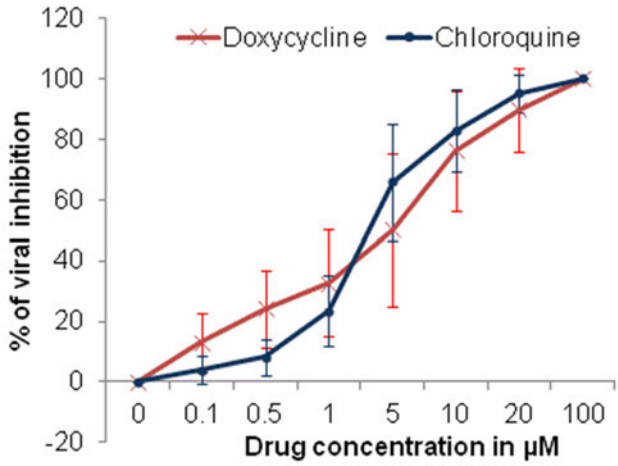

Figure 1. Comparative antiviral efficacy of doxycycline and chloroquine against SARS-CoV-2 infection in vitro (error bar represents standard deviation, 10 experiments).

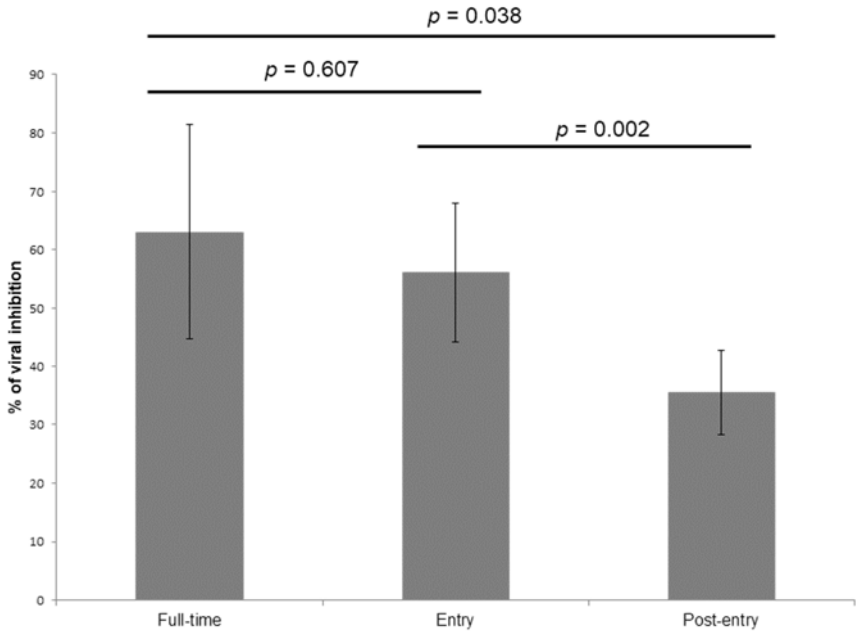

Figure 2. Antiviral activities of doxycycline at 5 µM against the SARS-CoV-2 IHUMI-003 strain in vitro. For full-time treatment, Vero E6 cells were pre-treated with doxycycline for 4 h and virus was then added for 48 h. For "entry" treatment, doxycycline was added to Vero E6 cells 4 h before viral infection and the virus-doxycycline mixture was replaced with fresh medium after 2 h post infection and was maintained for 46 h. For "post-entry" treatment, doxycycline was added 2 h post infection and was maintained for 46 h. Error bars represent the standard deviation of 10 experiments.

3. Discussion

The in vitro activity of doxycycline against the SARS-CoV-2 (EC_{50} = 4.5 µM) was consistent with those reported with hydroxychloroquine [27,29–31], with antimalarial drugs like chloroquine [27–29,32], amodiaquine [29,31,32], ferroquine [29], or mefloquine [29,31,33], antiviral agents like remdesivir [28,32,34] or lopinavir [32], and macrolides like azithromycin [34,35].

A daily oral uptake of 100 mg or 200 mg of doxycycline in healthy volunteers led to a C_{max} (maximum blood concentration) value of 1.7 and 5 µg/mL [36,37]. An intravenous doxycycline dose of 100 mg showed a C_{max} of 2.6 µg/mL [38]. The ratios C_{max}/EC_{50} and C_{max}/EC_{90} for doxycycline in plasma ranged from 0.75 to 2.21 and 0.07 to 0.41, respectively. The ratios C_{max}/EC_{50} and C_{max}/EC_{90} in plasma seem low to reach effective concentrations to inhibit SARS-CoV-2 in humans. However,

FOI 26-3132 - Document 5

in lungs, doxycycline were 2- to 4-fold higher than in plasma [39,40]. A daily oral uptake of 100 or 200 mg of doxycycline led to a C_{max} value from 3.4 to 20 μg/g of lungs. The ratios C_{max}/EC_{50} and C_{max}/EC_{90} for doxycycline in lungs ranged from 1.5 to 8.8 and 0.15 to 1.6, respectively.

Doxycycline interacted at both entry and post-entry stages of the SARS-CoV-2 infection in Vero E6 cells. Doxycycline inhibited in vitro both dengue virus replication by interaction with the dengue virus serine protease (DENV2 NS2B-NS3pro) and dengue viral entry by inhibition of the E2 envelope glycoprotein involved in virus entry [20,22]. Doxycycline interfered particularly with the adsorption and entry of the Chikungunya virus by interaction with the E2 envelope glycoprotein, but also inhibited viral replication in a lower manner [23]. However, doxycycline had no effect in vitro on the adsorption and entry of the vesicular stomatitis virus (VSV) and inhibited only viral replication [19]. Moreover, doxycycline enhanced the adsorption of the porcine reproductive and respiratory syndrome virus (PRRSV) and inhibited its replication after viral entry [25]. The inhibition of both entry and viral replication after SARS-CoV-2 entry is consistent with the results from combinatorial computational approaches. Docking analysis showed that doxycycline could strongly bind the spike protein (S) of SARS-CoV-2 [41]. The spike viral protein of SARS-CoV-2 used the ACE-2 receptor for entry [42]. Therefore, blocking these interactions offers a potential target for drug development. Moreover, doxycycline and more generally tetracyclines could bind the main protease (M^{pro}) of SARS-CoV-2 [43,44]. This protein, also called 3C-like protease, is essential to conduct the replication cycle of SARS-CoV-2 by leading to the formation of non-structural proteins (NSPs) [45,46]. Moreover, Alexpandi et al. showed that doxycycline inhibited the RNA-directed 5′-3′ polymerase activity of SARS-CoV-2 RNA-dependent RNA polymerase (RdRp) (Alexpandi et al., personal data), a key enzyme for the replication of the SARS-CoV-2 [47], like remdesivir [48,49].

However, these results must be taken with caution regarding the potential use of antimalarial drugs in SARS-CoV-2-infected patients: it is difficult to translate in vitro study results into actual clinical treatment in patients. For instance, experts agree on the in vitro activity of chloroquine or hydroxychloroquine against SARS-CoV-2 but disagree on the hydroxychloroquine efficacy in COVID-19 treatments, which remains controversial [50,51]. In vivo evaluation in animal experimental models is required to confirm the antiviral effects of doxycycline on SARS-CoV-2.

Besides its antiviral activity, doxycycline has anti-inflammatory effects by decreasing the expression of various pro-inflammatory cytokines including interleukins 1 (IL-1), 6 (IL-6), and 8 (Il-8) and tumor necrosis factor-alpha (TNF-α) by macrophages [17,52] and chemokines including monocyte chemotactic protein 1, macrophage inflammatory protein 1α and 1β [53]. The immunomodulatory activity of doxycycline improved survival of septic mice with pulmonary inflammation [54]. Moreover, doxycycline is effective for the treatment of several chronic inflammatory airway diseases, including acute respiratory distress syndrome [55]. Doxycycline was the more effective tetracycline in the reduction of IL-6 and TNF-α in patients with dengue fever [56]. Doxycycline ameliorated pulmonary inflammation in a murine polymicrobial sepsis model by decreasing levels of IL-1β, IL-6 and TNFα in plasma and lungs [54]. Doxycycline improved the lung function and quality of life in chronic obstructive pulmonary disease (COPD) [57]. Levels of IL-6, IL-8 and TNFα were reduced in doxycycline-treated COPD patients. Moreover, doxycycline reduced neuroinflammation and preserved oxidative balance in traumatic brain injury-induced cognitive/motor impairments in rats due to its anti-inflammatory and free scavenging mechanisms [58]. Doxycycline could be a potential partner of COVID-19 therapies due to its anti-inflammatory effects.

Moreover, doxycycline is a bacteriostatic antibiotic that is active against the bacterial causes of community-acquired pneumonia, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and atypical pathogens such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae* and *Legionella spp* [59]. Doxycycline is used commonly for lower respiratory tract infection [60]. The use of doxycycline as antimalarial prophylaxis is associated with a reduced risk of Influenza-like illness among travelers [61]. Even without antiviral effects, doxycycline could be a potential partner of COVID-19 therapies due to anti-inflammatory effects and antibiotic effects that could prevent co-infections and superinfections.

FOI 26-3132 - Document 5

Early treatment with doxycycline of 100 mg a day for 7 days (per os or intravenous) in 89 high-risk patients with moderate to severe COVID-19 infections was associated with early clinical recovery, decreased hospitalization and reduced mortality [62]. Another observational study on 54 high-risk patients in 3 long term care facilities in New York revealed that the use of a combination of 100 mg of doxycycline twice a day for 7 days and 400 mg of hydroxychloroquine twice a day on the first day and daily for the next 6 days was associated with a decrease in transfer to hospital and reduced mortality [63]. Results were compared and analyzed against the data observed in a long term care facility in Washington. However, these results must be confirmed by rigorous studies. Many clinical trials on doxycycline alone or in combination to treat COVID-19 are in progress [64–66].

4. Materials and Methods

4.1. Agent, Virus, and Cells

Stock solution of doxycycline hyclate (Sigma, Saint Louis, MO, USA) was prepared in methanol and diluted in Minimum Essential Media (MEM, Gibco, ThermoFischer, Waltham, MA, USA) in order to have 7 final concentrations ranging from 0.1 µM to 100 µM. Chloroquine diphosphate (Sigma) was used as comparator. The clinically isolated SARS-CoV-2 strain (IHUMI-3) [4] was maintained in production in Vero E6 cells (American type culture collection ATCC® CRL-1586™) in MEM with 4% of fetal bovine serum and 1% glutamine (complete medium).

4.2. Cytotoxicity Assay

In vitro cell viability evaluation on the VERO E6 cell line was performed according to the method described by Mosmann with slight modifications [67]. Briefly, 10^5 cells in 200 µL of complete medium were added to each well of 96-well plates and incubated at 37 °C in a humidified 5% CO_2. After 24 h incubation, 25 µL of complete medium and 25 µL of each concentration of methylene blue, hydroxychloroquine or azithromycin were added and the plates were incubated for 48 h at 37 °C. After removal of the surpernatant, 100 µL of MTT (3-(4,5-dimethyl-2-thiazolyl) -2,5-diphenyl-2*H*-tetrazolium bromide, Sigma Aldrich, St Quentin Fallavier, France) solution (0.5 mg/mL in MEM without FBS) was then added to each well. Cells were incubated for 2 h at 37 °C. After incubation, the MTT solution was removed and 100 µL of dimethyl sulfoxide (DMSO) was added to dissolve the formazan crystals. Then, plates were shaken at 700 rpm for 10 min at 37 °C. The absorbance was measured at 570 nm using a TECAN Infinite F200 Microplate Reader. DMSO was used as blank. The 50% cytotoxicity concentration (CC_{50}) was calculated with the inhibitory sigmoid E_{max} model, which estimated the CC_{50} through nonlinear regression by using a standard function of the R software (ICEstimator version 1.2) [68]. CC_{50} value resulted in the mean of 5 different experimentations.

4.3. Antiviral Activity Assay

Briefly, 96-well plates were prepared with 5.10^5 cells/mL of Vero E6 (200 µL per well), as previously described. Doxycycline and chloroquine concentrations were added 4 h before infection. Vero E Cells were infected with IHUMI-3 strain at an MOI of 0.25. After 48 h post-infection, the replication was estimated by RT-PCR using the Superscrit III platinum one step with Rox kit (Invitrogene) after extraction with the BIoExtract SuperBall kit (Biosellal, Dardilly, France). The primers used were previously described [69]. The percentage of inhibition of SARS-CoV-2 replication was estimated for each drug concentration as following: (mean $CT_{\text{drug concentration}}$ − mean $CT_{\text{control 0\%}}$)/(mean $CT_{\text{control 100\%}}$ − mean $CT_{\text{control 0\%}}$) × 100. EC_{50} (median effective concentration) and EC_{90} (90% effective concentration) were calculated with the inhibitory sigmoid E_{max} model, which estimated the EC_{50} and EC_{90} through nonlinear regression by using a standard function of the R software (ICEstimator version 1.2). EC_{50} and EC_{90} values resulted in the mean of 10 different experimentations.

FOI 26-3132 - Document 5

4.4. Determination of the Inhibition Stage

Determining in vitro at what stage doxycycline is acting against the SARS-CoV-2 IHUMI-003 strain was assessed at a concentration of at 5 μM. For "full-time treatment", Vero E6 cells were pre-treated with doxycycline for 4 h and virus was then added for 48 h. For "entry" treatment, doxycycline was added to Vero E6 cells 4 h before viral infection and the virus-doxycycline mixture was replaced with fresh medium after 2 h post infection and was maintained for 46 h. For "post-entry" treatment, doxycycline was added 2 h after post infection and was maintained for 46 h. The percentage of inhibition of SARS-CoV-2 replication by 5 μM of doxycycline was estimated for each drug concentration as following: (mean $CT_{\text{drug concentration}}$ − mean $CT_{\text{control 0\%}}$)/(mean $CT_{\text{control 100\%}}$ − mean $CT_{\text{control 0\%}}$) × 100. The result was the mean of 10 different experiments.

4.5. Data Analysis and Interpretation

Results were estimated as a mean and standard deviation of 5 to 10 experiments. Selectivity index (SI) as a ratio of CC_{50}/EC_{50} was estimated for doxycycline. The expected maximum blood concentration (C_{max}) was estimated from the literature for doxycycline at doses commonly administered in oral or intravenous treatment. The ratios C_{max}/EC_{50} and C_{max}/EC_{90} were estimated to find out if the effective concentration in plasma to cure SARS-CoV-2 is achievable in humans. The ratios C_{lung}/EC_{50} and C_{lung}/EC_{90} were estimated from the data on doxycycline accumulation into the lung.

5. Conclusions

In conclusion, doxycycline showed a high in vitro antiviral effective activity against SARS-CoV-2 with IC_{50} (4.5 μM) compatible with oral uptake and intravenous administrations. Doxycycline interacted both on SARS-CoV-2 entry and in replication after virus entry. Besides its in vitro antiviral activity against SARS-CoV-2, doxycycline has anti-inflammatory effects by decreasing the expression of various pro-inflammatory cytokines and could prevent co-infections and superinfections due to broad-spectrum antimicrobial activity. Therefore, doxycycline could be a potential partner of COVID-19 therapies. However, these results must be taken with caution regarding their potential use in SARS-CoV-2-infected patients: it is difficult to translate in vitro study results into actual clinical treatment in patients. In vivo evaluation in animal experimental models is required to confirm the antiviral effects of doxycycline on SARS-CoV-2 and more trials of high-risk patients with moderate to severe COVID-19 infections must be initiated.

Author Contributions: Conceptualization, M.G., B.L.S. and B.P.; validation, M.G., S.H., H.B. and B.P.; formal analysis, B.P.; investigation, M.G., J.A., O.D., M.B., J.M. and I.F.; resources, S.H., P.J., M.L.B., I.D. and C.R.; writing—original draft preparation, M.G., B.L.S. and B.P.; writing—review and editing, J.A., and S.H.; supervision, B.L.S. and B.P.; project administration, B.P.; funding acquisition, B.L.S. and B.P. ABSTRACT Doxycycline, an FDA-approved tetracycline, is used in tuberculosis *in vivo* models for the temporal control of mycobacterial gene expression. In these models, animals are infected with recombinant *Mycobacterium tuberculosis* carrying genes of interest under transcriptional control of the doxycycline-responsive TetR-*tetO* unit. To minimize fluctuations of plasma levels, doxycycline is usually administered in the diet. However, tissue penetration studies to identify the minimum doxycycline content in food achieving complete repression of TetR-controlled genes in tuberculosis (TB)-infected organs and lesions have not been conducted. Here, we first determined the tetracycline concentrations required to achieve silencing of *M. tuberculosis* target genes *in vitro*. Next, we measured doxycycline concentrations in plasma, major organs, and lung lesions in TB-infected mice and rabbits and compared these values to silencing concentrations measured *in vitro*. We found that 2,000 ppm doxycycline supplemented in mouse and rabbit feed is sufficient to reach target concentrations in TB lesions. In rabbit chow, the calcium content had to be reduced 5-fold to minimize chelation of doxycycline and deliver adequate oral bioavailability. Clearance kinetics from major organs and lung lesions revealed that doxycycline levels fall below concentrations that repress *tet* promoters within 7 to 14 days after doxycycline is removed from the diet. In summary, we have shown that 2,000 ppm doxycycline supplemented in standard mouse diet and in low-calcium rabbit diet delivers concentrations adequate to achieve full repression of *tet* promoters in infected tissues of mice and rabbits.

KEYWORDS doxycycline, TetR, tuberculosis, animal models, tissue penetration, genetic regulation *in vivo*

Transcriptional regulators derived from the tetracycline repressor (TetR) of *Escherichia coli* have been exploited for more than 2 decades to chemically regulate gene expression with tetracyclines in eukaryotic cells (1–3). The specificity of the Tet repressor-operator-effector interaction and the favorable *in vivo* pharmacokinetics of tetracyclines make this regulatory system well suited for the temporal control of gene expression *in vivo*, such as in transgenic animals (4) and animals infected with recombinant pathogenic bacteria carrying genes of interest under the TetR-*tetO* transcriptional control unit (5–7).

Promoters that can be controlled by TetR and tetracyclines were initially developed *in vitro* in Gram-positive and Gram-negative bacteria (8). More recently, such systems have also been developed for medically relevant acid-fast bacteria, including *M. tuberculosis* (9, 10). Owing to its excellent oral bioavailability and pharmacokinetic properties in mice and its relative lack of activity against *M. tuberculosis* with an MIC of 8 to 16 μg/ml (11), doxycycline (DOX) has frequently been used in tuberculosis (TB) mouse

models to induce or repress *M. tuberculosis* genes (12–15). In general, the affinity of DOX for TetR is several orders of magnitude higher than its affinity for the ribosome, providing a safe range within which genetic regulation can be achieved without affecting bacterial growth (16).

To regulate *M. tuberculosis* gene expression during infection, DOX is administered either in the drinking water at up to 2 mg/ml or in commercially available modified diets at 200 to 2,000 ppm, where it was reported to be stable for at least 7 days and 6 months, respectively (17, 18). Supplementation of DOX in mouse feed is considered the most convenient method to achieve adequate and consistent plasma levels (18).

Since DOX is commonly used as a broad-spectrum antibiotic in veterinary medicine and the food industry, tissue distribution studies have been conducted in animals such as horses and broiler chickens to assess its penetration into various organs and cell types. DOX shows favorable tissue partitioning and equilibration of free drug concentrations (with a free fraction in plasma of 20%) between plasma and interstitial fluid at steady state. Accumulation in specific cell types, such as polymorphonuclear leukocytes (19) and fibroblasts (20, 21), has been observed. However, no tissue penetration study has been conducted to determine whether adequate DOX levels are achieved in TB-infected organs and immune cell types in which the pathogen resides.

This work was undertaken to (i) identify the range of DOX concentrations that achieve full repression of Tet-OFF promoters *in vitro*, (ii) measure DOX concentrations in major organs and in lung lesions in TB-infected mice and rabbits in order to determine the lowest DOX feed content required to achieve the target concentrations identified *in vitro*, and (iii) explore the clearance kinetics of DOX from lung tissue and lesions to determine the number of days required for DOX levels to fall below concentrations sufficient to induce or repress *tet* promoters after DOX is removed from the diet.

RESULTS

Concentrations required for control of Tet-OFF constructs by tetracyclines *in vitro*. Anhydrotetracycline (ATc) is conventionally used as the *in vitro* inducer or repressor of TetR-*tetO* constructs due to its lack of growth inhibitory activity against *M. tuberculosis*. DOX, on the other hand, is the preferred transcriptional regulator *in vivo* because it is orally bioavailable and inhibits *M. tuberculosis* growth only at high concentrations (11). To determine the concentrations of ATc and DOX required to achieve complete silencing of target genes in *M. tuberculosis in vitro*, we resorted to genetically engineered strains in which a dual-control switch combining repression of transcription and controlled proteolysis had been chromosomally integrated to silence gene and protein activities (14, 22–24). Three *M. tuberculosis* strains, each with a dual-control switch targeting either *fum*, *rho*, or *trxB2* (three essential *M. tuberculosis* genes), were exposed to increasing concentrations of ATc or DOX. ATc concentrations ranging from 1 to 2 μg/ml were required to achieve 90% growth inhibition resulting from effective silencing in all three strains (Fig. 1A). When DOX was used as the TetR ligand *in vitro*, 50% growth inhibition was achieved at 80, 120, and 200 ng/ml for *trxB2*, *rho*, and *fum*, respectively; 90% growth inhibition was achieved between 230 and 350 ng/ml (Fig. 1B). Thus, lower DOX than ATc concentrations are required to control TetR-*tetO* constructs in *M. tuberculosis*. To ensure that these concentrations do not interfere with the growth of wild-type *M. tuberculosis* and to confirm published MICs, full dose-response curves were obtained with *M. tuberculosis* H37Rv exposed to both tetracyclines. *M. tuberculosis* growth remained unaffected by ATc up to the highest concentration tested (4 μg/ml), while DOX achieved approximately 30% growth inhibition at 4 μg/ml (Fig. 1C), consistent with the published MICs of 8 to 16 μg/ml (11). These results indicate that the concentrations required to achieve maximum control of TetR-*tetO* constructs do not affect growth of *M. tuberculosis in vitro*.

Pharmacokinetics and tissue distribution of DOX in mice. To compare the DOX concentrations achieved in mice relative to DOX MICs and concentrations required to regulate TetR-controlled promoters, we first measured DOX concentrations in the

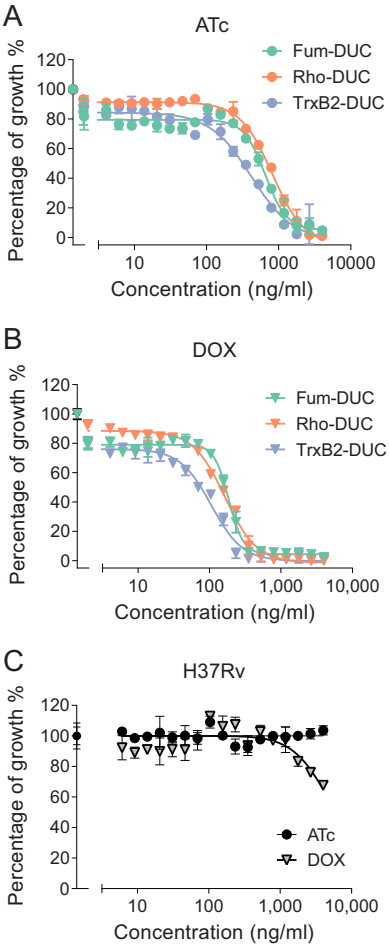

FIG 1 Effect of tetracyclines on *in vitro* growth of *M. tuberculosis* H37Rv harboring essential genes under TetR control compared to wild type. (A and B) Growth inhibitory dose response of anhydrotetracycline (ATc) and doxycycline (DOX) in *M. tuberculosis* strains that harbor a TetR-dependent dual-control genetic switch (14) driving expression of Fum (fumarate hydratase, green symbols), Rho (transcription termination factor, orange symbols), or TrxB2 (thioredoxin reductase, blue symbols). (C) Growth inhibitory dose response of ATc and DOX against wild-type *M. tuberculosis* H37Rv.

plasma of TB-infected mice receiving 2,000 ppm DOX in the diet. Plasma was collected on days 1, 2, 3, and 7 following the switch from DOX-free to DOX-medicated chow, 3 weeks postinfection with *M. tuberculosis* strain H37Rv. Plasma levels of DOX ranged from 300 to 1,190 ng/ml (average, 637 ng/ml; standard deviation [SD], 411 ng/ml) on day 1 and reached an average of 1,081 ng/ml (SD, 386 ng/ml; range, 757 to 1,850 ng/ml) on day 7 (Fig. 2A), thus achieving the concentrations required to inhibit 90% of the growth of strains harboring representative Tet-OFF-controlled essential genes *in vitro* (Fig. 1B). To assess potential lot-to-lot variability in DOX chow, groups of 3 mice were fed three different lots, and plasma DOX concentrations were measured in serial blood samples from 0 to 5 h on day 1 (see Fig. S1 in the supplemental material), showing consistent plasma levels across lots. Actual DOX concentrations were measured in each lot and found to be within 25% of the target content of 2,000 ppm (Table S1).

To quantify penetration into tissues, we measured DOX concentrations in all major organs in the TB-infected mice that had received DOX-medicated chow for 7 days (Fig. 2B), showing favorable penetration in all organs except for brain tissue. In infected lung, spleen, and lymph node homogenates, total DOX concentrations were 2- to 4-fold higher than in plasma, thus exceeding levels required to achieve 90% growth inhibition, while not reaching the MIC of 8 to 16 μg/ml (Fig. 2B). To determine the time required for DOX to clear plasma and infected organs below concentrations sufficient

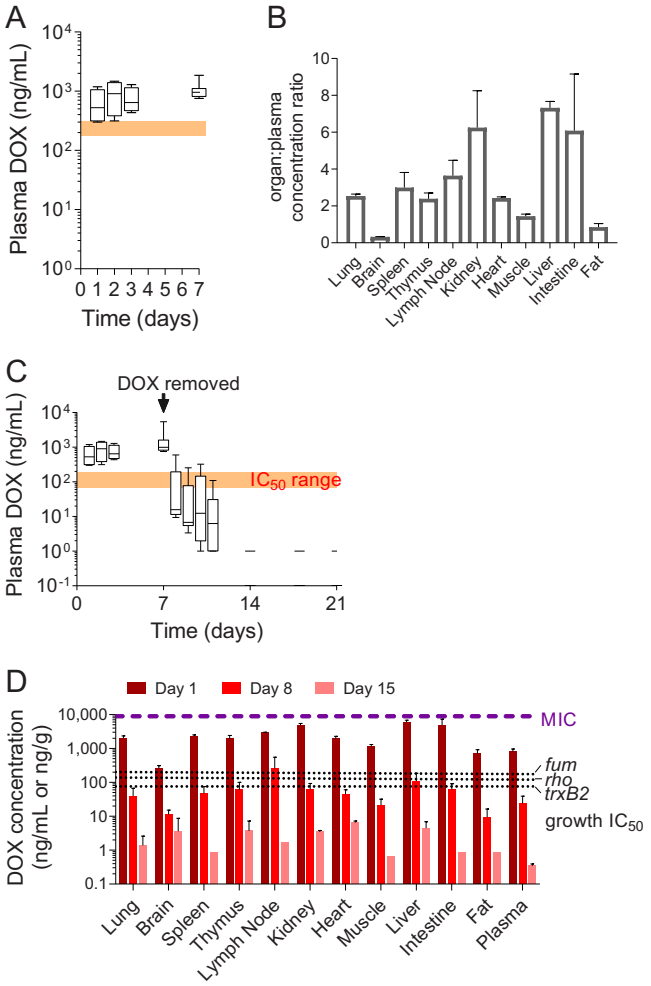

FIG 2 Plasma and tissue pharmacokinetics of DOX in mice receiving DOX-supplemented diet. (A) Box and whisker plot of DOX plasma concentrations in mice receiving 2,000 ppm DOX in standard diet for 7 days. Mean values (bar), minimum and maximum (box) and standard deviations (error bars) are shown for $n = 4$ to 11 mice per group. The orange shaded window indicates the range of *in vitro* DOX concentration that inhibits 90% of bacterial growth (IC_{90}) for the three reporter strains shown in Fig. 1. (B) DOX concentrations in mouse organs relative to plasma after 7 days on the DOX diet. Mean values and standard deviations (error bars) are shown ($n = 3$). (C) Kinetics of DOX clearance in plasma following removal of DOX from the diet for 14 days. Mean values (bar) and minimum and maximum (box) and standard deviations (error bars) are shown ($n = 3$ to 12). The orange shaded window indicates the range of *in vitro* DOX concentrations that inhibit 50% of bacterial growth (IC_{50}) for the three reporter strains shown in Fig. 1. (D) Kinetics of DOX clearance from major organs of TB-infected mice 7 and 14 days after removal of DOX from the diet. Day 1 corresponds to DOX levels in mice that had received a DOX-supplemented diet for 1 week, after which it was replaced by a DOX-free diet for the duration of the experiment. The purple dotted line indicates the lower boundary of published MIC ranges against wild-type *M. tuberculosis* (11), and the black dotted lines show individual DOX IC_{50}s for the three reporter strains (Fig. 1). Mean values and standard deviations (error bars) are shown ($n = 3$).

to induce or repress Tet-ON and Tet-OFF promoters, mice were switched to a DOX-free diet after 7 days on DOX chow, and DOX concentrations in plasma were measured at 1, 2, 3, 4, 7, 11, and 14 days post-DOX removal (Fig. 2C). To determine how this translated within tissue, we quantified DOX in homogenized organs from 3 mice per group at 1, 8, and 15 days post-DOX removal, showing that concentrations fell below the levels required to achieve 50% growth inhibition in all organs except lymph nodes within 8 days post-DOX removal (Fig. 2D).

Dose finding pharmacokinetics of DOX in rabbits. The rabbit model of TB disease is well suited to assess the essentiality and vulnerability of bacterial targets in mature cellular and necrotic lesions resembling those found in human TB (25, 26). However,

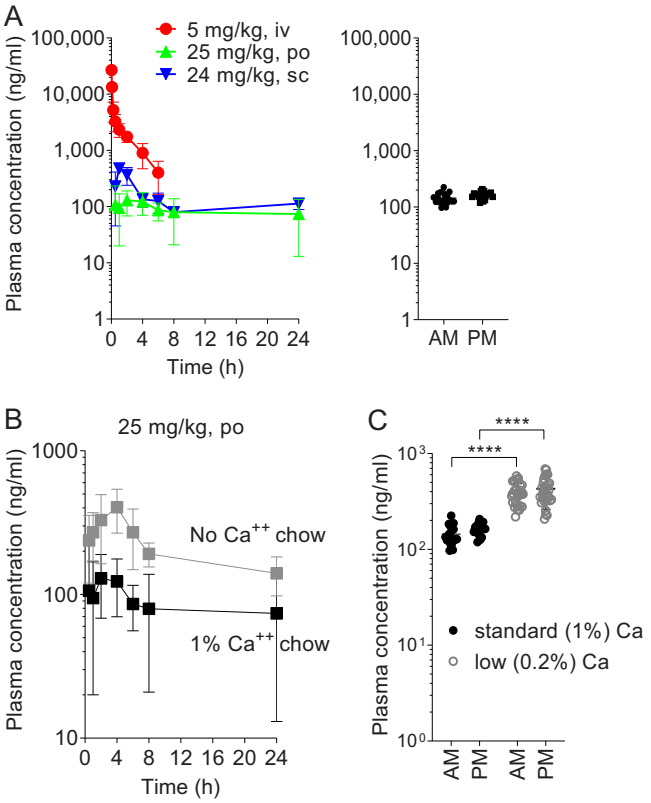

FIG 3 Plasma and tissue pharmacokinetics of DOX in rabbits receiving DOX-supplemented chow. (A) Left panel: DOX concentration-time profile in rabbit plasma following a single DOX dose administered intravenously (i.v.), by oral gavage (p.o.), and subcutaneously (s.c.), as indicated. Right panel: DOX plasma concentrations in rabbits receiving 2,000 ppm DOX in standard chow for 7 days. AM, immediately prior to receiving daily DOX-supplemented feed in the morning; PM, 6 h after receiving DOX feed. (B) Effect of dietary calcium removal on the plasma pharmacokinetics of DOX in rabbits following a single oral dose of 25 mg/kg. (C) Effect of dietary calcium lowering (0.2% total calcium content, or 5-fold lower than in standard chow) on DOX plasma levels in rabbits that received 2,000 ppm DOX in chow for 5 to 7 days. AM and PM time points are as described for right panel A. Data are represented as scatter dot plots of individual animal values and are pooled from two separate experiments with 4 and 6 rabbits, respectively (horizontal bar indicates mean, $n = 20$ to 34 blood samples from 10 rabbits).

DOX pharmacokinetics (PK) and distribution in pulmonary lesions have not been characterized in rabbits. Preliminary PK studies in rabbits that received a modified diet with 200 and 400 ppm DOX showed unexpectedly low plasma levels (Fig. S2A). When the DOX content of the rabbit diet was increased to 2,000 ppm (corresponding approximately to 100 mg/kg), plasma levels increased proportionally, but remained lower than in mice, at 100 to 200 ng/ml throughout the 10-day PK study (Fig. 3A).

To determine whether poor oral bioavailability or species-specific metabolism was the reason for the low DOX concentration in rabbits, we dosed uninfected rabbits with DOX via the intravenous (i.v.), oral (p.o.), and subcutaneous (s.c.) routes. Following bolus i.v. dosing, a biphasic concentration-time profile was observed in plasma, with a distribution and elimination phase, consistent with a two-compartment PK model (Fig. 3A, Table 1). The volume of distribution at steady state (steady-state volume of distribution [V_{dss}] or volume of distribution [V_d] area) was high, reaching a maximum of approximately 1 liter/kg, corresponding to total body volume and similar to the V_d measured in domestic rabbits (27) and in pigs (28). The clearance was low at 26 ml/min or 15% of liver blood flow (Table 1). The i.v. concentration time profile and PK parameters were consistent with published data that used a bioassay for DOX quantitation following i.v. injection in domestic rabbits (27). DOX administration by oral gavage resulted in 3.2% bioavailability (Fig. 3A, Table 1), indicating that poor absorption rather than fast metabolism may partially account for the low oral bioavailability.

[b]V_{dss} = dose · [(A/alpha^2 + B/beta^2)/AUC^2]; *V* area = dose/beta kel · AUC (45).

To determine whether pharmaceutical grade formulation might improve oral absorption, we dosed rabbits with DOX tablets at approximately 15 and 30 mg/kg, which did not result in detectable exposure improvement (Fig. S2B). Lastly, subcutaneous injection resulted in a 1.5-fold increase in the area under the concentration-time curve (AUC) and average concentration throughout the dosing interval (Fig. 3A, Table 1).

Calcium found in dairy products interferes with tetracycline oral absorption because it forms insoluble chelates resulting in decreased bioavailability (29). While most mammals tightly regulate blood calcium, rabbits absorb nearly all dietary calcium and excrete the excess through the kidneys. This results in a surge of blood calcium following food intake (30), proportional to calcium levels in the diet. We therefore hypothesized that DOX absorption and plasma concentrations may increase in rabbits receiving a calcium-free or low-calcium diet. Rabbits were fed a calcium-free or 1% calcium diet for a minimum of 2 days, at which point they received a single 25-mg/kg dose of DOX via oral gavage. As hypothesized, exposure (AUC) after a single dose was twice as high in rabbits on a calcium-free diet (Fig. 3B, Table 1).

To determine whether a similar improvement in DOX exposure would be seen when DOX is provided in the chow, under dietary conditions compatible with long-term experiments (i.e., not calcium-free), we placed rabbits on either standard (1% calcium) chow with DOX at 2,000 ppm or 0.2% calcium chow with DOX at 2,000 ppm, as described in Materials and Methods. Blood samples were collected twice a day (a.m. and p.m.) after 5 to 7 days on DOX chow as indicated. The respective mean a.m. and p.m. plasma DOX concentrations were 144 and 163 ng/ml in the standard-calcium group and 385 and 429 ng/ml in the low-calcium group (Fig. 3C), showing a 2 to 3-fold increase in the low-calcium group and reinforcing the trend observed when DOX was received as a single oral dose. Having optimized constant DOX exposure when provided in the diet, we next studied its distribution in the cellular and necrotic compartments of mature rabbit lesions in order to determine the DOX concentrations to which *M. tuberculosis* bacilli are exposed in tissues.

***In vitro* lesion pharmacokinetics.** Previous work by our group indicated that drug distribution and partitioning within lesions is a function of uptake into macrophages and binding to caseum macromolecules (31, 32). To predict the penetration of DOX in cellular lesions and its behavior at the interface between the cellular rim and necrotic core of TB lesions, we measured DOX uptake into macrophages and caseum binding. DOX uptake was quantified in THP-1 macrophages, where it reached an intracellular to extracellular concentration ratio of 4.1 (SD, 0.6). This favorable cellular uptake predicted good penetration into cellular lesions. The average unbound drug fraction in caseum ($f_{u\text{-caseum}}$) was moderate to high at 12 to 14% (SD 3%) of total drug. Together with the moderate uptake in macrophages, the DOX fraction unbound predicted favorable partitioning at the cellular/caseum interface and good passive diffusion through nonvascularized caseum. Taken together, these results suggest that DOX should reach higher concentrations in both cellular and necrotic lesions than plasma.

Distribution of DOX in cellular and necrotic lesion compartments. Uninvolved lung, cellular, and necrotic lesions were dissected from the lungs of TB-infected rabbits

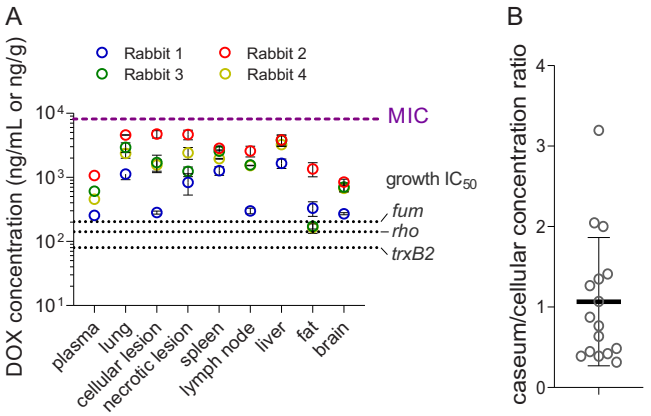

FIG 4 DOX penetration in major organs, lung lesions, and necrotic caseum of TB-infected rabbits. (A) DOX concentrations in plasma, uninvolved lung tissue, lung lesions, and major organs in 4 rabbits receiving a low-calcium 2,000 ppm DOX diet for 7 days. Mean values and standard deviations (error bars) are shown ($n = 3$). (B) Scatter dot plots of caseum-to-cellular DOX concentration ratios in necrotic granulomas collected from TB-infected lungs. Ratios obtained in 10 lesions from 5 infected rabbits are shown.

receiving 2,000 ppm DOX in low-calcium (20% of standard or 0.2% final) chow for 7 days. DOX was also quantified in spleen, lymph nodes, liver, fat, and brain tissue. We found higher DOX levels in cellular and necrotic lesions than in plasma (Fig. 4A), indicating that DOX accumulates in infected tissues relative to plasma, as predicted by the macrophage uptake assay and consistent with the reported accumulation in polymorphonuclear leukocytes (19). Favorable penetration was also measured in spleen, liver, and lymph nodes. All tissue concentrations were above the levels required to achieve 90% growth control, with the exception of one animal with borderline DOX concentrations in some of the tissues. These lower concentrations were explained by low food consumption (Table S2). DOX levels were below the *M. tuberculosis* MIC in all tissues (Fig. 4A). To quantify the partitioning of DOX at the cellular/caseum interface, we used laser-capture microdissection in thin sections of large necrotic lesions (33) from the same rabbits and found caseum-to-cellular DOX concentration ratios ranging from 0.3 to 3.2 with a mean value of around 1.0 (Fig. 4B). Overall, we found (i) higher DOX concentrations in fully cellular lesions than in plasma in line with the macrophage uptake data and (ii) comparable concentrations in caseum and cellular rims, confirming the favorable passive diffusion of DOX through avascular caseum predicted by the caseum binding assay. Collectively, these results indicate that in rabbits on low-calcium chow supplemented with DOX at 2,000 ppm, DOX concentrations are sufficient to achieve complete repression of Tet-OFF genetic constructs but not high enough to affect growth and viability of wild-type *M. tuberculosis*.

DISCUSSION

We have shown that 2,000 ppm DOX supplemented in a standard mouse diet and in a low-calcium rabbit diet deliver DOX concentrations adequate to achieve full repression of representative Tet-OFF promoters in infected tissues of both mice and rabbits. These concentrations remain below the DOX MIC in all tissues and are thus likely to primarily affect *M. tuberculosis* growth and viability by regulation of genes under the control of TetR. The clearance kinetics of DOX from lung lesions and other infected organs indicate that DOX levels fall below concentrations sufficient to repress *tet* promoters within 7 days after DOX is removed from the diet.

DOX bioavailability is species specific and subject to food effect. It is very poor in rats (34) and moderate to low (20%) in pigs (28) but almost complete in calves (35) and humans (36). In nonfasted rabbits that received 150 mg/kg tetracycline by oral gavage (27), bioavailability was estimated at 4% (Data Set S1), in line with the present findings. Interestingly, DOX exposure was also very low in rabbits that received subcutaneous

injections as part of this work, indicating that low bioavailability is not exclusively due to poor oral absorption. Tetracyclines are known to localize in bones and teeth, where 99% of the body calcium is found and where they form calcium-bound depots. They also accumulate in liver and spleen, where they are more highly bound than in plasma (http://www.cyto.purdue.edu/cdroms/cyto2/17/chmrx/tetra.htm). Such trapping in selected tissues could contribute to species-specific plasma levels. In early studies, the distribution of DOX in tissues was described in rats (37) and in patients undergoing biopsies during surgery (38). DOX concentrations were measured in plasma/serum and in major organs using a bioassay and indicated lung-to-serum concentration ratios between 2 and 3, consistent with our findings. Penetration was highest in kidneys and intestines and lowest in fat tissue (37, 38), again in line with our results (Fig. 2B).

Rabbits possess a unique calcium metabolism. Most mammals regulate blood calcium to maintain levels within a narrow range by controlling the absorption of calcium from the diet according to need. Rabbits have adopted the different strategy of absorbing nearly all dietary calcium ingested and renally excreting the excess. As a result, blood concentrations transiently reflect calcium levels in the diet, and calcium carbonate is excreted in large amounts in the urine (30). It has been determined that 0.2% calcium in rabbit chow is sufficient to sustain normal growth and weight gain (30), whereas standard diets contain 1% calcium. Reducing calcium content to 0.2% in rabbit chow supplemented with 2,000 ppm DOX led to improved oral bioavailability and at least 2-fold higher plasma levels throughout the day. DOX concentrations in all relevant organs, in lung lesions, and in plasma were higher than the minimum required to regulate *tet* promoters and did not reach the lower threshold of published MICs in broth (8 to 16 mg/liter [11]). Similar MICs have been measured against intracellular *M. tuberculosis* in macrophages, and bactericidal activity was observed at 40 mg/liter (39). DOX showed favorable partitioning into the necrotic foci of caseous lesions, with an average caseum/cellular concentration ratio of 1/1. Since caseum *M. tuberculosis* is nonreplicating and overall phenotypically resistant to most TB drugs, DOX is not expected to affect *M. tuberculosis* viability in this lesion compartment. Given the similar penetration of DOX in uninvolved lung, cellular, and caseous lesions (Fig. 4A), partial lesion resolution over time due to effective gene silencing by DOX and reduction of bacterial burden is unlikely to impact DOX penetration. Slow tissue clearance has been reported for DOX (40), consistent with our observation that levels fall below effective concentrations after approximately 7 days on a DOX-free diet. These findings have implications as to the kinetics of *tet* regulation following DOX removal and should be taken into consideration when interpreting related data.

Many tetracyclines, including DOX, have anti-inflammatory properties (41) mediated by suppression of tumor necrosis factor-α (TNF-α) and matrix metalloproteases (MMP). *In vitro*, DOX inhibits secretion of MMPs induced by TB infection at 5 mg/liter and higher (39). Thus, fine-tuning the DOX dose in both mouse and rabbit diets to reach but not exceed effective concentrations is important to minimize anti-inflammatory side effects and potential gastrointestinal disturbances.

MATERIALS AND METHODS

***In vitro* repression of Tet promoters.** The construction of the ATc/DOX-controlled *M. tuberculosis* mutants (Fum-DUC, Rho-DUC, and TrxB2-DUC) has been described (22–24). Mutant strains were grown to mid-log phase and diluted to an optical density (OD) of 0.03 in 7H9 medium. Bacteria were then exposed to 1.5-fold serial dilution of ATc or DOX. Optical density was recorded after 14 days and normalized to the corresponding strains without drug treatment.

Animal infection and DOX administration. All animal studies were performed in biosafety level 2 (BSL2) and BSL3 facilities and approved by the Institutional Animal Care and Use Committee of the New Jersey Medical School, Rutgers University, Newark, NJ. All samples collected from *M. tuberculosis*-infected animals were handled and processed in the BSL3 facility in compliance with protocols approved by the Institutional Biosafety Committee of the New Jersey Medical School, Rutgers University, Newark, NJ.

For pharmacokinetic studies in uninfected mice, 4- to 6-week-old CD-1 female mice received a modified rodent diet containing 2,000 ppm DOX for the duration indicated in each experiment. Several diet lots from two different manufacturers were tested in pilot experiments. Laboratory rodent diet 5001 with DOX 2,000 ppm (DOX chow) from Purina (catalog number c113-200i) provided the highest and most consistent plasma levels and was selected for all experiments reported here. Blood was collected at

FOI 26-3132 - Document 5

various time points for up to 3 days while mice were receiving DOX chow, kept on ice, centrifuged at approximately 2,350 × *g* (5,000 rpm in a table-top centrifuge) for 5 min, and stored at −80°C until analyzed for DOX content.

For plasma and tissue pharmacokinetic studies in infected mice, 8- to 10-week-old female BALB/c mice were infected with a low dose of 100 to 200 CFU *M. tuberculosis* H37Rv (ATCC 27294) using a full-body inhalation exposure system (Glas-Col) as previously described (42). Mice received DOX chow for 7 days 4 weeks postinfection. For the determination of DOX content in major organs relative to plasma, one group of 3 mice was euthanized on day 7 and organs were collected, weighed, and stored at −80°C until analyzed for DOX content. Blood was collected at the time of euthanasia and processed as described above. To study the time to clearance of DOX from plasma and tissues after DOX chow (received for 7 days) was replaced with a DOX-free diet, groups of 3 mice were euthanized just prior to and then 1, 2, 4, and 7 h and 1, 2, 3, 4, 7, 10, and 14 days after replacement of DOX chow with standard rodent diet. Plasma and lungs were collected, processed, and stored as described above.

For pharmacokinetic studies in rabbits, female New Zealand white (NZW) rabbits (Millbrook Farm, Concord, MA), weighing 2.2 to 2.6 kg, were maintained under specific pathogen-free conditions and fed water and chow *ad libitum*. For dose-finding pharmacokinetic studies in uninfected animals, rabbits received DOX at the following doses/routes: 5 mg/kg intravenously formulated in saline, 20 mg/kg by oral gavage and formulated in deionized water, 24 mg/kg subcutaneously formulated in deionized water, or 15 and 30 mg/kg administered as DOX pills (either half a pill or one full pill of 100 mg doxycycline hyclate; Henry Schein Animal Health, Covetrus, OH) by oral gavage. Rabbit weights were approximately 3.0 to 3.5 kg at the time of dosing.

For plasma and tissue pharmacokinetics in TB-infected NZW rabbits, animals were infected with *M. tuberculosis* HN878 using a nose-only aerosol exposure system as described (43). At 12 to 20 weeks postinfection, once mature cellular and necrotic lesions had developed, rabbits received LabDiet 5001 supplemented with DOX at 200 ppm, 400 ppm, or 2,000 ppm (Research Diets, Inc., New Brunswick, NJ) for the duration indicated in each experiment.

For pharmacokinetic studies of DOX in a modified diet containing low or no calcium, uninfected rabbits received a gradually phased diet as follows. To test DOX PK in a calcium-free diet, rabbits received 25/75% calcium-free chow mixed with standard high-fiber rabbit chow (Laboratory Rabbit Diet HF 5326; LabDiet)—containing 10,000 ppm or 1% calcium—for 2 days, followed by 50/50% calcium-free chow mixed with standard chow for 2 days, then 75/25% calcium-free chow mixed with standard chow for 2 days, and finally, 100% calcium-free chow for 2 days, at which point they received a single oral dose of 25 mg/kg DOX formulated in deionized water (data shown in Fig. 3B). To test DOX PK in a low-calcium diet (20% of standard calcium content or 2,000 ppm), rabbits received 20/80% calcium-free chow mixed with standard high-fiber rabbit chow for 2 days, followed by 50% calcium-free chow mixed with 50% standard chow for 2 days, and finally, 80/20% calcium-free chow mixed with standard chow for 2 days, at which point DOX was added to the chow at 2,000 ppm final content (data shown in Fig. 3C). Customized calcium-free chow was manufactured with purified ingredients aiming to resemble the dietary parameters of standard high-fiber rabbit chow (18.2% protein, 56.2% carbohydrate, 3.6% fat; per kg of chow: 175 g casein, 390 g corn starch, 25 g maltodextrin, 125 g sucrose, 150 g cellulose, 25 g inulin, 35 g soybean oil, 38.3 g calcium-free mineral mix, 10 g vitamin mix, and 2 g choline bitartrate). Modified rabbit chow was obtained from Research Diets, New Brunswick, NJ.

***In vitro* pharmacokinetic assays and analytical methods.** Caseum binding and macrophage uptake of DOX were measured as described previously (31, 44).

High-pressure liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) methods for plasma and whole tissue analysis DOX-HCl and Verapamil were purchased from Sigma-Aldrich. DOX-d3 internal standard was purchased from Toronto Research Chemicals. Drug-free K_2EDTA plasma and lungs from CD1 mice and NZW rabbits were obtained from BioIVT for use as blank matrices to build standard curves. Neat 1 mg/ml dimethyl sulfoxide (DMSO) stocks DOX were serial diluted in 50/50 acetonitrile (ACN)/Milli-Q water to create neat standards. Control tissue homogenate and study sample homogenate were created by adding 9 parts phosphate-buffered saline (PBS) buffer to 1 part tissue (10× dilution) and shaking the samples using a Fisher bead mill for 1 min at 6,000 × *g* with zirconia beads. Standard, quality control, and study samples for DOX were extracted by adding 10 μl of tissue homogenate or plasma, 10 μl of DOX-d3 internal standard, and 100 μl of extract solvent containing 33% trichloroacetic acid. Extracts were vortexed for 5 min and centrifuged at 2,350 × *g* for 5 min. Then, 100 μl of supernatant was transferred to a 96-well plate for LC-MS/MS analysis. LC-MS/MS analysis was performed on a Sciex Applied Biosystems Qtrap 6500+ triple-quadrupole mass spectrometer coupled to a Shimadzu Nextera X2 ultrahigh-performance liquid chromatography (UHPLC) system to quantify each drug in plasma. Chromatography was performed on an Agilent Zorbax SB-C8 column (2.1 × 30 mm; particle size, 3.5 μm) using a reverse-phase gradient elution with aqueous mobile phase. Milli-Q deionized water with 0.1% formic acid (FA) and 0.1% heptafluorobutyric acid (HFBA) was used for the aqueous mobile phase, and 0.1% FA and 0.1% HFBA in ACN was used for the organic mobile phase. Multiple-reaction monitoring (MRM) of precursor/fragment transitions in electrospray positive-ionization mode was used to quantify the analytes. MRM transitions of 445.20/428.20 and 449.00/432.00 were used for DOX and DOX-d3, respectively. Sample analysis was accepted if the concentrations of the quality control samples were within 20% of the nominal concentration. Data processing was performed using Analyst software version 1.6.2 (Applied Biosystems Sciex).

Laser-capture microdissection coupled to LC-MS/MS. Laser-capture microdissection (LCM) sample quantification was carried out according to a previously published protocol (33). Briefly, 1 mg/ml neat DMSO stocks of DOX were serial diluted in 50/50 ACN/Milli-Q water to create neat standards. Control

FOI 26-3132 - Document 5

tissue homogenate was created by adding 25.6 parts PBS buffer to 1 part tissue (26.7× dilution) and shaking the samples using a Fisher bead mill for 1 min at 6,000 rpm with zirconia beads. Standard, quality control, and control samples were extracted by adding 2 μl of blank homogenate, 10 μl of neat standard, 5 μl of DOX-d3 internal standard, and 50 μl of extract solvent containing 33% trichloroacetic acid. LCM study samples were extracted that were identical to standards using 2 μl of PBS in place of tissue homogenate. Extracts were bath sonicated for 10 min and centrifuged at 2,350 × *g* for 5 min. Then, 50 μl of supernatant was transferred to a 96-well plate for HPLC-MS/MS analysis. HPLC-MS/MS analysis was performed as described above using the whole-tissue analysis methods.

Mini-Review

The Pharmacokinetics and Interactions of Ivermectin in Humans—A Mini-review

Aránzazu González Canga,[1,2] Ana M. Sahagún Prieto,[1] M. José Diez Liébana,[1] Nélida Fernández Martínez,[1] Matilde Sierra Vega,[1] and Juan J. García Vieitez[1]

Received 14 September 2007; accepted 10 December 2007; published online 25 January 2008

Abstract. Ivermectin is an antiparasitic drug with a broad spectrum of activity, high efficacy as well as a wide margin of safety. Since 1987, this compound has a widespread use in veterinary medicine and it use has been extended in humans. Here we present a brief review of the information availabile regarding the pharmacokinetics and interactions of ivermectin in humans. Awareness of these characteristics could improve the clinical efficacy of Ivermectin. All Authors declare that they do not have any Conflict of interest and that the work is original. All Authors agree that the contents of the manuscript are confidential and will not be copyrighted, submitted, or published elsewhere (including the Internet), in any language, while acceptance by the Journal is under consideration.

KEY WORDS: humans; interactions; ivermectin; pharmacokinetics.

INTRODUCTION

Ivermectin is a semisynthetic derivative of avermectin B_1 and consists of an 80:20 mixture of the equipotent homologous 22,23 dehydro B_{1a} and B_{1b}. This antiparasitic agent, developed by Merck & Co., is frequently used in veterinary medicine, due to its broad spectrum of activity, high efficacy and wide margin of safety (1,2).

The first formulation destined to humans was launched in 1987, when Merck Laboratories had enough data to register ivermectin for use against onchocerciasis. The company announced that the drug would be provided at no cost to treat onchocerciasis, anywhere in the world, for as long as it was needed (3).

To control onchocerciasis, the *Onchocerciasis Control Programme in West Africa* was launched in 1974. The main goal of this program is to interrupt the parasite transmission cycle. Since 1987, the use of ivermectin in combination with aerial larviciding has had a remarkable impact on the transmission of the disease and greatly reduced the effect on humans. This led to the development, in 1992, of the *Onchocerciasis Elimination Programme in the Americas*, launched in 6 countries and, in 1995, of the *African Programme for Onchocerciasis Control*, both based mainly on distribution and treatment with ivermectin (4). In 1998, the *Global Programme to Eliminate Lymphatic Filariasis*, based on the regular mass administration of albendazole with either ivermectin or diethylcarbamazine, was initiated, confirming the safety and efficacy of the drug combinations (5).

Presently, ivermectin is approved for use in humans in several countries (Australia, France, Japan, The Netherlands, USA, etc.), to treat onchocerciasis, lymphatic filariasis, strongiloidiasis and/or scabies.

Ivermectin is exceptionally potent, with effective dosages levels that are unusually low. In the treatment of onchocerciasis, the optimal dose of ivermectin is 150 μg/kg, but the frequency of administration is still controversial, ranging from 150 μg/kg once to three times yearly. The optimal duration of treatment has not been established (6). It is effective in most patients with scabies after a single oral dose of 200 μg/kg, but often the regimen involves two or three repeated doses, separated by interval of 1 or 2 weeks (7).

Due to the extended use of this compound in humans, the knowledge of ivermectin pharmacokinetic behavior becomes essential. Nevertheless, little is known about the kinetics and interactions of ivermectin in humans compared to animals (even if the majority of fundamental work is veterinary, there is little evidence that such knowledge has helped to inform clinicians).

Thus, in this paper, we review the literature concerning the absorption, distribution, metabolism and excretion of ivermectin in man, as well as the interactions of the compound.

PHARMACOKINETICS

The oral route is the only approved for ivermectin administration in humans. The one-compartmental model (8, 9), as well as the two-compartmental model (10) have been used to describe ivermectin kinetic behavior after its oral administration. In the rest of the studies cited here,

FOI 26-3132 - Document 5

pharmacokinetic parameters were determined using a model-independent method.

Absorption

In healthy subjects that received 12 mg of ivermectin as oral solution, tablets or capsules, it was shown that the solution had approximately twice the systemic availability as either of the solid forms (tablets and capsules showed similar systemic availability; Table 1). The oral solution was given as an ethanolic solution. This may affect bioavailability and could explain why the solution resulted in a twice as high availability as tablets and capsules. Nevertheless, the rate of absorption was similar in the three cases (11).

In healthy and onchocerciasis volunteers treated with 150 μg/kg, no significant differences were found in the pharmacokinetic parameters calculated. After an initial decrease, both groups showed a tendency for a second rise in plasma levels (mostly occurring between 6 and 12 h after the dose) suggesting an enterohepatic recycling of the drug (12).

It was also investigated whether diminished ivermectin absorption could explain the fact that some severely infected onchocerciasis patients experience relatively few adverse effects following ivermectin treatment, although the occurrence and extent of adverse reactions have been related to infection intensity (17). According to this study, there was no observable relation between the plasma concentration after a single oral dose (150 μg/kg) and the occurrence of adverse reactions. Neither parasite load nor ivermectin concentrations had an influence on the occurrence of adverse reactions in the entire group of patients.

The ability to achieve adequate levels of ivermectin after oral administration in patients with disseminated strongyloidiasis may be impaired, highlighting the need for alternative routes of administration of ivermectin in these patients. Thus, ivermectin levels, in a patient with disseminated strongyloidiasis, were below the average of those reported by other authors following oral administration (1.1 $ng \cdot ml^{-1}$ after ingesting a total dosage of 1,000 μg/kg over 3 consecutive days). This was followed by the administration of three subcutaneous doses (200 μg/kg), injected every 2 days, increasing ivermectin levels to 7.9 $ng \cdot ml^{-1}$ at 1 week after the last dose, with evidence of additional metabolite accumulation and also a sustained antiparasitic effect. Thus, in these patients, who are unable to absorb oral medication, parenteral ivermectin (not licensed for use in humans) is a better option (18). In another report, a man with disseminated strongyloidiasis, severe hypoalbuminemia and paralytic ileus, received ivermectin by the oral route. Three hours after the third daily dose, the serum ivermectin concentration was only 0.8 $ng \cdot ml^{-1}$, but it increased to 5.8 $ng \cdot ml^{-1}$ 16 hours after the first subcutaneous dose. Over the next 15 days, subcutaneous ivermectin (200 μg/kg, once a day) produced serum ivermectin levels between 11.4 and 17.2 $ng \cdot ml^{-1}$ with no significant accumulation (19).

Distribution

Due to the high lipid solubility of ivermectin, this compound is widely distributed within the body.

In healthy men, the volume of distribution in the central compartment, V_c, was 3.1 and 3.5 $l \cdot kg^{-1}$, after ingesting 6 and 12 mg of ivermectin, respectively (8). In onchocerciasis patients, with 6 mg (tablet), the volume of distribution of the area (V_λ) was 9.9 $l \cdot kg^{-1}$ and the mean residence time (MRT) was 3.7 days (16).

The tissue distribution of ivermectin was similar in healthy and onchocerciasis volunteers treated orally. So,

Table 1. Pharmacokinetic Parameters Obtained after Ivermectin Oral Administration

		Absorption			Elimination	
Reference	Dose	C_{max} ($ng \cdot ml^{-1}$)	t_{max} (h)	$t_{1/2(abs)}$ (h)	$t_{1/2}$ (h)	Cl ($1\ kg^{-1} \cdot day^{-1}$)

[a] One-compartment model

FOI 26-3132 - Document 5

infection with *Onchocerca volvulus* does not appear to affect the distribution of this drug. The compound was present in fat, skin, subcutaneous fascia and nodules and in worm fragments. Fat showed the highest and most persistent levels, whilst values for skin, nodular tissues, and worms were comparable, being the lowest concentrations found in the subcutaneous fascia (12). In patients with *Onchocerca volvulus* infection treated orally with ivermectin (150 μg/kg), Elkassaby (15) also detected the drug in the nodular tissue of the parasite and in worm fragments. After subcutaneous administration (500 μg/kg) to cattle with nodules of *Onchocerca ochengi* (a cattle parasite that can be used as a model of *O. volvulus*), high concentrations were detected in the capsule wall and inside the nodule (55 and 45 $ng \cdot g^{-1}$ on day 2; 60 and 30 $ng \cdot g^{-1}$ on day 7). So, the poor penetration of ivermectin into the nodules could not explain the lack of efficacy against adult filariae (20).

In the skin, the peak concentration of the drug in squames, sebum and sweat on the forehead and the antithenar was 8 h after a 12 mg oral dose and decline quickly beyond 24 h (21).

Ivermectin binds strongly to plasma proteins in healthy subjects (93.2%) (22). It was also high in onchocerciasis patients (93.1%), with a specific binding for serum albumin. There were two binding sites, with an association constant of 2×10^8 mol^{-1} at the primary site. Such avid binding assumes great importance as the drug is administered in world areas where malnutrition and hypoalbuminemia are common, so in these patients a decrease in plasma proteins and, consequently, a higher free fraction of ivermectin could be expected. Nevertheless, acetylsalicylic acid does not interfere with ivermectin binding (16).

Ivermectin was not detected in the cerebrospinal fluid of a man with disseminated strongyloidiasis, severe hypoalbuminemia and paralytic ileus, after five subcutaneous doses of ivermectin, when the serum level was 12.1 $ng \cdot ml^{-1}$ (18).

Elimination

Studies regarding the *metabolism* of ivermectin in humans are scarce. This drug is extensively metabolized by human liver microsomes by cytochrome P450. The predominant isoform responsible for the biotransformation of this compound in the liver of humans is cytochrome P-4503A4, converting the drug to at least 10 metabolites, most of them hydroxylated and demethylated derivatives (23). In plasma, radioactive metabolites were reported after the oral administration of ivermectin to healthy volunteers (10).

Data concerning *excretion* can be observed on Table 1. No differences in the elimination half-life were detected among healthy and onchocerciasis subjects (12). It was also suggested that the kinetics of ivermectin (its elimination half-life is around a day) were somewhat disconnected from its pharmacodynamics (antiparasitic events persisting for several months after a single dose of the drug) (11).

A significant effect of gender was found in ivermectin pharmacokinetics in healthy volunteers orally treated with 150 μg/kg, with a lower total body Cl/F in males compared to females (see Table 1) (14).

In connection with the excretion pathways, ivermectin and its metabolites were excreted mainly in faeces and only 1% in urine. Positive identification was obtained for the presence of 3"-*O*-desmethyl-H_2B_{1a}, and 22,23-dihydroavermectin B_{1a} monosacharide in urine and faeces, respectively [10]. Other authors who tried to determine ivermectin in urine (8, 9, 16) did not find the parent drug nor its metabolites.

Finally, in the milk of healthy women administered 150 μg/kg, the maximum concentration (14.1 $ng \cdot ml^{-1}$) was reached in 6.5 h (13). On the basis of this information, a breast-fed child would receive an average dose of only 2.75 μg/kg via milk. Thus, these authors did not recommend excluding breastfeeding mothers from mass ivermectin therapies, as they only represent 5–10% of the population in the areas hyperendemic with onchocerciasis.

INTERACTIONS

Several authors evaluated the effect of ivermectin coadministration with different drugs employed to control helminthes. To interrupt the transmission of onchocerciasis in humans, the combination of ivermectin and doxycycline is highly effective as, in infested patients, the ingestion of the anthelmintic (200 μg/kg, single dose) and the antibacterial (100 mg/kg, daily for 6 weeks), kept the microfiladermia levels low more time than did ivermectin alone. Doxycycline enhanced ivermectin-induced suppression of microfiladermia, as it sterilize adult female worms for a few months by depletion of symbiotic endobacteria of filariae, *Wolbachia* spp. (24) (essential for their survival and reproduction). Other studies showed that, to control onchocerciasis, the combination of ivermectin with other drugs offers no advantage over ivermectin alone. Thus, in infected patients, the ingestion of ivermectin had no effect on the kinetics of an oral dose of albendazole and there was no additive effect of both drugs against the parasite compared to ivermectin given alone (25, 26, 27). Albendazole (400 mg) did not modify the kinetic behavior of a single oral ivermectin dose (12 mg) (27). Also in onchocerciasis patients, the antiparasitary efficacy was similar when administering a single ivermectin dose (150 μg/kg, on day 1) followed by amorcazine (3 mg/kg twice daily, on days 8, 9 and 10) than when administering ivermectin alone (28). Similarly, the combination of ivermectin (200 μg/kg) and levamisole (2.5 mg/kg) was neither macrofilaricidal nor more effective against the microfilariae and the adult worms than ivermectin alone, although levamisole increased ivermectin plasma bioavailability in these patients (29).

The efficacy of drugs available for the treatment of infection with *Trichuris trichiura* is low in humans. Nevertheless, single-dose treatment with albendazole (400 mg)-ivermectin (200 μg/kg) appears to be highly effective against trichuriasis, being higher than when administering albendazole alone or with diethylcarbamazine (6 mg/kg) (30).

Thus, ivermectin interactions with another concurrently administered drugs can occur. This issue becames important, as combination chemotherapy is being used with increasing frequency as resistance to antiparasitic agents is becoming more widespread.

Regarding bleeding disorders, haematomatous swellings were reported in 2 out of 28 onchocerciasis patients treated with ivermectin (150 μg/kg), and prothrombin times were significantly above baseline by one week to one month after

drug ingestion, suggesting an antagonist effect against vitamin K (31). Nevertheless, in other 20 subjects, no changes were observed in prothrombin nor in thromboplastin times compared with baseline results, during 13 days after the ingestion of 220–420 μg/kg of ivermectin (32); bleeding disorders were not found in 15,000 patients treated with ivermectin (150 μg/kg) (33). Moreover, prolonged prothrombin ratios were observed in 148 subjects given ivermectin orally. Although no patients suffered bleeding complications, factor II and VII levels were reduced in most of them, suggesting interference with vitamin K metabolism. Ivermectin has a minimal effect on coagulation and concern about mass treatment for this reason appears to be unjustified (34). Finally, a man that had been on long-term oral anticoagulant therapy with acenocoumarol showed a persistent, excessive hypocoagulability while using insecticides (ivermectin and metidation) without protection to treat trees. So, it is to be taken into account that these types of interactions can exist and could cause hemorrhagic complications (35).

Information about the influence of foods in the pharmacokinetics of ivermectin is scarce. The knowledge of the influence of alcohol in ivermectin kinetic behaviour is scarce; co-ingestion of alcoholic drinks however is not recommended, because of ivermectin association with GABA receptors and the effect of alcohol in the central nervous system. In healthy volunteers administered ivermectin orally (150 μg/kg), plasma levels were significantly higher when coadministered with 750 ml of beer than with 750 ml of water; the plasma concentrations were significantly higher in patients who drank beer (66.3, 109, and 97.2 ng/ml at 1, 3 and 4 h, respectively) *vs*. those who drank water (44.0, 67.5, and 58.7 ng/ml, respectively, $P<0.01$ at each time point) (36).

Finally, ivermectin (150 μg/kg) was administered to 16 individuals with water or orange juice (750 ml). Orange juice decreased AUC (15.7 $ng \cdot d \cdot ml^{-1}$) and C_{max} (20.7 $ng \cdot ml^{-1}$) (water: 33.8 $ng \cdot ml^{-1}$; 24.3 $ng \cdot d \cdot ml^{-1}$), possibly because fruit juices and constituents are potent inhibitors of certain drug transporters (14).

CONCLUSION

Although the efficacy of ivermectin has been established in humans against several parasite diseases, the pharmacokinetic properties of this compound are less well known in humans compared to animals. Potential drug-drug interactions and drug-food interactions exist for ivermectin, which should be considered during therapeutic use of this drug.

Hospital Preparedness for COVID-19: A Practical Guide from a Critical Care Perspective

Kelly M. Griffin[1], Maria G. Karas[2], Natalia S. Ivascu[3], and Lindsay Lief[1]

[1]Division of Pulmonary and Critical Care Medicine and [2]Division of Cardiology, Department of Medicine, and [3]Department of Anesthesiology, Weill Cornell Medicine, New York Presbyterian Hospital, New York, New York

Abstract

In response to the estimated potential impact of coronavirus disease (COVID-19) on New York City hospitals, our institution prepared for an influx of critically ill patients. Multiple areas of surge planning progressed, simultaneously focused on infection control, clinical operational challenges, ICU surge capacity, staffing, ethics, and maintenance of staff wellness. The protocols developed focused on clinical decisions regarding intubation, the use of high-flow oxygen, engagement with infectious disease consultants, and cardiac arrest. Mechanisms to increase bed capacity and increase efficiency in ICUs by outsourcing procedures were implemented. Novel uses of technology to minimize staff exposure to COVID-19 as well as to facilitate family engagement and end-of-life discussions were encouraged. Education and communication remained key in our attempts to standardize care, stay apprised on emerging data, and review seminal literature on respiratory failure. Challenges were encountered and overcome through interdisciplinary collaboration and iterative surge planning as ICU admissions rose. Support was provided for both clinical and nonclinical staff affected by the profound impact COVID-19 had on our city. We describe in granular detail the procedures and processes that were developed during a 1-month period while surge planning was ongoing and the need for ICU capacity rose exponentially. The approaches described here provide a potential roadmap for centers that must rapidly adapt to the tremendous challenge posed by this and potential future pandemics.

Keywords: pandemics; SARS virus; ICUs

As the novel coronavirus disease (COVID-19) pandemic emerged as a cause of profound respiratory failure in Wuhan, China (1, 2), healthcare facilities in the United States took notice. When the United States first reported cases in Washington state (3, 4) and epidemiologists estimated the potential impact on New York City hospitals, our institution (New York Presbyterian Hospital), like many other centers, prepared for an influx of critically ill patients. Excellent reviews of approaches to ICU preparedness in the setting of pandemics have been published, generally focusing on broad concepts of infection control, ways to increase staffing capacity, and community engagement (5). Similarly, others have highlighted the difficult issues involved in allocating scarce resources (6), particularly mechanical ventilators, in these challenging settings (7) (Table 1).

Given rapidly evolving data on the infectiousness of COVID-19 (8, 9), including virus transmission from asymptomatic or paucisymptomatic individuals (10, 11), the initial highest priorities included obtaining an adequate supply of personal protective equipment (PPE) (12) for the staff and evaluating and expanding ICU and ventilator capacity (13), among numerous other measures. As of this writing, there has been a rapid increase in the number of new cases, deaths, and healthcare use in New York State (Figure 1).

As the first patients arrived soon after planning began at our institution, surge plans for this pandemic were highly dynamic and iterative, requiring frequent updates and clear communication of changes. Here, we describe the procedures that were implemented over a 4-week time frame as patient admissions for COVID-19 increased exponentially. These approaches provide a potential roadmap for centers that must rapidly adapt to the tremendous challenges posed by a pandemic. We hope that even for medical centers with a much

Table 1. Solutions to Encountered Challenges

Challenge	Local Solution
Infection control	Define aerosolizing procedures; use guidelines to define appropriate PPE
Clinical challenges	
Decision to intubate	Evolving; determined by clinical judgment with no predefined criteria
Airway management	Intubation by RSI by most experienced operator; periintubation team to assist in gathering PPE and medications and to assist in transport
Engagement of infectious disease team	Universally consulted to assist with therapies and entry into clinical trials
Extracorporeal organ support	Patients evaluated by a multidisciplinary team on a case-by-case basis
Cardiac arrests	Policy limits the number of responders and promotes enhanced PPE
Standardization	Frequent conferences, daily e-mail updates, and shared files
Approaches to efficient use of time in the ICU	Create procedure team, proning team, and tracheostomy team; display results and patient data outside the room
Minimizing exposure	Bundle care, trial intravenous pumps, and ventilator monitors outside of the patient room
Education	Frequent, multidisciplinary conferences, and journal clubs
Communication with families	Daily calls to a patient surrogate; involvement of palliative care
ICU surge capacity	Increase COVID-19 capacity in multiple units simultaneously to expand expertise
Expansion to operating rooms	Multidisciplinary approach to understand differences between critical care ventilators and anesthesia machines
Efficient bed management	Appoint a clinical bed manager
Staffing	
Physician staffing	Create a model with ideal ratios of critical care physicians to ICU patients; use critical care experts from all backgrounds
Research faculty	Redeployed to clinical service if not doing COVID-19–specific research
Nursing and respiratory therapy	Rapid training in ICU skills; expedited recredentialing, education on newly introduced ventilators
Nonclinical staff	Acknowledge support from nonclinical staff
Ethical dilemmas	Use institutional ethics committees, with guidance from local laws, to approach each ethical decision
Staff wellness	Partner with mental health professionals for staff

Definition of abbreviations: COVID-19 = coronavirus disease; PPE = personal protective equipment; RSI = rapid sequence induction.

smaller footprint and lower surge capacity, some of the granular and practical advice provided here will aid others in rapidly adapting to this unprecedented challenge.

Background

Our campus of the greater New York Presbyterian system is jointly operated by physicians from Weill Cornell Medicine (medical college) and nurses, respiratory therapists, advanced practitioners, and nonclinical staff from New York Presbyterian Hospital. This campus is one of two quaternary centers within the hospital enterprise and receives transfers from smaller surrounding hospitals. We have six adult ICUs divided into subspecialties (medical, surgical, burn, cardiac, cardiothoracic, and neurosurgical), as well pediatric and neonatal ICUs and several step-down units.

Given previous recommendations (5, 6, 14), multiple categories were rapidly considered in preparation for a pandemic of massive scale, including infection control; clinical operational challenges; ICU bed surge capacity; adequate staffing of physicians, nurses, and respiratory therapists; complex ethical dilemmas; and staff wellness. Procedures to address these issues were created and implemented in collaboration with nursing, respiratory therapy, and hospital leadership.

Infection Control

Initial planning began in collaboration with hospital epidemiologists and infection control staff, and relied heavily on available information about the infectivity of COVID-19 (9, 15). These contributors, with guidance from the CDC (16), helped determine the appropriate PPE, define an "aerosol-generating procedure," and attempted to clarify and communicate the rapidly changing guidelines offered by the federal, state, and city governments. Importantly, hospital epidemiology personnel rapidly educated staff in COVID-19 units on the optimal format for donning and doffing PPE, and online videos and education materials were distributed hospitalwide.

Clinical Challenges

The Decision to Intubate

Given the initial impressions about the format for transmission of this novel coronavirus, the initial clinical approach was to avoid high-flow nasal cannula and noninvasive ventilation (9). When a patient who was under investigation or tested positive for COVID-19 experienced an oxygen saturation of ⩽88% on 6 L of oxygen via nasal cannula, intubation was recommended. Within 2 weeks, these

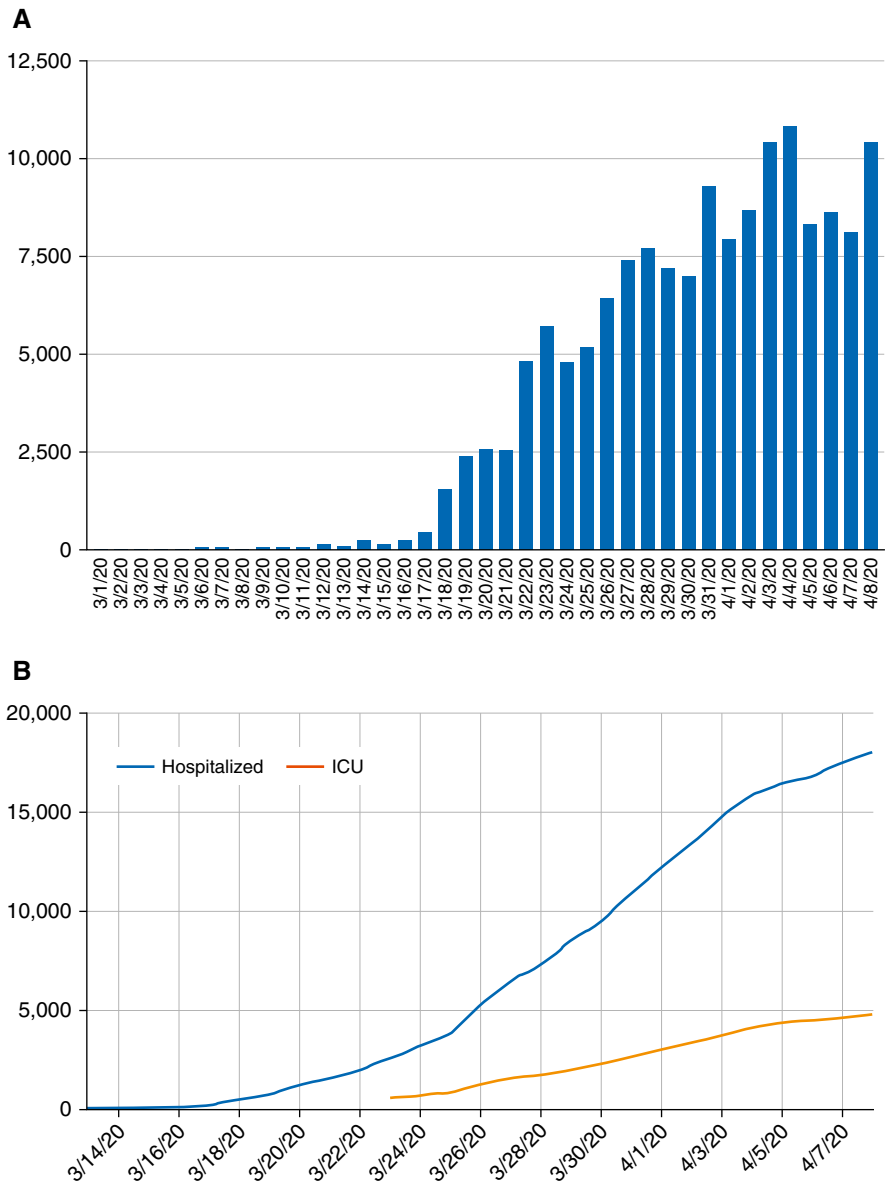

Figure 1. (*A*) New coronavirus disease (COVID-19) cases. (*B*) Total COVID-19 hospitalizations (blue) and ICU hospitalizations (orange) in New York State from March 14, 2020, to April 8, 2020. Reprinted by permission from Reference 34.

criteria were adapted to an oxygen saturation of <88% on 6 L of oxygen via nasal cannula in addition to a nonrebreather mask at 10 L of oxygen per minute. As the number of critically patients increased and international guidelines were refined, high-flow nasal cannula was increasingly used, preferably in a negative-pressure room (17), to possibly delay or avoid the need for intubation. The decision to intubate relies on the clinical judgment of the critical care physician and is based on factors such as hypoxemia, tachypnea, increased work of breathing, and gas exchange (18). These practices continue to develop as recommendations evolve.

Airway Management and the Intubation and Periintubation Teams

To maximize patient outcomes and minimize the risk to healthcare practitioners, a comprehensive airway policy was adapted from rapidly evolving international recommendations (19, 20). These procedures ensured that the most experienced operator would attempt intubation using rapid sequence induction (RSI) and a video laryngoscope. To enhance efficiency and optimize patient care, when a critical care physician identified a patient who required intubation, that physician notified the dedicated COVID-19 intubation team. Preparations included obtaining induction, sedation, and vasopressor medications; ensuring the use of appropriate PPE for this high-risk procedure (impervious gown, gloves, head covers, goggles or welder's mask, and optional shoe covers); and moving the patient to a negative-pressure room (with one reserved on each hospital floor) for intubation. The initial team included an anesthesiologist, a respiratory therapist, and a critical care nurse. The anesthesiologist intubated the patient using RSI and a video laryngoscope, and the multidisciplinary critical care team moved the patient to an ICU bed.

As the pace of hospital admissions and intubations accelerated, this process evolved. Two anesthesia airway teams were made available 24 hours a day, 7 days a week, dedicated to COVID-19 intubations. This team brought with them the appropriate PPE and a video laryngoscope. Hospital pharmacologists created virtual RSI kits, which could be rapidly accessed on every floor. Finally, a periintubation team led by certified registered nurse anesthetists assumed the role of coordinating periintubation procedures, including gathering medications and staff, and transporting patients to the negative-pressure room before intubation and to the ICU after intubation.

Engagement with Infectious Disease Consultants

Given the infectious nature of the disaster and the rapidly evolving therapeutic landscape, infectious disease consultants immediately established a dedicated COVID-19 team and pager. This team consults on every critically ill patient with COVID-19 daily to provide advice about available therapies (antiviral and antimicrobial) (21) and potential immunosuppressive approaches and innovative therapies (22, 23). Moreover, they serve as a gateway to rapidly evolving therapeutic trials (24).

Extracorporeal Organ Support

Institutional policies regarding extracorporeal membrane oxygenation are

FOI 26-3132 - Document 5

evolving with the publication of efficacy and risk data (25). Although extracorporeal membrane oxygenation has potential benefit in a subset of patients with COVID-19, the decision to cannulate must include the ability to provide appropriate staffing and resources, in addition to the usual criteria. Potential patients are discussed on a case-by-case basis by a multidisciplinary team. Renal replacement has been offered to all patients with acute or chronic renal failure via traditional hemodialysis, continuous venovenous hemodialysis, or peritoneal dialysis, with an awareness of the resources involved in each scenario.

Cardiac Arrests

Given the highly infective nature of the novel coronavirus, approaches to resuscitation have evolved (26, 27). As such, institutional cardiac arrest policies were instituted that limited the number of responders to cardiac arrests outside the ICU. Mechanical compression devices were rapidly introduced to further reduce the number of medical and nursing staff responding to an arrest. Medical ICU nurses, who respond to every cardiac arrest in our institution, carried a COVID-19 backpack to every cardiac arrest, which included high-risk PPE (welder-style face shields, N95 masks, and impermeable gowns) given the aerosolizing nature of cardiopulmonary resuscitation. Resuscitations in the ICU continue to be conducted in a standard fashion, with attempts to minimize aerosolization by leaving the patient on the ventilator or, if absolutely necessary, using a bag valve mask with a high-efficiency particulate air filter attached to the expiratory port.

Standardization of Care across All Critical Care Delivery Areas

Given the rapid expansion of ICU space and the broad number of caregivers involved in the care of critically ill patients with COVID-19, frequent formal and informal communication among all the groups has been essential. This is particularly important because some clinicians do not routinely care for patients with acute respiratory distress syndrome. Daily evaluation by a member of the pulmonary and critical care division is provided to all of the locations outside the medical ICU now caring for these patients. The development and distribution of informal guidelines outlining the granular aspects of caring for critically ill patients with COVID-19 have proved to be invaluable tools for providing standardized care in all areas. Secure electronic file sharing and daily e-mail updates give providers easy access to the latest hospital statistics and guidelines.

Approaches to Efficient Use of Time in the ICU

Dedicated smart phones with chargers are placed in each patient room so that staff members inside the room can contact additional staff outside the room without doffing their PPE.

A dedicated procedure team comprised of surgeons and interventional radiologists was created to perform ICU procedures such as central line, arterial line, or nasogastric tube insertion around the clock. This freed the intensivists to facilitate critical patient care. A multidisciplinary tracheostomy team led by thoracic surgery, otorhinolaryngology, and critical care specialists provides a similar focused approach to another pivotal aspect of critical care. A dedicated proning team was formed by specialists in critical care medicine and physical therapy to minimize the unit-specific staff needed for pronation or supination of patients while providing a standardized approach to this therapeutic maneuver (28). In an innovative adaptation, current drips, ventilator settings, and arterial blood gas results were written on the glass doors of the room so that staff could be informed without having to enter the room (Figure 2). This technique was made possible by the restriction of visitors to the hospital.

Minimizing Exposure to Staff

Care has been bundled as much as possible. Laboratory sampling was timed with medication dosing. Larger bags of intravenous fluid or more concentrated solutions were used to limit the number of times a nurse had to enter the room. Imaging studies and ECGs were limited to those deemed absolutely necessary. In some (but not all) rooms, intravenous pumps were placed outside the room with the use of extra intravenous tubing (Figure 2). Although this approach allows medications to be managed outside the room, its limitations include the length of time required for a bolus to travel to the patient. A buddy system including one staff member by the medication pumps became necessary to allow delivery of boluses or adjustments of medication to be made from outside the room while staff inside the room turned or cleaned the patient. The monitor for the most frequently used ventilators was detached and similarly kept outside the room (Figure 2). The advantages and drawbacks of this system mirror those of the intravenous pumps.

Education

Led by pulmonary and critical care physicians, a rapid simulation curriculum focused on pronation and COVID-19 cardiac arrests was instituted and provided for both day- and night-shift nurses in nonmedical ICUs. Our provider teams have been monitoring the rapidly evolving diagnostic and therapeutic approaches in the global arena to improve and optimize

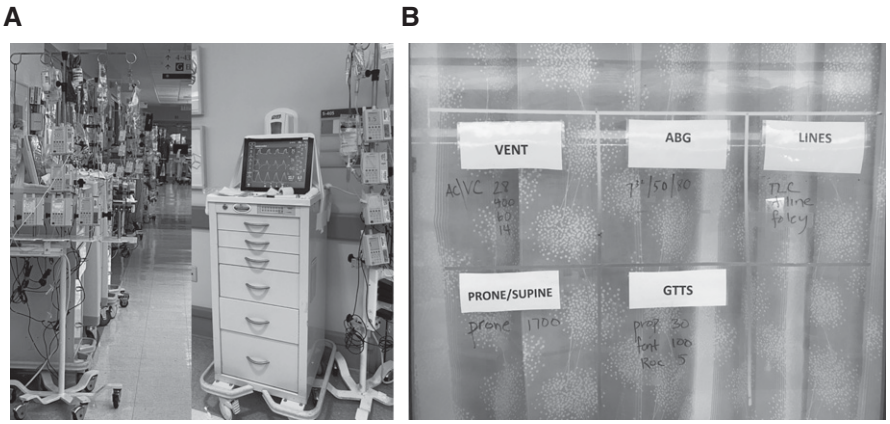

Figure 2. (*A*) Photos of ventilator screens and intravenous infusion pumps outside patient rooms. (*B*) Photo of patient data on the glass door of a patient's room. ABG = arterial blood gas; GTTS = guttae.

care on a local level. Remote-access conferences and journal clubs referencing seminal articles on acute respiratory distress syndrome continue to be conducted frequently. Topics have included fluid management, ventilator management, pronation, and sedation, among others. Recommendations from international colleagues are discussed in these multidisciplinary conferences.

Communicating with Families

The infectious nature of this pandemic has markedly impacted the ability of physicians and staff to communicate with patients' families, a key aspect of critical care. With limitations in visitation, family communication has become complex and fragmented. To address this aspect of patient care, a limited number of patient surrogates are designated to communicate with physicians. In addition, each family member is offered a second supportive call from a palliative care team member. The palliative care team discusses cases with each COVID-19 unit daily to assess for participating surrogates. In the setting of imminent death or immediately after death, a single family member in PPE is provided an opportunity to visit. If visitation is impossible, the staff can creatively use video conferencing to allow loved ones to visualize and speak to their dying family member.

ICU Surge Capacity

While creating ICU surge capacity, the first critically ill patients with COVID-19 were admitted to negative-pressure rooms divided among all of the ICUs. Initial surge plans were designed to accommodate an increased number of patients in the early stages (Figure 3), and later plans incorporated up to threefold higher numbers. Initially, for efficiency we designated half of the beds in multiple ICUs as COVID-19 units. This decision allowed units to acclimate to COVID-19 patients before the entire unit was filled, allowed staff members to perfect donning and doffing techniques, provided an opportunity to place pumps and ventilator monitors outside the room (Figure 2), and enabled multiple staff members to develop expertise in managing COVID-19. Having half of three separate ICUs simultaneously develop this expertise allowed a rapid doubling of ICU capacity.

Within 3 weeks of admitting our first critically ill patients with COVID-19, we had completely filled multiple ICUs. To respond to this challenge, less critical patients, when clinically feasible, were transferred to floor care, thereby freeing up the ICU beds. Subsequently, all critically ill patients without COVID-19 were grouped together in distinct or newly created ICUs. Elective surgeries were reduced to minimize surgical admissions and preserve PPE. As we entered the next phase of the surge plan, all cardiac patients without COVID-19 were grouped together in a new ICU. As units were opened and filled, additional units were rapidly identified. We began to care for patients with COVID-19 in operating rooms, with two ICU beds and two anesthesia machines per room. Similarly, step-down units and recovery rooms were rapidly converted to COVID-19 ICUs.

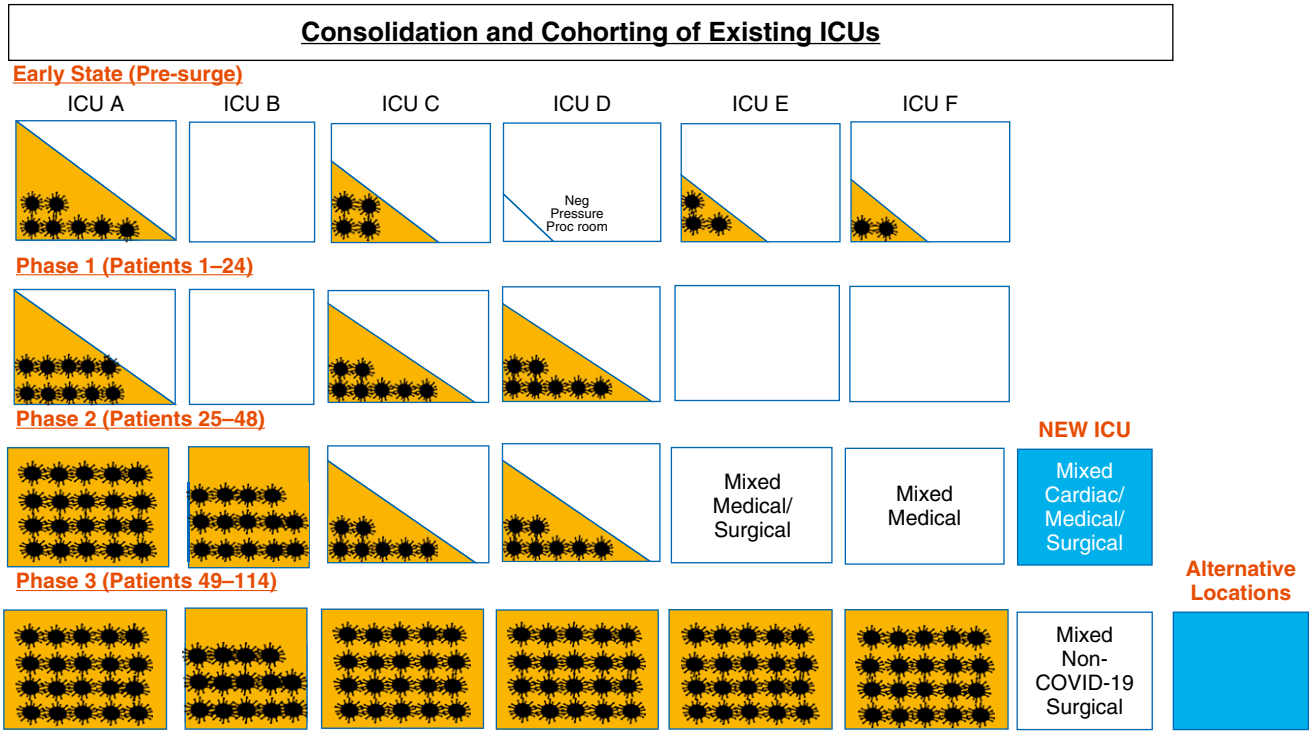

Figure 3. Each symbol denotes a patient with coronavirus disease (COVID-19). In the presurge period, patients were placed according to bed availability. Phase 1: unit readiness with partial COVID-19 census. Phase 2: start of ICU cohorting and creation of a new unit to displace patients without COVID-19 requiring specialty care. Phase 3: exhaustion of traditional ICU capacity. Patients who were not positive for COVID-19 were primarily postsurgical patients who were grouped together. Neg Pressure Proc room = negative pressure procedure room.

FOI 26-3132 - Document 5

Expanding to Operating Rooms

Expanding to operating rooms has created unique challenges, distinct from standard staffing and supply issues. Few caregivers outside of anesthesiologists and certified registered nurse anesthetists understand the intricacies of an anesthesia machine. The maximum flow rate of 15 L/min of fresh gas became important in patients with respiratory failure and a high $\dot{V}_E$ requirement. The proportion of fresh gas flow to recirculated air impacts the ultimate delivered $F_{I_{O_2}}$. Heat moisture exchangers may be added to the circuit but may not provide sufficient moisture to prevent desiccated secretions from occluding endotracheal tubes. Measuring airway pressures is challenging. In addition, providing nebulizers and checking inspiratory pauses on these machines requires breaking the circuit, which in general has been avoided in the interest of infection control.

Efficient Bed Management

Bed assignments and unit-to-unit transfers are typically managed by a centralized group of nurses in our patient placement operations center. This group also works in close collaboration with our transfer center, which organizes the incoming transfer of patients from other hospitals. During this time of rapid expansion, one of our critical care physicians partnered with these nurses around the clock, on a rotating basis, to triage all critically ill patients to streamline bed assignments and facilitate transfers into the newly created ICUs.

Staffing

Physician Staffing

ICU physician staffing has been rapidly expanded, and additional pulmonary and critical care physicians and critical care anesthesiologists have been redeployed to units with the goal of achieving a ratio of two senior physicians (with at least one being an intensivist) to 20 patients. The number of intensivists and critical care fellows in house each night rapidly increased fourfold with strong collaboration among the pulmonary and critical care, cardiology, neurointensive care, surgical critical care, and anesthesia teams. Twice-daily huddles occurred among all in-house leaders in critical care, including the airway team, to coordinate care and facilitate interdisciplinary teamwork. Additional hospitalist, trainee, and physician-extender teams were redeployed to provide patient care around the clock, as well as to provide medical expertise to nonmedical intensivists.

Research Faculty

All research activities at the medical college have been drastically curtailed to free up caregivers for clinical work. Ongoing research is limited to that which is focused on COVID-19. In addition, multiple clinical trials for possible therapeutic agents have been approved by the institutional review board and are enrolling patients.

Nursing and Respiratory Therapy Staffing

In phase 1 of the surge plan, medical and step-down nurses began training and shadowing in ICUs. Training fairs to teach ICU skills were held daily to help prepare nurses for caring for the critically ill. To facilitate staffing, nurses who previously worked at our institution were contacted and offered expedited recredentialing if they were willing and available. Respiratory therapists are an invaluable part of the care team for patients with respiratory failure. Given the pressures on the healthcare system, it has been challenging to rapidly and adequately increase the number of respiratory therapists. Critical care faculty and trainees have assisted in ventilator management. As the standard fleet of critical care ventilators became limited, transport ventilators were obtained and operationalized for ICU care. Because intensivists are less familiar with these devices, respiratory therapists created innovative approaches to rapidly educate clinicians in their use.

Nonclinical Staff

Members of the institutional facilities staff have played a key role in rapidly creating innovative barriers and negative-pressure rooms. The environmental services staff members became expert at donning and doffing PPE and clearing refuse at an accelerated rate in COVID-19 rooms owing to the increased PPE requirements. They devised impressive approaches to rapidly turn over rooms that are vitally required for aerosolizing procedures. It is evident that every staff member plays a key role in rapidly expanding ICU capacity and care in the setting of a highly infective agent in the setting of a pandemic. Within days of the first COVID-19 admission to our institution, our colleagues in laboratory medicine implemented in-house testing, allowing us to rapidly scale the number of patients we could test each day.

COVID-19 poses a potential infectious risk to all personnel in the hospital, and protection of staff has remained a top priority. Adequate PPE has been provided to all staff. In collaboration with the Division of Infection Control and Prevention, the hospital and medical college have ensured appropriate education on donning and doffing of PPE and precautions regarding aerosolizing procedures.

Ethical Dilemmas

The rapid and unprecedented growth in the number of critically ill patients (Figure 1) raised the specter of difficult ethical decisions. Several groups globally have provided general guidelines regarding resource allocation in the setting of a challenging pandemic (14, 29, 30). Given the increased negative outcomes in older individuals or those with multiple comorbid illnesses (31, 32), the need for discussions with palliative care and ethics consultants has become more acute. We used the New York State guidelines as a framework for these conversations (33). We have encouraged our colleagues in emergency medicine and hospital medicine to pursue early, honest conversations with patients and families regarding goals of care and clarifying advance directives. A program that provides access to palliative care and ethics consultants, 24 hours a day, has helped facilitate these conversations.

Staff Wellness

This challenging pandemic has created tremendous moral distress among healthcare personnel. We pride ourselves on the personalized care of our patients. One challenging aspect of care in this pandemic is the inability to provide care in the usual manner, which normally involves including patients' families as their support system throughout their illness. Staff members have facilitated emotional, life-altering conversations over video chats with family members and have watched families say

goodbye to each other without the benefit of privacy; the staff cannot leave the room while they hold the phone or tablet. Physicians and nurses work to balance being present and offering comfort while minimizing their personal exposure to COVID-19. In addition to this heartbreaking reality, we work while watching this pandemic take over our city. Staff fear for their own health and that of loved ones. Many providers have isolated themselves from their families, either by staying in hotels or by sending their families away. Some have created or updated wills and advance directives. For all of these reasons and because of sheer exhaustion, we have seen our staff become overwhelmed with emotions ranging from anxiety to helplessness. To deal with these challenges, it has been vital to engage mental healthcare providers with expertise in the management of trauma and acute stress to offer individual and group support to our staff. Referrals have been made as needed for psychological support, and staff members have been given 24-hour direct access to a mental health professional.

Conclusions

As New York City has become the current global epicenter of the COVID-19 pandemic, our institution has creatively expanded our caregiving capabilities in multiple ways. This outline provides an understanding of how we, in collaboration with and appreciation of our colleagues in the departments and divisions of pulmonary and critical care, anesthesiology, cardiology, neurocritical care, surgical critical care, hospital medicine, infectious diseases, palliative care, ethics, nursing, physical therapy, and respiratory therapy, are meeting this challenge. We provide potential guidelines for other centers to adapt as needed to help further streamline this expansion. ■

Author disclosures are available with the text of this article at www.atsjournals.org.

Acknowledgment: The authors thank Dr. Kate Heilpern for her tremendous support and leadership during this challenging period. They also thank their partner physicians in pulmonary and critical care, cardiology, anesthesiology, surgery, neurology, infectious diseases, and hospital medicine, and the medicine trainees, physician assistants, and nurse practitioners who have worked tirelessly for their patients. They acknowledge the nurses, respiratory therapists, physical and occupational therapists, chaplains, aides, and other front-line staff for their dedication to patient care. The authors could not have accomplished this work without the aid of their colleagues in environmental services, facilities, patient transport, and procurement, among countless others.

Submitted 11 February 2010; accepted in final form 27 June 2010

Griffin MO, Fricovsky E, Ceballos G, Villarreal F. Tetracyclines: a pleitropic family of compounds with promising therapeutic properties. Review of the literature. *Am J Physiol Cell Physiol* 299: C539–C548, 2010. First published June 30, 2010; doi:10.1152/ajpcell.00047.2010.—There must be something unique about a class of drugs (discovered and developed in the mid-1940s) where there are more than 130 ongoing clinical trials currently listed. Tetracyclines were developed as a result of the screening of soil samples for antibiotic organisms. The first of these compounds chlortetracycline was introduced in 1948. Soon after their development tetracyclines were found to be highly effective against various pathogens including rickettsiae, Gram-positive, and Gram-negative bacteria, thus, becoming a class of broad-spectrum antibiotics. The mechanism of action of tetracyclines is thought to be related to the inhibition of protein synthesis by binding to the 30S bacterial ribosome. Tetracyclines are also an effective anti-malarial drug. Over time, many other "protective" actions have been described for tetracyclines. Minocycline, which can readily cross cell membranes, is known to be a potent anti-apoptotic agent. Its mechanism of action appears to relate to specific effects exerted on apoptosis signaling pathways. Another tetracycline, doxycycline is known to exert antiprotease activities. Doxycycline can inhibit matrix metalloproteinases, which contribute to tissue destruction activities in diseases such as gingivitis. A large body of literature has provided additional evidence for the "beneficial" actions of tetracyclines, including their ability to act as oxygen radical scavengers and anti-inflammatory agents. This increasing volume of published work and ongoing clinical trials supports the notion that a more systematic examination of their possible therapeutic uses is warranted. This review provides a summary of tetracycline's multiple mechanisms of action and while using the effects on the heart as an example, this review also notes their potential to benefit patients suffering from various pathologies such as cancer, Rosacea, and Parkinson's disease.

protease inhibitors; doxycycline; minocycline

Classical Uses of Tetracyclines

THE TETRACYCLINES are an aging family of broad-spectrum antibiotics. The parent compound chlortetracycline (tradename Aureomycin) was first isolated from *Streptomyces aureofaciens* in 1947 (21). Soon after, other natural tetracyclines were isolated, including tetracycline, for which the family of molecules is named. Since then, the modifications of naturally occurring tetracyclines and the synthesis of novel compounds within the tetracycline family have generated many compounds. Two of the more common semisynthetic tetracyclines used clinically as antibiotics are doxycycline (DOX) and minocycline (MIN), which are essentially well-tolerated and safe compounds. Because of its broad-spectrum antibiotic efficacy, DOX is indicated for the treatment of a variety of infections, including anthrax, chlamydial infections, community-acquired pneumonia, Lyme disease, cholera, syphilis, *Yersinia pestis* (plague), periodontal infections, and others. MIN also displays broad-spectrum efficacy and is most often used clinically in the treatment of severe acne, but it is also indicated for many of the same infections as DOX (50).

The tetracyclines exert their antibiotic effect primarily by binding to the bacterial ribosome and halting protein synthesis (39). Bacterial ribosomes have a high-affinity binding site located on the 30S subunit and multiple low-affinity sites on both the 30S and 50S subunits (89). Upon binding the ribosome, the tetracyclines allosterically inhibit binding of the amino acyl-tRNA at the acceptor site (A-site), and protein synthesis ceases (76). However, the use of tetracyclines has declined in recent decades due to the emergence of resistant strains of bacteria (Fig. 1). The primary mechanism of resistance is mediated by increased drug efflux out of the cell by a family of Tet proteins located on the cytoplasmic surface of the cell membrane (55, 97). Whereas an understanding of the mechanisms of bacterial resistance (42) to the tetracyclines is important clinically, it also has led to the development of the

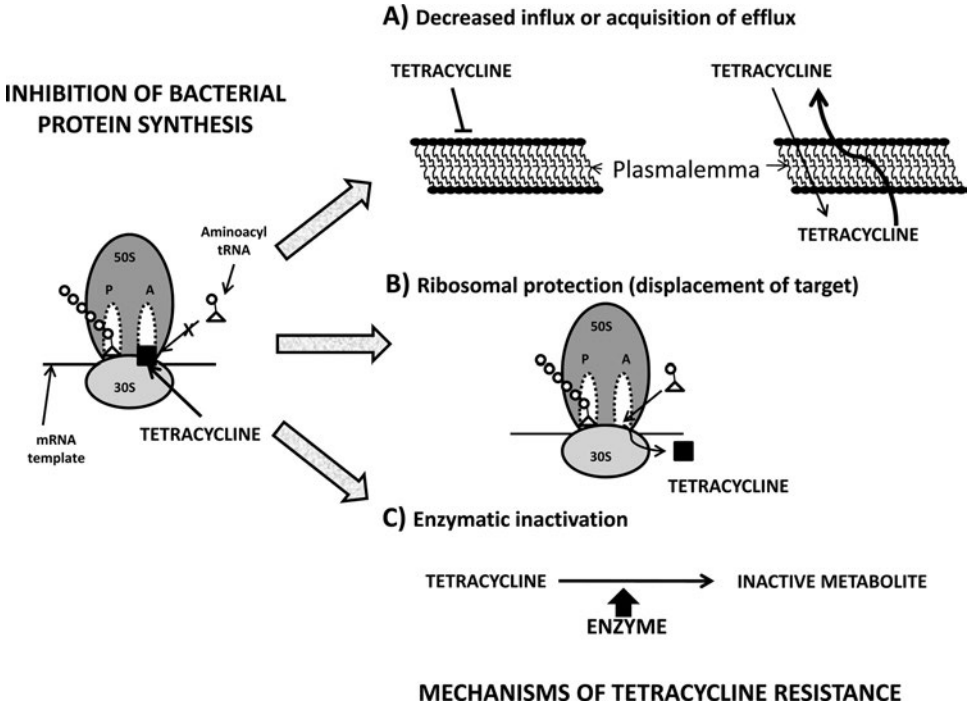

Fig. 1. Illustration of the means by which tetracyclines may lose their protein synthesis inhibitory capacity in pathogens such as bacteria. This may occur secondary to the enhanced extrusion of the drug, decreased entry, displacement from the target (ribosomes), or enzymatic inactivation.

Tet regulatory system, an important transcriptional regulation tool that is used extensively for targeted gene regulation in eukaryotes (35).

Tetracyclines are also effective but slow-acting anti-malarial drugs. DOX-treated parasites appear morphologically normal until late in the second cycle of treatment but fail to develop into merozoites (15). DOX specifically impairs the expression of apicoplast genes. Apicoplast (nonphotosynthetic major organelles found in cells of plants) are abnormal in the progeny of DOX-treated parasites. The loss of apicoplast function in the progeny of treated parasites leads to a slow but potent anti-malarial effect.

Chemical Properties

While the complex chemistry of the tetracyclines is beyond the scope of this review, a basic understanding of the important features of these compounds is necessary to appreciate their ability to interact with such a wide variety of biomolecules. Tetracycline, DOX, and MIN are all composed of a four-ring core to which are attached various side groups (Fig. 2). The dimethylamino group at the C4 carbon on the upper half of the molecule has been shown to be necessary for antimicrobial activity. 4-De-dimethylamino tetracyclines, also called chemically modified tetracyclines (CMTs), lack antimicrobial activ-

ity in vivo presumably due to the inability of the molecule to adapt a zwitterionic form necessary for activity (56). However, CMTs do retain the ability to bind other nonmicrobial targets, such as matrix metalloproteinases (MMPs), facilitating their use in the treatment of other disease processes (32). The oxygen-rich lower half of the molecule is critical for binding to both prokaryotic and eukaryotic targets, and interference with this region reduces or eliminates the effectiveness of the drug (33). This region is relevant as site for metal ion chelation. Binding of tetracyclines to proteins, including TetR, may be greatly enhanced when the tetracycline is complexed with divalent metal ions such as Ca^{2+} or Mg^{2+} (86). The binding of tetracyclines to MMPs is thought to be mediated by the chelation of structural and catalytic Zn^{2+} ions within the enzyme (Fig. 3) (33, 70). In addition, binding to the bacterial ribosome involves binding to RNA-bound Mg^{2+} (29). The strength of tetracycline-metal interaction is dependent on both the tetracycline and the metal ion present. In general, the affinity of the tetracyclines for different divalent metals is in order of decreasing affinity: $Cu^{2+} > Co^{2+} = Fe^{2+} > Zn^{2+} > Mn^{2+} > Mg^{2+} > Ca^{2+}$ (61). The relative affinities of different tetracyclines for a given metal also differ and are highly dependent on pH and the presence of other metal ions (4, 6, 53). The relative superiority of DOX as an MMP inhibitor is due to its increased affinity for Zn^{2+} compared with tetracycline or MIN (7). In general, there is a direct relationship between lipophilicity and activity against Gram-positive bacteria. The lipophilicity of tetracycline, DOX, and MIN, as determined by partitioning between octanol and aqueous buffer, has been determined to be 0.025, 0.600, and 1.1, respectively (11), and the minimum inhibitory concentration against *Staphylococcus aureus* is 0.21, 0.19, and 0.10 μg/ml, respectively (5). Lipophilicity also affects tissue distribution. MIN is able to cross the blood-brain barrier much more readily than DOX or tetracycline. MIN attains levels in the brain nearly threefold higher than DOX, and tetracycline is undetectable in the brain (3).

Matrix Metalloproteinase Inhibition by Tetracyclines

Probably the best characterized non-antimicrobial property of the tetracyclines is their ability to inhibit members of the MMP family of endopeptidases. The MMPs are a family of zinc-dependent proteases that are involved in many physiological and pathophysiological processes including embryogenesis, tissue remodeling, inflammation, and tumor invasion (58). MMPs can be subdivided based on crude substrate specificities into the collagenases, gelatinases, stromelysins, and membrane-type MMPs (MT-MMPs) (82). The collagenase group includes MMP-1, MMP-8, and MMP-13, and all cleave fibrillar collagens (types I and III). Collagen fragments subsequently denature into gelatins. The gelatinases, which include MMP-2 and MMP-9, proteolyze the gelatins. The gelatinases also degrade basement membrane collagen (type IV). The stromelysins includes MMP-3, MMP-7, MMP-10, and MMP-11, and they are capable of degrading proteoglycans, laminin, fibronectin, collagen IV, and others. The cell membrane-anchored MT-MMP include six different MMP, of which MT1-MMP is the best characterized (19).

Inhibition of MMPs is beneficial in many pathological conditions in which MMP-mediated proteolysis of the extracellular matrix (ECM) contributes to the pathogenesis, such as heart remodeling, tumor invasion, and inflammation (58, 64, 67). Numerous synthetic compounds with potent and specific in

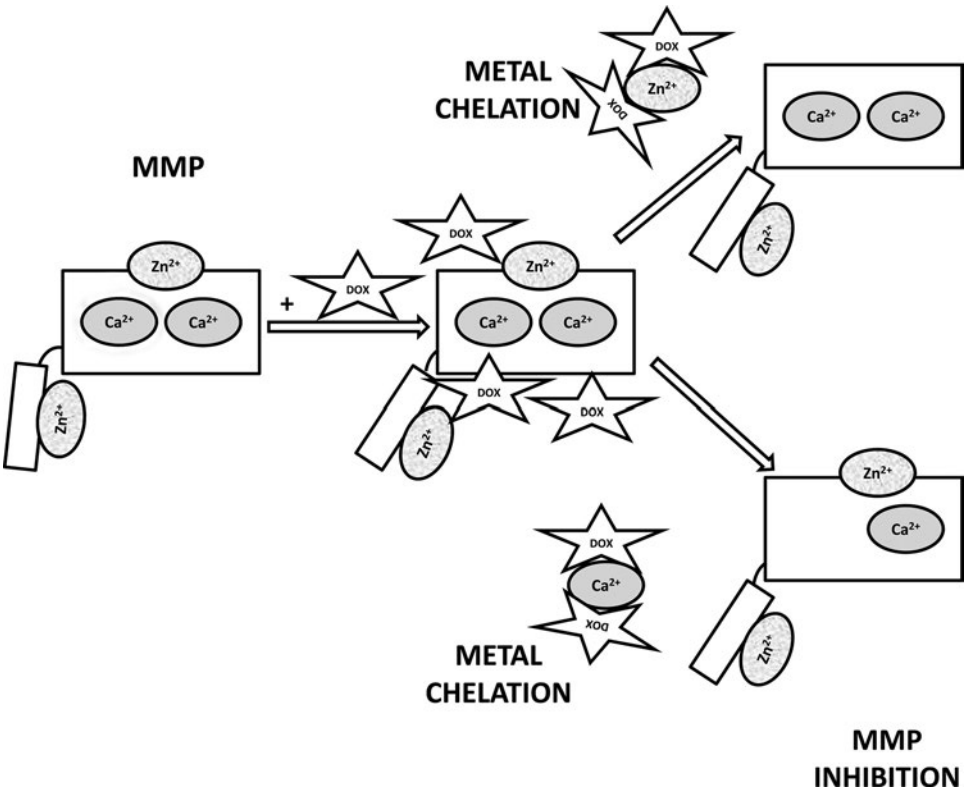

Fig. 3. Illustration of the means by which doxycycline through zinc and calcium chelation may act to inhibit matrix metalloproteinases (MMPs). Both ions are crucial to allow for enzyme activity.

vitro MMP inhibitory activities were developed, and many have entered clinical trials (64). However, because of the lack of efficacy and serious musculoskeletal side effects, none progressed to phase III clinical trials. Currently, the only clinically available MMP inhibitor is DOX, which is marketed as Periostat, and it is indicated only for the treatment of periodontitis (64). Following the seminal experiment by Golub et al. (31) showing that MIN inhibited collagenase derived from rat gingiva, tetracyclines became increasingly studied for their ability to inhibit MMPs.

The mechanism by which tetracyclines inhibit MMPs has not been completely elucidated. It is believed that they exert their anti-proteolytic effects by both direct inhibition of MMPs and by inhibiting their expression. Direct inhibition of MMPs appears to be mediated by an interaction between the tetracycline molecule and metal ions within the MMP. MMP inhibition can be reversed by the addition of millimolar amounts of Ca^{2+} (30) or micromolar amounts of Zn^{2+} (100). Interestingly, it appears that the mechanism of inhibition is dependent on chelation of structural metals rather than chelation of the active site Zn^{2+} (78). In addition, it was recently shown that DOX binds to MMP-7 near the structural Zn^{2+} and Ca^{2+} ions and does not bind to the catalytic Zn^{2+} (28) (Fig. 3). The effectiveness of tetracycline inhibition against various MMPs depends on the tetracycline species, MMP species, and the pH. It has been shown that DOX is more potent than MIN or tetracycline against collagenases purified from rabbit corneas, with IC_{50} values of 15 μM, 190 μM, and 350 μM, respectively, and this trend may be explained by the relatively high affinity of DOX and low affinity of tetracycline for Zn^{2+} (7). The IC_{50} values for DOX against the collagenases MMP-8, MMP-13, and MMP-1 is 1–10 μM, 5–30 μM, and >200 μM, respectively (36, 34, 79); the reasons for the differences in inhibition of the various MMPs are not clear. The pH of the system also affects inhibition as evidenced by the ability of DOX to inhibit MMP-8 at pH > 7.1 and inability to inhibit at pH < 7.1 (77). In addition to inhibiting MMPs directly, tetracyclines also inhibit MMP synthesis. DOX inhibited cytokine-induced MMP-8 mRNA and protein accumulation in cultured rat synovial fibroblasts (41). In cultured human skin fibroblasts, tetracycline inhibited interleukin-1 (IL-1)-induced MMP-3 expression (48). Since MMP transcription is induced by a host of proinflammatory cytokines and other growth factors, including IL-1, IL-6, tumor necrosis factor-α (TNF-α), epidermal growth factor, and others (13), it is likely that these upstream signaling cascades leading to MMP expression are important targets of tetracyclines. An interesting consequence of MMP inhibition is the indirect inhibition of serine proteases. MMPs can inactivate serine protease inhibitors (SERPINs) (17, 57), and MMP inhibition with DOX or CMTs preserves SERPINs thereby blocking serine protease activity (14, 30, 37, 80, 81).

MMP activity is upregulated early following a myocardial infarction (MI), suggesting an important role in mediating the acute injury and healing processes of the heart, including inflammation, angiogenesis, scar formation, and remodeling. However, early MMP activity may be a double-edged sword, leading also to early damage of the cardiac ECM. MMP activity increases within minutes of ischemia, reflecting activation of preformed latent MMPs within the myocardium (16, 23, 68). The simultaneous appearance of type I collagen fragments in serum indicates that this early MMP activity contributes to significant collagen proteolysis (90). This early damage may set the stage for long-term adverse remodeling. In addition to their role in mediating post-MI healing and remodeling, there is emerging evidence that the MMPs may actually contribute to myocyte death and dysfunction following ischemia-reperfusion (I-R) injury. MMP-2 activity is increased in isolated, perfused rat hearts following I-R, and treatment with DOX attenuated the increase in MMP-2 activity upon reperfusion and improved the recovery of contractile function (10). MMP-2 activation following I-R resulted also in proteolysis of troponin I and myosin light chain, and DOX prevented their proteolysis (74, 94). It is possible that MMP-mediated disruption of the normal myocyte-matrix architecture leads to myocyte cell death, since disruption of normal cell-ECM interactions has been shown to contribute to the induction of myocyte apoptosis both in vitro (71) and in vivo (18). These studies demonstrate that inhibition of MMP activity holds promise for salvaging myocytes and preserving cardiac structure and function post-MI. However, for pharmacological MMP inhibition to be beneficial, the timing of MMP inhibition will likely be important. For example, early short-term MMP inhibition post-MI (<48 h) may block the early damage to the ECM while still allowing later events (>48 h), such as inflammation and wound healing, to proceed normally. Indeed, significant anti-remodeling (i.e., beneficial) effects can be observed in the infarcted heart when DOX is given for a limited period of time after injury (27).

Reactive Oxygen Species Scavenging by Tetracyclines

Another well-characterized nonantimicrobial property of the tetracyclines is their ability to scavenge reactive oxygen species (ROS). Excess ROS are produced under many pathological conditions, including myocardial I-R injury and inflammatory processes, and can lead to the oxidative destruction or dysfunction of many cellular constituents. ROS are highly reactive and include the free radicals superoxide ($O_2^{\cdot -}$) and hydroxyl radical ($OH^{\bullet}$), the non-free radicals hydrogen peroxide (H_2O_2), hypochloride (HOCl), and peroxynitrite ($ONOO^-$) (62). DOX, MIN, and tetracycline all have a multiple-substituted phenol ring, similar to vitamin E. The phenol ring is key to the ROS-scavenging abilities of these compounds. The reaction of the phenol ring with a free radical generates a phenolic radical that becomes relatively stable and unreactive due to resonance stabilization and steric hindrance by the phenol ring side groups (52). MIN directly scavenge ROS in several cell-free mixed-radical assays with a potency comparable to vitamin E, and its scavenging ability was not dependent on chelation of Fe^{2+} (i.e., inhibition of the Fenton reaction) (52). Depending on the assay used, MIN had an IC_{50} of 3–40 μM and is 9–250 times more potent as scavenger than that of DOX and 200–300 times more potent than of tetracycline. The superior scavenging ability of MIN is likely due to the presence of the diethyamino group on the phenolic carbon (Fig. 4), which is unique to MIN and provides improved steric hindrance (52). Other groups have shown DOX to be an effective ROS scavenger. DOX inhibits both HOCl and a mixture of neutrophil-derived ROS in vitro, with an IC_{50} of ~2 μM (43). In addition, DOX inhibits HOCl-mediated activation of MMP-1 from osteosarcoma cells, with an IC_{50} of ~50 μM (66).

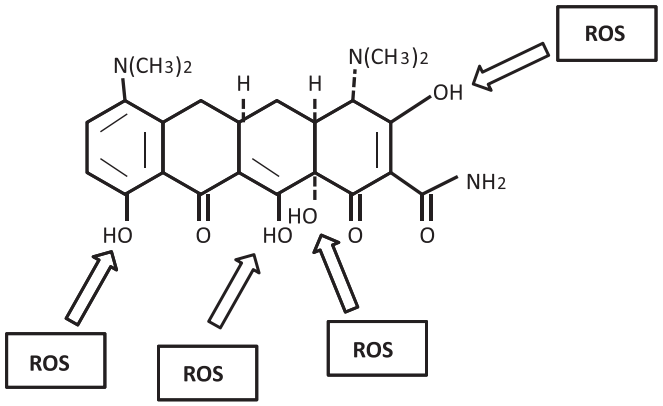

Fig. 4. Illustration highlights minocycline hydroxyl radicals that may react with reactive oxygen species (ROC) thus yielding antioxidant activity.

The generation of ROS upon reperfusion of ischemic myocardium is thought to be one of the primary mediators of reperfusion injury. It has also been shown that administration of exogenous SOD (9, 93, 99) and/or catalase reduces the extent of I-R injury in canine (1, 47) and porcine (60) models. The addition of $ONOO^-$ (which degrades to NO_2 and $OH^\bullet$) to isolated adult cardiac myocytes caused impaired calcium homeostasis and contractile dysfunction (54). DOX treatment normalized calcium transients and reduced the decline in contraction induced by $ONOO^-$.

Anti-Apoptotic Effects of Tetracyclines

A key event in the execution of the apoptotic cascade is the activation of caspases, a family of cysteine proteases. Caspases can be divided into upstream "initiator" caspases, which function to activate downstream caspases, and the downstream "executioner" caspases that are responsible for the proteolytic destruction of the cell (25). Caspases may be activated by either the extrinsic (death receptor) pathway or the intrinsic (mitochondrial) pathway. In the extrinsic pathway (88), death signal proteins such as TNF-α and Fas ligand bind to their cell surface receptors and, through signal transduction cascades, lead to the activation of an initiator caspase caspase-8. Caspase-8 in turn activates downstream caspases, such as caspase-3. In the intrinsic pathway (72), a variety of extracellular and intracellular stress stimuli converge on the mitochondria to destabilize it and cause the release of pro-apoptotic factors into the cytosol. A key factor mediating mitochondrial destabilization is opening of the mitochondrial permeability transition pore (mPTP), a large, high-conductance pore that spans both the inner and outer mitochondrial membranes (40). Once the mPTP opens, there is an influx of water, which leads to swelling of the mitochondrial matrix and eventually rupture of the outer mitochondrial membrane. Cytochrome c and other pro-apoptotic proteins, such as Smac/DIABLO [mitochondria-derived activator of caspases/direct inhibitor of apoptosis protein (IAP) binding protein with low PI]and apoptosis-inducing factor (AIF) are released from the intermembrane space into the cytosol. Cytochrome c binds the cytosolic adapter protein Apaf-1, which allows the recruitment and activation of an initiator caspase caspase-9, which then activates downstream caspases (46). Smac/DIABLO binds and inhibits caspase inhibitor proteins thereby disinhibiting caspase activity (59). AIF translocates to the nucleus and induces chromatin condensation and DNA fragmentation in a caspase-independent manner (85). The mitochondrial apoptosis pathway is also partly regulated by the Bcl-2 family of proteins (12). Bcl-2 family members may be pro-apoptotic (Bax, Bad, Bid) or anti-apoptotic (Bcl-2, Bcl-xL).

There is an increasing body of evidence suggesting that the tetracyclines possess anti-apoptotic properties (Fig. 5). In a seminal study by Yrjanheikki et al. (101), it was found that MIN and DOX increased the survival of hippocampal neurons following global brain ischemia in gerbils, and this protection was associated with reduced caspase-1 expression. MIN was subsequently evaluated in several other models of neuronal injury and found to also be protective against Huntington's disease (8), traumatic brain injury (73), and Parkinson's disease (20). In each of these cases, the neuroprotection by MIN was associated with a reduction in caspase-1 and/or caspase-3 expression, suggesting MIN was protective by inhibiting the expression of key factors within the apoptotic cascade. In addition to inhibiting caspase expression, MIN has also been shown to inhibit caspase activity by blocking activation. Zhu et al. (103) demonstrated that MIN inhibits cytochrome c release and caspase-3 activation in mice with amyotrophic lateral sclerosis. Using isolated mitochondria, Zhu and colleagues also showed that MIN inhibited Ca^{2+}, and Bid induced mitochondrial swelling and cytochrome c release, indicating that the mitochondria, and perhaps the mPTP, were direct targets of MIN (103).In a follow-up study, the same group showed that MIN inhibited mitochondrial release of cytochrome c, Smac/DIABLO, and AIF in both a culture model and an in vivo mouse model of Huntington's disease, indicating MIN inhibits both caspase-dependent (cytochrome c and Smac/DIABLO) and caspase-independent AIF mitochondrial death pathways (95). MIN also protected cultured renal epithelial cells from I-R injury and inhibited mitochondrial cytochrome c release (92). Interestingly, this group found that protection by MIN was dependent on MIN-induced upregulation of Bcl-2, as antisense-mediated downregulation of Bcl-2 abolished the protective effects of MIN. Taken together, these studies demonstrate that MIN, and possibly also DOX, possess anti-apoptotic effects mediated by inhibition of caspase expression and by mitochondrial stabilization.

MIN has been shown to also improve myocyte survival and reduce infarct size, and this was correlated with reduced caspase expression and reduced mitochondrial release of cytochrome c and Smac/DIABLO (75). These studies demonstrate that blocking apoptosis by directly inhibiting factors within the apoptotic cascade can salvage myocytes and reduce infarct size. MIN has been shown to effectively block apoptosis in models of neuronal injury, and there is at least preliminary evidence that MIN can reduce infarct size by blocking apoptosis in the heart. Additional studies are needed to clarify this potentially important role of tetracyclines in the heart.

Anti-Inflammatory Effects of Tetracyclines

A class of compounds that can act as anti-proteolytic and ROS scavenger is likely to exert anti-inflammatory actions. It is well accepted in the dermatology field that rosacea is a disease of inflammatory nature (51). DOX are successfully used in the treatment of skin conditions such as acne and

Downloaded from journals.physiology.org/journal/ajpcell (059.100.186.202) on September 7, 2022.

FOI 26-3132 - Document 5

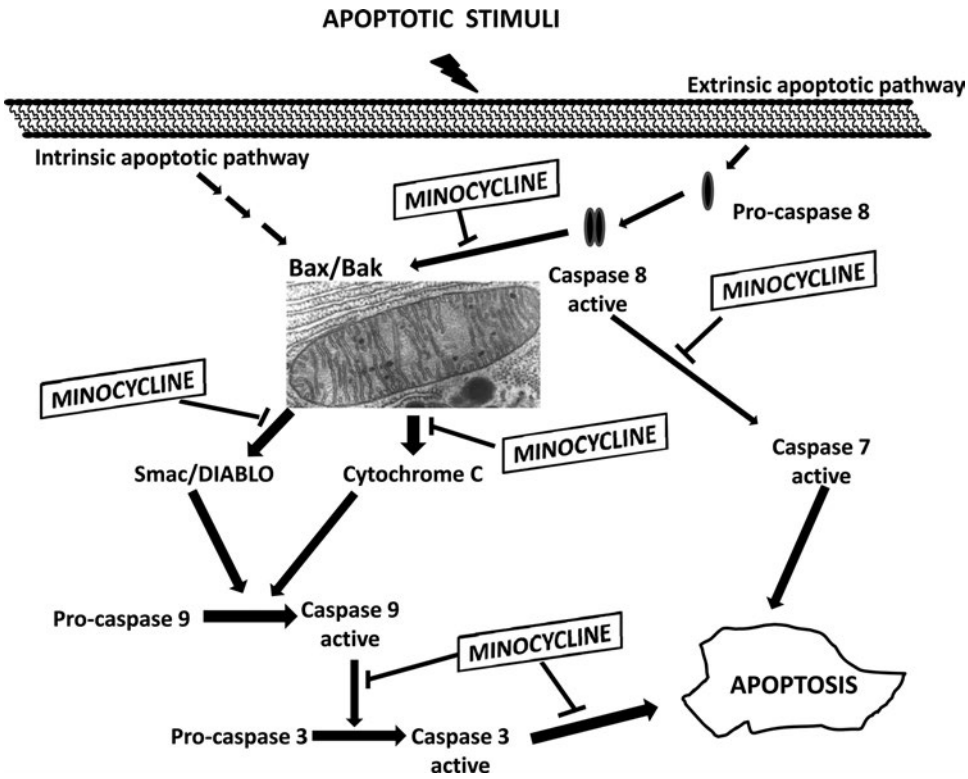

Fig. 5. Summarization of possible sites of action of minocycline on suppressing apoptotic signals in cells.

rosacea. Biopsies of inflammatory lesions of patients with acne yield increases in proinflammatory cytokines TNF-α and IL-1β (63). These cytokines are known inducers of increases in MMP levels and of their activity. ROS and nitric oxide (NO) have also been described as playing a role in the pathophysiology of rosacea (49). NO likely mediates increases in vessel permeability and edema and may support erythema development that occurs with rosacea. The beneficial effects of TTCs are likely associated with their aggregate "beneficial" actions including inhibiting proinflammatory cytokine levels, MMPs, and ROS. However, other actions add to their anti-inflammatory profile. MIN and to a lesser extent DOX can inhibit both pancreatic and nonpancreatic phospolipase A2 (65). This enzyme plays important roles in joint inflammation with a less clear participation in rosacea. The migration of white blood cells is critical for inflammation to occur. TTCs can inhibit neutrophil migration (22), adherence (26), and the proliferation of lymphocytes (87). Granuloma formation is a salient feature of many inflammatory diseases including rosacea. TTCs have been shown to inhibit granuloma formation of blood mononuclear cells in in vitro systems (996). Thus the cumulus of these features aggregates into the anti-inflammatory profile of TTCs.

Tetracycline Uptake by Tissues and Cells

Tetracyclines have been reported to concentrate at the site of tissue injury. In the 1970s investigators using radiolabeled tetracycline noted its capacity to accumulate in damaged myocardium and serve to diagnose infarcts (44, 45). Results demonstrated a correlation between infarct size, as determined by radiolabeled tetracycline, and serum creatine kinase. The ability of tetracycline to concentrate in other tissues is well known (2). Dentists take advantage of the high concentration of DOX (Periostat) in saliva as a means to treat gingivitis. To investigate tetracycline accumulation in gingival tissue, Yang et al. (98) examined the capacity of gingival fibroblasts to uptake the compounds. Gingival fibroblasts transport MIN in a concentration- and temperature-dependent manner. At steady state, the cellular/extracellular concentration ratio was >60 for MIN. The uptake of tetracyclines also has been observed in neutrophils and may partly explain high levels observed in injured tissues (91). Romero-Perez et al. (69) explored the capacity of MIN to accumulate in myocardial tissue and cells. MIN accumulated in myocardium severalfold greater than plasma levels. Accumulation was more pronounced in ischemic than normal myocardium. Cardiac fibroblasts and myocytes possess a comparable uptake system to that reported for gingival cells (98). Their intracellular concentration could in theory reach millimolar levels. At these concentrations mass action effects are likely seen where the drugs may at the same time exert potent antioxidant, anti-MMP, and other effects that in balance ultimately translate into cytoprotective effects.

Other Potential Uses of Tetracyclines

The pleiotropic properties of tetracyclines are not necessarily limited to those described above. Indeed, this class of drugs have been reported as exerting unique effects on complex pathologies. In an experimental simian immunodeficiency virus (SIV) model of HIV central nervous system (CNS) disease, MIN reduced the severity of encephalitis, suppressed viral load in the brain, and decreased the expression of CNS inflammatory markers (102). Tetracyclines also demonstrate protective effects on prion [PrP(Sc)]-mediated brain damage. In one study Syrian hamsters were injected intracerebrally with scrapie-infected brain homogenate that was coincubated with 1 mM tetracycline before inoculation (25). Animals showed a significant delay in the onset of clinical signs of disease and

Downloaded from journals.physiology.org/journal/ajpcell (059.100.186.202) on September 7, 2022.

FOI 26-3132 - Document 5

prolonged survival time. Effects were paralleled by a delay in the appearance of magnetic-resonance abnormalities in the thalamus, neuropathological changes, and PrP(Sc) accumulation. When tetracycline was preincubated with highly diluted scrapie-infected inoculum, one third of hamsters did not develop disease. Thus tetracyclines appear to reduce prion infectivity through a direct interaction with PrP(Sc) and are potentially useful for inactivation of bovine spongiform encephalopathy (BSE)- or variant Creutzfeldt-Jacob disease-contaminated products and prevention strategies.

There are few agents as acutely damaging to tissues and living organisms as mustard gas. This alkylating agent causes massive blistering of the skin and severely damages the lungs by activating proteases (including elastases and MMPs) among other effects. In a study by Guingabert et al. (38) guinea pigs were given mustard gas intratracheally (38). A group of animals were pretreated with DOX resulting in decreased gelatinase activity, decreased inflammation, and notable decrease in histological lung epithelial lesions. Acute respiratory distress syndrome (ARDS) develops in the setting of diseases such as sepsis. With ARDS an infiltration of the lungs by neutrophils can lead to a massive activation of the cells yielding local tissue destruction and possibly the death of the subject. The destruction of lung tissue can be documented in bronchial lavage by the presence of protease such as elastases, MMP, collagen, and elastin fragments. In a study by Steinberg et al. (83) the prophylactic use of the CMT COL-3 was examined in a chronic insidious onset animal model of sepsis-induced ARDS. COL-3 prevented the development of ARDS and also prevented septic shock. The emergence of new epidemics where ARDS may be an important component to the cause of severe disease or death raises the spectrum of the possible use of tetracyclines to prevent or limit the development of respiratory system complications. Such is the case for H1N1 influenza and SARS (severe acute respiratory distress syndrome caused by a coronavirus). A potential scenario may be where there is high risk of exposure and contamination by a mutated version of a virus (such as in the case of the H1N1 influenza) by medical personnel where the use of tetracyclines may be justified as a means of preventing serious complications from developing upon exposure and infection.

CMT (in particular COL-3) have also been examined for their anti-cancer therapeutic potential. MMP are involved in tumor metastasis and angiogenesis and are overexpressed in Kaposi's sarcoma (KS) cells. In a phase II study, there were significant declines in MMP-2 and MMP-9 plasma levels from baseline to minimum value with treatment, and the most common adverse events were photosensitivity and rash. COL-3, when administered at 50 mg/day, demonstrated antitumor activity similar to other promising investigational KS drugs.

Ongoing Clinical Trials

Table 1 summarizes the most relevant clinical trials implemented (excluding those associated with their antibiotic or dermatologic effects). As can be ascertained from the list, this class of drugs is receiving a great amount of attention pertaining to their apparent capacity to beneficially modulate various apparently unrelated diseases. The table also includes (in very general terms) the apparent cause associated with a particular disease where tetracyclines are being tested.

Table 1. *Most relevant clinical trials implemented using minocycline, doxycycline, and chemically modified tetracycline COL-3*

Disease	Cause
Minocycline	
Acute kidney injury	Ischemia
Acute spinal cord injury	Ischemia
Amyothrophic lateral sclerosis	Autoinmmune
Asthma	Immune - inflammation
Autism	Unknown
Cognitive function/endarterectomy	Ischemia
Dry eye syndrome	Inflammation
Fragile X syndrome	Hereditary mental retardation
Gum disease	Inflammation
HIV – cognitive impairment	Viral - inflammation
Huntington's disease	Degenerative
Idiopathic pulmonary fibrosis	Unknown - inflammation
Ischemic stroke	Ischemia
Multisystem atrophy	Degenerative
Parkison's disease	Degenerative
Pneumothorax	Inflammation
Psychosis	Unknown
Rheumatoid arthritis	Inflammation
Schizophrenia	Unknown
Sclerosis cholangitis	Inflammation
Doxycycline	
Abdominal aneurysm	Inflammation - proteases
Alzheimer's disease	Degenerative
Bone loss	Hormonal imbalance
Brain hemorrhage	Ischemia
COPD	Inflammation
Coronary artery bypass	Ischemia
Diabetic retinopathy	Inflammation
Diabetic ulcers	Inflammation - healing
Lymphangioleiomyomatosis	Noncancerous tumor
Osteoarthritis	Inflammation
Postmyocardial infarction remodeling	Inflammation - healing
COL-3	
Metastatic cancer	Cancer
Kaposi's sarcoma	Cancer
Recurring brain tumors	Cancer
Advanced solid tumors	Cancer

Partial listing of clinical trials in different phases of execution as gathered from www.clinicaltrials.gov for minocycline (20/54 total), doxycycline (11/88), and the chemically modified tetracycline COL-3 (4/4). The listing only includes nonconventional uses.

Conclusions

Tetracyclines have been recognized slowly over time as a genre of drugs with interesting pleiotropic properties. Their accumulation in injured tissues makes them almost appear to act as a smart drug. The recognition by scientists and clinicians of these collection of properties and of the safety profile of this class of drugs has led to the implementation of clinical trials to explore their possible beneficial effects in the setting of a wide variety of diseases. Clinical trial efforts so far have been mostly isolated but, as a whole they would appear to require the formation of a consensus group that would lead to a more systematic understanding (and examination) of their therapeutic potential. As CMT have proven to generate useful derivatives with unique properties, a rational modification of this class of drugs may lead to the development of novel compounds with greater therapeutic potential and safety profiles.

Downloaded from journals.physiology.org/journal/ajpcell (059.100.186.202) on September 7, 2022.

Indeed, such creative efforts are currently the focus of various research groups (84). However, it should be recognized that each member of the TTC family has both similar and more importantly, distinct properties from each other such as half life and lipophilicity. Scientists when anticipating their use, need to make extensive considerations towards the desired "preferred" action (e.g., antiapoptotic vs. antiprotease) and anticipated outcomes.

Abstract

Background Recognizing only sharp elevation in a short period of time, the COVID-19 SARS-CoV-2 propagation is more and more marked in the whole world. Induced inflammation afterwards infection engenders a high infiltration of immune cells and cytokines that triggers matrix metalloproteinases (MMPs) activation. These endopeptidases are mediators of the lung extracellular matrix (ECM), a basic element for alveoli structure and gas exchange.

Methods When immune cells, MMPs, secreted cytokines and several other mediators are gathered a pathological matrix remodeling occurs. This phenomenon tends to tissue destruction in the first place and a pulmonary hypertrophy and fibrosis in the second place.

Findings After pathological matrix remodeling establishment, pathological diseases take place even after infection state. Since post COVID-19 pulmonary fibrosis is an emerging complication of the disease, there is an urge to better understand and characterize the implication of ECM remodeling during SARS-CoV-2 infection.

Conclusion Targeting MMPs and their inhibitors could be a probable solution for occurred events since there are many cured patients that remain with severe sequels even after the end of infection.

Keywords MMPs · Matrix remodeling · Immune cells · Cytokine · SARS-CoV-2 · Therapeutic target

Introduction

The emerging pandemic caused by the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) brought a state of alert around the world. SARS-CoV-2 belongs to the *Betacoronavirus* family which includes two other viruses known for other pandemic diseases: the Middle East Respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV), respectively [1–4]. SARS-CoV-2 shares 79.6% of its genome with SARS-CoV-1 and 96% with the bat coronavirus (RaTG13) which make it most likely deriving from the later [1, 5]. SARS-CoV-2 shares important sequence homology with SARS-CoV but also a common entry receptor angiotensin-converting enzyme 2 (ACE2). For such reason, several authors have suggested that their biological properties could be similar and understanding host response to SARS-CoV-1 may help us understanding SARS-CoV-2 implication at various levels [4, 6, 7].

Latest models suggest that following SARS-CoV-2 invasion in type II pneumocytes (via ACE2) leads to a rapid virus replication as well as concomitant intense secretion of pro-inflammatory cytokines, chemokines, and other proteases are mainly secreted by the innate immune cells' response [8]. Subsequent excess inflammation, especially in the lung further (the so-called "cytokine storm") leads to acute respiratory distress syndrome (ARDS), pulmonary edema and endothelial damage [1].

On a molecular scale, when all of these inflammatory mediators are gathered, there is an increase of matrix metalloprotease (MMPs) secretion in site of the inflammation. This increase leads to a pathological remodeling of lung's extracellular matrix (ECM) [1, 8–10]. MMPs are members of the proteolytic zinc-dependent family. There are 24 recognized members until today and they are included in several vital mechanisms and pathways including majorly wound healing, ECM degradation, angiogenesis, proliferation and

signaling pathways [11, 12]. While present in low quantity at homeostasis, their increased secretion and imbalance have been widely studied in various lung pathologies in chronic and acute nature.

Since they are involved in different pathways and physiological phenomena, disequilibrium in their levels opens the door to pathological situations translated by serious diseases like cancer, cardiovascular diseases, neurodegenerative diseases and chronic inflammation which explains why they drew so much attention lately. Even though the fact that they are capable of modulating cellular behavior in a non-specific way, they could be considered as therapeutic targets [13]. Secreted MMPs enhance pro-inflammatory cytokines, bioactive chemokines and oxygen reactive. They are even included in infection propagation in the organism through their members with transmembrane domain like ADAM-17 which leads us to ask about their real implication even with fluctuated levels [14–16]. In fact, metallopeptidases are probably included in immune cells infiltration since they are mediators of ECM and basement membrane breakdown that surrounds the parenchymal ECM and blood vessels.

The combination of ARDS and hyper-inflammation has the potential of driving pulmonary fibrosis. Since post-COVID-19 pulmonary fibrosis is an emerging complication of the disease, there is an urge to better understand and characterize the implication of ECM remodeling during SARS-CoV-2 infection. This review focuses on current and emerging evidence regarding the pathophysiological role of metallo-endopeptidases, particularly MMPs, in determining the remodeling process in lung tissue damage during SARS-CoV-2 infection.

The SARS-COV-2/ACE2 pathway to infection

Through genome sequencing and by homology modeling, the angiotensin-converting enzyme 2 (ACE2) has been reported to be the target for SARS-CoV-2 [3]. Specific binding between spike (S) glycoprotein of coronavirus and the ACE2 receptor followed by S cleavage by serine protease 2 (TMPRSS2) allows for virus entry to cell [1, 4, 17]. Several studies of gene expression datasets have reported that ACE2 more than TMPRSS2 may be the limiting factor for viral entry at the initial stage [3]. Moreover, the study reported a high expression of ACE2 in nasal secretory and ciliated cells as well as type II alveolar epithelial cells (AEC). At homeostasis, quiescent types II AEC are the major source of ACE2 within the lung. During lung fibrosis, those cells actively proliferate and downregulate the expression of this enzyme. ACE2 expression is severely downregulated in the context of pneumocyte proliferation and lung fibrosis [18].

The viral spike protein (~ 1300 amino acid residues) is formed by two functionally subunits: S1 contains the receptor-binding domain (RBD) attached to S2, which contains the post-fusion core [19, 20]. This process is crucial for the virus cell entry resulting in shedding S1 subunit from the viral surface [4]. The S-protein undergoes conformational rearrangements allowing the S2 subunit a post-fusion conformation [19, 21, 22]. Besides the proteolytic cleavage of SARS-CoV-2 S by TMPRSS2, a smaller rate of endosomal cysteine proteases cathepsin B (CatB) and cathepsin L (CatL) has been reported to assist in priming and entry process [4, 23] (Fig. 1A). A distinctive feature of the SARS-CoV-2 S-protein is the Furin cleavage site acquirement, polybasic cleavage site (RRAR) at S1–S2 junction which is cleaved efficiently by furin enzyme [24]. The S1/S2 junction and S2′ are the two cleavage sites in viral S-protein, allowing the activation and priming process through host cell enzymes trypsin, cathepsins, furin and TMPRSS2 [4, 25]. After this bond, the virus membrane and the host cell membrane fuse together through their ligand–receptor link and then the virus enters the host cell [26]. The angiotensin-converting enzyme 2 (ACE2) is a homolog of the ACE.

ACE2 is a widely expressed enzyme with pleiotropic roles which is part of the Renin–Angiotensin System (RAS). ACE2 is the homologous of ACE and shares a high affinity to the angiotensin II (ANG-II) [6, 27, 28, 31, 32]. There are three discovered receptors for the ANG-II until today. Among these receptors, the angiotensin I (AT1R) leads to vasoconstriction, induces inflammatory responses and enhances matrix remodeling, whereas the AT2R reverses the ANG-II effects [28, 29], while ACE–ANG-II–AT1R axis activation has been proven to causes deleterious effects, such as vasoconstriction, inflammation, and fibrosis [28–30]. The ACE2–ANG I–7–Mas axis appears to counter-regulate the ACE–ANG-II–AT1 negative effects anti-thrombotic, anti-proliferative, anti-fibrotic, and anti-inflammatory properties [31, 32].

ACE2 acts like a transmembrane enzyme with an extracellular domain and presents a target site for the SARS-CoV-2 to mediate its actions [33]. When the SARS-CoV-2 enters into the organism, it binds directly through its glycoprotein spike existent on its viral membrane to the host cell receptors [4, 34]. The recently made study by Zhou and its collaborators demonstrated that SARS-CoV-2 entry to the host cell is mainly insured by the ACE2 cell receptor since cells that do not express this receptor are not infected [1]. However, on T lymphocytes in vitro, SARS-CoV-2 is capable of using other cellular receptors of S-protein to infect cells that do not express the ACE2 receptor [35]. It is plausible that interaction of ACE2 with SARS-COV-2 may induce its downregulation and thereby enhance the ACE-AngII-AT1 axis leading to vasoconstriction, pro-inflammatory and oxidative stress. In a recent study, Liu et al. reported higher serum Ang II levels in patients with higher viral load which further supports this hypothesis [36]. Afterwards, the viral RNA is injected into

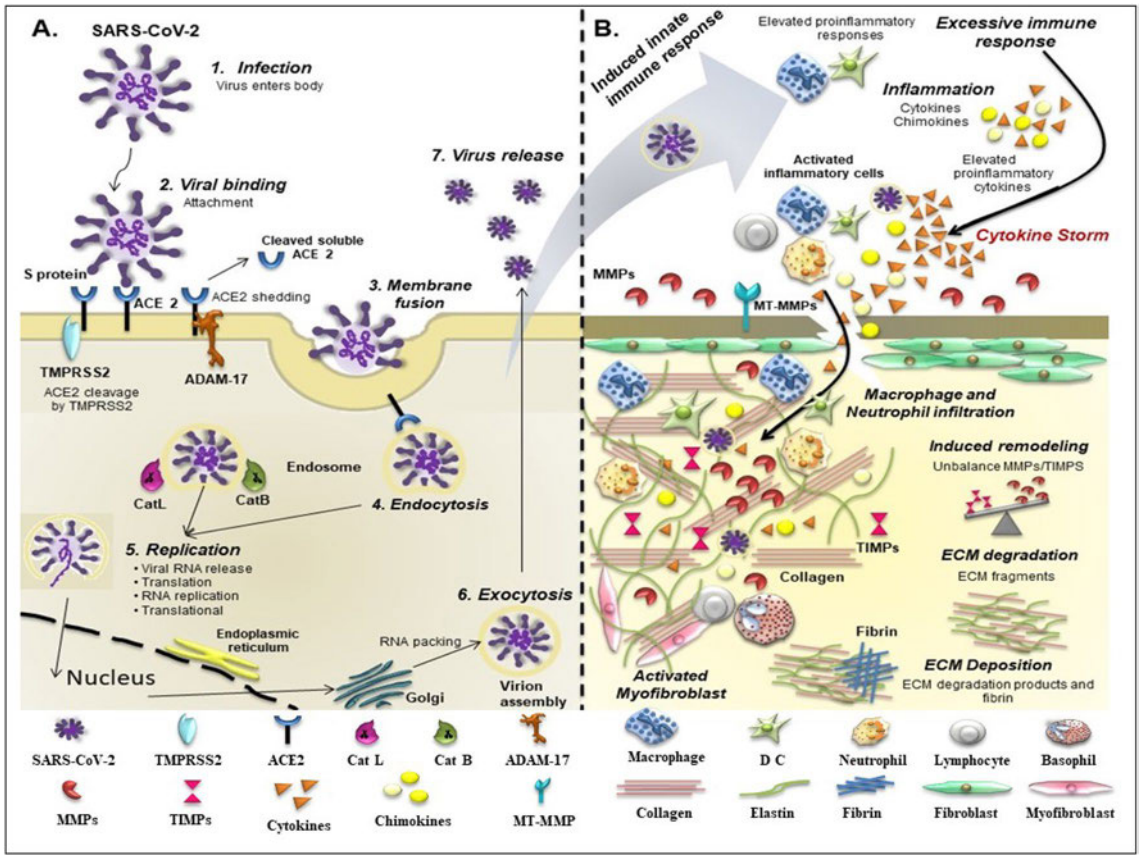

Fig. 1 Induced pathological matrix remodeling after SARS-CoV-2 infection. **A** Cell entry mechanism of SARS-CoV-2 summary: the initial step of SARS-CoV-2 infection involves a specific binding of S-protein to host cell entry receptors, angiotensin-converting enzyme 2 (ACE2). Gathered together and with the host cell surface serine protease TMPRSS2, the entry process is activated. Following the endocytosis, cathepsins are released. These proteases modify once again the S-protein and promote the release of viral RNA into the cytoplasm. **B** SARS-CoV-2 Physio-pathological implications: when virus propagation occurs, a massive destruction of tissues takes place. An epithelial damage is the initial hallmark of SARS-CoV-2 infection. A specific immune response is induced to eliminate the virus and initiate the inflammatory response. The immune cells, in particular, macrophages identify the virus and release pro-inflammatory mediators (cytokines, chemokines, growth factors…). Cytokines activate more immune cells, which in turn produce more cytokines creating an uncontrolled cycle of inflammatory response "cytokine storm". Activated immune and non-immune cells produce MMPs which lead to ECM breakdown disruption and this unresolved infection gives rise to damages. These damages do happen during the cytokine storm which includes the unbalance of the MMPs/TIMPs ratio, the increase deposition of ECM fragments, and the massive formation and deposition of fibrin. *ACE2* angiotensin-converting enzyme 2, *ADAM-17* ADAM metalloprotease domain 17, *Cat L* cathepsin L, *Cat B* cathepsin B, *TMPRSS2* transmembrane protease serine 2, *DC* dendritic cell, *MMPs* matrix metalloproteinases, *MT-MMPs* membrane-type matrix metalloproteinases, *TIMPs* tissue inhibitors of matrix metalloproteinases

the cell cytoplasm, and its open reading fragment (ORF) is directly translated into proteins. These proteins are cleaved by their viral proteases generating their RNA-dependent RNA polymerase (RdRp) necessary for RNA replication. Genomic RNA is thereby replicated by its specific RdRp in presence of structural proteins (Spike, envelop protein, Membran Protein and Nucleocapsid) and is translated by the Golgi complex and the endoplasmic reticulum's host cell. The replicated RNA and structural proteins are gathered to produce new viral particles and are secreted by exocytosis [6, 7] (Fig. 1A).

From lung infection to extracellular matrix remodeling

A very thin alveolocapillary membrane allows oxygen and CO_2 to diffuse through the cells. During the first level of infection, the viral spike binds to the ACE2 receptor on the host cell surface. This bond leads to the incapacity of regulating ANG-II which provokes a sudden increase of the inflammatory response. This increase induces the activation of a large scale of cells including cytokines, and MMPs [37–39]. The sudden activation of these endopeptidases induces matrix disequilibrium and this phenomenon leads in turn to the collapse of matrix. On the one hand, MMPs will be highly activated since the inflammatory response implies a storm of cytokines. On the other hand, the ANG-II increase leads to MMPs increase. In a study made on tuberculosis pleural effusion, ACE2 and MMP-9 do correlate negatively, more precisely when ACE2 receptors are taken by the virus, an increase in ANG-II arises leading to the MMP-9 activation [40]. ACE2 is a pleotrope receptor; it counterattacks the ANG-II and leads to vascular wall hypertrophy. This receptor captures the ANG-II and converts it to reverse its effect. During the infection, the receptor is linked to the virus for its profit. In response to the infection, a lung injury and organ failure occur. As SARS-CoV-2 emerges in human body, a huge storm of inflammatory cytokines comes by. Tissue damage is specific to the virus and then it also appears in multiple other damages [39]. Induced proteolysis by secreted MMPs through the activated inflammatory cells and cytokines has been included in a fatal process. MMPs' proteolytic action seems to be involved in COV-2 pathogenesis, similar to several diseases that are related to tissue damage (Fig. 1B).

The role and fate of the pulmonary extracellular matrix

The lung has a very specific ECM. At healthy state, the ECM forms a thin membrane which allows for passive diffusion of passive diffusion of gas through alveolar-interstitial membrane. The alveoli air exchange structure is composed mainly of an air barrier. This barrier comprises a capillary and an alveolar epithelium, an extracellular matrix and alveolar mediators including fibroblasts and macrophages [41]. To facilitate ventilation, this structure maintains in the same time gas exchange and ECM mechanical properties. ECM is also implicated in inter-cell signaling, in cell function, proliferation and shape. It is highly sensitive to growth factors, such as TGF-Beta. Type I alveolar cell ensures the gas exchange through basal lamina. As for the rest of the solute and liquid exchange, it is ensured by ECM components [41, 42]. During fibrosis, the ECM expands which limits gas diffusion. Also, a pathological fibro-proliferation of the alveoli ECM arises [43, 44]. Lung ECM is a complex and dynamic tissue that has a tremendous role in maintaining a normal connective structure. In lungs, ECM is mainly composed of a thin basement membrane and an interstitial tissue that forms the lung's parenchyma [45] and provides structural support for gas exchange by developing a branched architecture [46]. Also, ECM is widely implicated in signaling pathways through its specific mediators, in cell function and shape, in proliferation mechanisms and in responding to growth factors [47–49]. Lung ECM major components are collagen and elastin fiber that are overlapping with glycosaminoglycans, proteoglycans, fibronectin fibrils and sequestered water [46] (Fig. 2A). Resident fibroblasts are abundant and are mainly in charge of ECM production. Furthermore, laminin, heparan sulfate, hyaluronate, nidogen/entactin, and matricellular proteins like thrombospondin, tenascin C, and tenascin-X have been also identified in alveolar tissues. With all of this wealth in the matrix structure, collagen is the most abundant protein in lung tissue. In lung parenchyma, collagen types I and III predominate the alveolar membrane [46, 50]. After SARS-CoV-2 infiltration in lungs, an acute severe inflammatory response occurs. Following viral entry into host cell, RNA is recognized by the cytoplasmic pattern recognition receptor (PRR) leading to transcription factors activation through the toll interleukin receptor 1 containing interferon beta (TRIF). This activation leads to interferon-γ (IFN-γ) secretion [51, 52]. However, an insufficient level of IFN-1 for infection control enhances viral replication. In other patients, IFN-γ serum level is more important. This fact is the reason behind the cytokine storm particularly myeloid cytokine (IFN-γ; GM-CSF). Their activation attracts immune cells (monocytes, lymphocytes, peripheral blood mononuclear cells) in the infection site [53].

IFN-γ production during early infection phase is the immune defense key against the virus emerge [51] and a delay in their release at early stages of COVID-19 makes it harder for the antiviral response. This release enhances cytokine secretion and through the chemiotactic phenomena, more inflammatory cells are attracted. Afterwards, an extreme infiltration in lung tissue arises [54, 55]. The emerging concept elaborated by McGonagle and his collaborators discussed the probability that the induced cytokine storm during SARS-CoV-2 infection result from the immune system failure to eradicate the virus. They divided the storm in two phases [53]. At a first level, there is a loss of the first anti-viral line defense. In fact, the Toll receptor like-3 (TLR-3) is capable of recognizing the double-stranded viral RNA. This fact leads to TRIF activation which in turn activates Interferon Regulated Factor 3 (IRF-3) and Nuclear Factor-kappa B (NF-κB) to enhance IFN-γ and Tumor Nescrosis Factor-β (TNF-β) production. Theses pro-inflammatory

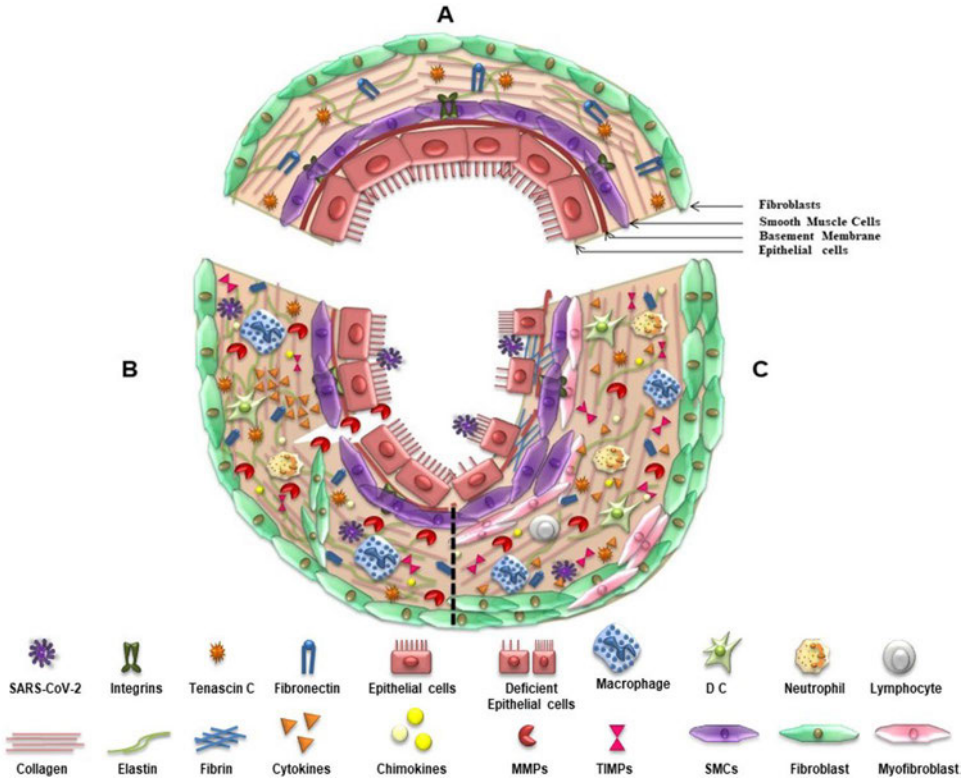

Fig. 2 ECM lung evolution from healthy to a pathological matrix. **A** Healthy lung matrix structure is preserved by the presence of fibroblasts, collagen, elastin and anchored fibronectin to basal membrane. **B** ECM breakdown after virus infiltration and MMP overexpression (from day 1 to 5 of infection): collagen fibers destruction through secreted MMPs by inflammatory cells. This destruction leads to basement membrane disruption. **C** ECM lungs fibrosis and hypertrophy (from day 5 of infection and more): after increased degradation, a remodeling takes place to respond to lung injuries. However, ECM mediators' imbalance and SMC migration lead to increased collagens and matrix degradation products deposition that are presumed in a thickened matrix. *SARS-CoV-2* severe acute respiratory syndrome coronavirus-2, *MMP* matrix metalloproteinase, *TIMP* tissue inhibitor of matrix metalloproteinase, *ECM* extracellular matrix, *SMC* smooth muscle cells, *DC* dendritic cells

cytokines are considered to be in the first line of defense and the loss of this is due to the viral charge and hypo-secretion of IFN-1 [51, 53, 55].

As a consequence, a second storm is activated, that is more tissue aggressive than the first one to cover up for the first target failure during the first response [55, 56]. During this phase, myeloid IFN-γ pathway and derived cytokine that includes TNF, GM-CSF and IL-1 are overexpressed in blood, rendering it in a hyper-cytokinaemic mode. The cytokine shock is explained until this day as the ultimate uncontrolled systemic inflammation that is triggered by cytokines hypersecretion after infection which leads to organ failure and that might cause death [57].

When all of these factors are gathered all together, a tissue destruction could occur. In fact, following the viral infection by the SARS-CoV-2 virus, an ECM breakdown takes place which leads to the aggravation of lung state and provokes lung pathologies progression (Fig. 2B). The immune cells influx into lungs does protect the host cell against excessive immune responses including both innate and adaptive. This fact enhances chronic inflammation which in turn destroys the lung's parenchyma [58, 59]. T lymphocytes, the adaptive immune cells, are headed to ECM lung's components. These mediators are capable of inducing abnormal immune responses that enhance lung destruction. During innate and adaptive immunity activation, triggered immune cells induced innate inflammation in the lung. Excessive immune response starts a sequence of signals that overlaps lung stroma which are exposed to antigen-presenting cells (APCs) towards lymphocytes for generating the major histocompatibility complex (MHC) [60]. To activate APCs, specific signals must be secreted. ECM breakdown and degradation products may engender new antigens that are recognized by immune cells resident in lung [60–63]. This injury engenders an alveolar basement membrane disruption and the accumulation of matrix degradation products that are rich in fibrin [64]. ECM bioactive fragments are in turn mediators of inflammation since collagen degradation is implicated in neutrophil migration. Collagen I Proteolytic

FOI 26-3132 - Document 5

fragment is capable of acting like chemokines and attracts immune cells by binding to their receptors [65, 66].

Lung ECM major components were absent in infected lungs with SARS-CoV-2 which leads to a severe mechanical damage presumed in COVID-19 characteristics [67]. In their recent proteomic analysis of lung tissues from deceased patients suffering from severe forms of COVID-19, Leng et al. reported several major components of ECM homeostasis to be downregulated. For example, the ECM protein annexin A2 (ANXA2), which regulates surfactant secretion by type II pneumocyte was significantly downregulated [67]. Surfactant dysregulation plays a major role in ARDS pathophysiology [68]. Thereby, maintaining a normal state of surfactants could improve the prognosis of severe patients suffering from COVID-19 [69]. ECM fate is related to a balance between degradation and secretion of matrix components. It is related to myofibroblasts after injury for a fibrotic repair since interactions between fibroblasts and ECM components enhance matrix production and stimulate signaling pathways [35, 70] (Fig. 2C).

Mediators of lung ECM breakdown

ECM breakdown is mediated by MMPs that are capable of degrading ECM components and are characterized by the presence of the metallic ion Zn^{2+} that confers the catalytic activity [11]. There are 28 MMPs discovered in vertebrates until this day [71], 24 of which are expressed in human tissues; they are divided according to their structure and their substrate specificity [72]. Their basic structure is limited to a pre-domain which represents a signal peptide for secretion and is eliminated after its secretion. The pre-domain is followed by a pro-domain that ensures the enzyme latent form and is mainly formed by a peptide sequence containing a cysteine residue which interacts with the catalytic site. This site has a zinc atom maintained by three histidine residues in a tri-dimensional structure [11, 73]. Thereby comes the catalytic domain which comprises a linked site to zinc with a highly conserved sequence *HEXXHXXGXXH* [74]. Pro-domain cleavage releases the zinc ion and activates the catalytic site that can bind afterwards to its substrate through H_2O penetration.

According to their specificity and primary structure, the first group is composed of collagenases (MMP-1, MMP-8 and MMP-13). The second group englobes the gelatinases (MMP-2 and MMP-9) and the third the Stromelysines (MMP-3, 10 and 11). MMPs that contain a membrane-type (MT-MMPs) are members of the fourth group that can be subdivided into two subgroups, type I transmembrane proteins (MMP-14, 15, 16, and 24) and glycosylphosphatidylinositol (GPI) anchored proteins (MMP-17 and -25) [75]. The enzyme structure is also formed by a hinge region and a hemopexin domain that interferes into MMPs recognition of their substrate except for MMP-7, 23 and 26 that do not possess the hemopexin domain [13, 73, 76]. Secreted MMPs at site of lung inflammation are capable of modulating inflammatory mechanisms whether by affecting chemokine activity, disposal or by targeting proteins that are in a direct association with their activity [77–79].

As for adamalysins, they are in the same time metalloproteinase and disinegrin and are characterized by a thrombospondin motif [80]. Their structure is mainly composed of a pro-domain, a zinc-binding domain, a disintegrin domain that confers interaction to the ADAM, a cysteine-rich domain for ECM interaction, an epidermal growth factor domain and a cytoplasmic tail [81, 82]. Also, the fact that ACE2 contains a HEXXH zinc-binding motif makes it a metalloproteinase [33]. MMPs are capable of modulating inflammatory mechanisms whether by affecting chemokine activity, disposal or by targeting proteins that are in a direct association with their activity [77, 78].

Secreted MMPs by macrophages like MMP-12 and MMP-28 are included in the pro-inflammatory process by enhancing macrophage infiltration in lungs [83]. Another mediator of immune cells is the matrilysin (MMP-7). This MMP does promote neutrophil infiltration via the epithelial barrier by degrading the transmembrane proteoglycan coordinated to the KC. The KC is a murine chemokine (CXC) that is implicated in attracting inflammatory cells [77]. The MMP-8 nearly shares this characteristic from the MMP-7 and possesses a chemiotactic effect on neutrophils but in a more active structure. Under the influence of chemokines, neutrophils secrete MMP-8 which in turn facilitates neutrophils efflux through degrading the ECM in a feedback way. In the same meaning, gelatinase A and B (MMP-2 and MMP-9) interfere with recruited immune cells from peribroncho-vascular in alveolar space through modulating chemokines [84, 85]. A recently made study showed that MMP-9 level was higher in first 3–5 days of infection. This elevation correlated negatively to the arterial partial pressure of oxygen/fraction of inspired oxygen ratio (P/F) which means sicker patients [86].

MMP-9 has been related to lung diseases through tissue remodeling like acute lung injuries asthma pulmonary fibrosis and pleural effusion. Released MMP-9 from inflammatory cells does promote alveolar capillary destruction leading to lung injury [83, 84, 87]. Also, Shi et al. suggested that MMP-3 serum level may be a valuable marker of COVID-19 by indicating a significant difference found between novel coronavirus pneumonia-infected patients and healthy people [88]. This particular MMP is widely expressed in human tissues since it is capable of cleaving several components of ECM components. Its main role is the ability to activate other pro-MMPs. During matrix turnover, MMP-3 or stromelysin-1 activates matrilysin, collagenases, gelatinase

FOI 26-3132 - Document 5

B and pro-MMP-1 to generate an active form of MMP-1. Its capacity of cleaving type I collagen makes it different from collagenase [13, 89].

Following the emerging cytokines flow after infection, tissue inhibitors of metalloproteinase (TIMPs) are secreted to maintain the matrix equilibrium and to regulate cytokines shedding, playing therefore a tremendous role after injury caused mainly by inflammation [90–93]. The TIMP-3 is a specific inhibitor of MMPs and ADAM family (metalloproteinase and disintegrin) and is expressed by several cell types via many tissues. This inhibitor is capable of inhibiting the very particular ADAM-17 [94–96], a metalloprotease and a disintegrin that cleave not only tumor necrosis factor alpha (pro-TNF-alpha) [97, 98], but also responsible of shedding the ACE2 receptor and seem to be implicated in the propagation and the aggravation of the infection. Binding SARS-CoV-2 to the ACE2 induces its shedding by ADAM-17, and its uptake by the virus in turn [14–16]. This shedding enhances probably several cellular signals including PKC activation [15] and is involved in virus uptake towards target cells [95]. The emergent hypothesis is that ACE2 down-regulation by ADAM-17 could be responsible for lung tissue damage and respiratory failure aggravation by the virus. It has been reported, in vivo and in vitro, that the inhibition of ADAM-17/TACE blocks ACE2 shedding and limits viral entry [15, 16]. Its exact role in SARS-COV-2 invasion needs further investigations, indeed, while ADAM17 ability to cleave ACE2 is undisputable, it was demonstrated that only cleavage by TMPRSS2, and not by ADAM17 can promote virus entry into the cells in a SARS-CoV-1 model [95]. To more understand SARS-CoV-2 implication, we went through other possible pathways on viruses that belong to the same family. On an induced MHV-A59-infected mice model (MHV is a mice hepatitis virus that belongs to the same family of Beta-coronaviruses, where SARS-CoV-2 is a considered member of this family) [17, 99–103], there was an upregulation in MMP-3, MMP-12 transcript levels. There was also an elevation in TIMP-1 circulating levels and mRNA [101]. This inhibitor is found to be correlated with viral virulence and suggests a probable implication in the antiviral response [101]. Since Beta-coronaviruses entry depends on cellular protease for a successful penetration in host cell, there is a probable downregulation of TIMP-2, TIMP-3 and TIMP-4 [92, 104, 105]. In fact, basic TIMP-1 levels are in first place low but are highly induced after triggered immune response on the contrary of TIMP-2, TIMP-3 and TIMP-4 that are constitutively secreted and modifications in their levels are lower than those of TIMP-1 in immune response [105–109]. The increase of MMP-3 [88] and MMP-9 [85] circulating levels during first days of infection on the optimum of the viral charge and a probable downregulation

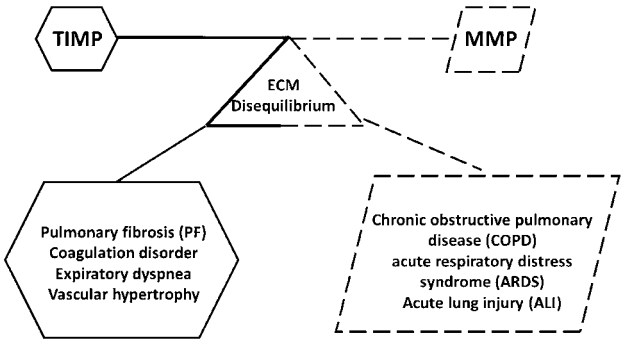

Fig. 3 Targeting ECM mediators as a therapeutic solution after SARS-CoV-2 infection could prevent from severe complications: matrix equilibrium is primordial for maintaining a healthy lung structure, when MMP/TIMP ration is in favor of MMPs, a matrix destruction occurs and when it is in favor of TIMPs a thickened matrix is observed. *MMP* matrix metalloproteinase, *TIMP* tissue inhibitor of matrix metalloproteinase, *ECM* extracellular matrix

of their specific inhibitors could put the puzzle in this way: the virus turns all of the mediators in its favor by enhancing MMPs secretion during first days of infection that triggers a matrix disequilibrium. Their decrease in the upcoming period suggests an upregulation of their specific inhibitors to respond their sudden elevation. More precise experiments, subsequent measurements and longitudinal analyses could better explain this phenomenon.

Are MMPs and their inhibitors probable therapeutic targets?

An elevation in MMPs level implies a matrix disequilibrium that will probably modulate in turn their specific inhibitors (Fig. 3). These inhibitors are addressed towards MMPs to regulate their action. TIMPs used in lung injury mice models reduced the inflammatory state and ameliorated the injuries [109]. Induced inflammatory markers during the cytokine storm, enhance TIMPs secretion particularly TIMP-3 since it is mainly secreted by macrophages [110]. TIMP-3 is the highest ECM regulator because of its capacity to bind directly to the matrix [111]. Capable of shedding receptors and cleaving cytokines, this inhibitor has an anti-inflammatory effect that could restrain the explosive state of inflammatory markers after infection [112, 113]. To increase TIMP-3 bioavailability, different approaches were conducted, like injecting recombinant TIMP-3 or through a mediated adenovirus gene [114, 115]. Therefore, TIMP-3 wide substrates and targets may imbalance some of the signaling pathways and mechanisms. These experiments are able to change radically the cell behavior by cleaving and shedding cell surface proteins including receptors, disintegrins and chemotactic elements. That is why a determined interval

FOI 26-3132 - Document 5

of its circulating level could offer a good prognostic marker since higher level implies also an ECM disequilibrium with several harmful consequences [110]. COVID-19 infections could induce an alveolar damage and enhance vascular permeability presumed in progressive hypoxemia, an ARDS or even an acute lung injury. As a consequence of immune cells activation and overexpression of cytokines, proteases, a probable acute lung injury (ALI) is established [116, 117]. ALI is characterized by a severe damage of alveolar barrier and mainly caused by an enhanced inflammatory response. Ventilated associated lung injury (VALI) has shown to be a common complication for COVID-19 patients and this can be only for worse [117]. To demonstrate MMPs implication in ALI and their probable potential effect in therapeutic experiments, animal models were established on clinical perturbations. On a deficient MMP-8 mice model and by treatment with an MMP-8 inhibitor, there was an improvement in gas exchange and a reduced damage after induced-ventilator lung injury [118]. However, Dolinay and his collaborators found that mice with an MMP-8 deficiency developed a higher alveolar permeability after the mechanical ventilation than wild type mice [118]. In the same context, an induced lung injury by immune cells infiltration in MMP-9-deficient mice model showed a lower state of lung injury than wild type [119, 120]. In fact, this gelatinase is probably implicated in decreasing pulmonary edema through healing the alveolar epithelium [121]. On the other hand, in response to a severe injury in lungs, fibrocytes and macrophages enhance collagen availability. The MMP-3 is considered to be the pro-generator of other MMPs since it is responsible for their activation. This stromelysin-1 is implicated in reducing lung injury level in MMP-3-deficient mice through the reduction of the chemotactic activity. Chemotactic peptides generated by neutrophils were upregulated in MMP-3-deficient mice including macrophage inflammatory protein and the complement chemotactic (C5a) [122]. Furthermore, there has been evidence that MMP-12 known also as the macrophage elastase is able to regulate monocytes influx in lungs through generating elastin fragments that play the role of chemotactic elements for immune cells recruitment in a chronic lung injury and smoking model [122].

SARS-CoV-2 new variant and matrix remodeling?

Even though the emerging new variant of SARS-CoV-2, the SARS-CoV-2 VUI 20201201 (Variant Under Investigation, year 2020, month 12, variant 01) [123], is yet under investigation and by the limited existent data, we thought of elaborating this actuality from another perspective. This new variant has been identified via viral genomic sequencing and is characterized by several spike proteins mutation, namely deletion 144, deletion 69–70, N501Y, A570D, D614G, T716I, P681H, D1118H, S982A [124]. Preliminary investigations suggest that its probable increased transmissibility could reach the 70%. Among these mutations, the N501Y is capable of increasing the ACE2 affinity since it touches the contact residues of the receptor-binding domain and seems to be highly related to virulence and infectivity factors in mice models [125, 126]. As for the P681H mutation, it creates a new furin cleavage site among the S1 and S2 and this site appears to be absent in other coronaviruses. This genetic variation is probably capable of promoting the viral entry in epithelial respiratory cells [17, 127, 128]. As for the 69–70 spike deletion, it has been shown to be associated to multiple RBD mutations [128, 129]. In summary, these mutations do enhance viral infiltration in host cells which explains its high transmissibility but do not alter the infection severity until the recent findings [130]. Based on these limited data, we can suggest that matrix remodeling after SARS-CoV-2 and SARS-CoV-2 VUI 20201201 will take the same road. Both of them will engender matrix destruction in a first way after activating the first line of defense which is presumed in an innate response. Afterwards, the real worry could be in activating more matrix mediators that will probably increase their secretion in a sudden way and set off several complications. It remains for us to investigate their evolution in the periods to come since there are still not enough data for this cluster.

Conclusion

Matrix remodeling has been widely implicated in several physiological, pathological and homeostasis state. Its mediators are capable of changing the fate of an organ since they are present and implicated in cell–cell and in a circulating way. Coronavirus invasion in the human body did alter matrix equilibrium. After elucidating matrix remodeling from this point of view, it is clearer that these mechanisms are pathologically modified during SARS-CoV-2 emerging. Since the lack of data, it will be interesting to focus on MMPs and their inhibitors for a therapeutic journey and to consider them as probable targets for a long-term treatment as cured patients remain with sequels.

Safety, Tolerability, and Pharmacokinetics of Escalating High Doses of Ivermectin in Healthy Adult Subjects

Cynthia A. Guzzo, MD, Christine I. Furtek, BS, Arturo G. Porras, PhD, Cong Chen, PhD, Robert Tipping, MS, Coleen M. Clineschmidt, BA, David G. Sciberras, PhD, John Y-K. Hsieh, PhD, and Kenneth C. Lasseter, MD

*Safety and pharmacokinetics (PK) of the antiparasitic drug ivermectin, administered in higher and/or more frequent doses than currently approved for human use, were evaluated in a double-blind, placebo-controlled, dose escalation study. Subjects (*n = *68) were assigned to one of four panels (3:1, ivermectin/placebo): 30 or 60 mg (three times a week) or 90 or 120 mg (single dose). The 30 mg panel (range: 347-594* μg/kg*) also received a single dose with food after a 1-week washout. Safety assessments addressed both known ivermectin CNS effects and general toxicity. The primary safety endpoint was mydriasis, accurately quantitated by pupillometry. Ivermectin was generally well tolerated, with no indication of associated CNS toxicity for doses up to 10 times the highest FDA-approved dose of 200* μg/kg*. All dose regimens had a mydriatic effect similar to placebo. Adverse experiences were similar between ivermectin and placebo and did not increase with dose. Following single doses of 30 to 120 mg, AUC and* C_{max} *were generally dose proportional, with* t_{max} *~4 hours and* $t_{1/2}$ *~18 hours. The geometric mean AUC of 30 mg ivermectin was 2.6 times higher when administered with food. Geometric mean AUC ratios (day 7/day 1) were 1.24 and 1.40 for the 30 and 60 mg doses, respectively, indicating that the accumulation of ivermectin given every fourth day is minimal. This study demonstrated that ivermectin is generally well tolerated at these higher doses and more frequent regimens.*

Ivermectin is a derivative of the avermectins, a family of macrocyclic lactones produced by the filamentous bacterium *Streptomyces avermitilis*. It is a highly effective antihelmintic agent used in animals and humans. Ivermectin was first approved for human use in 1987 and is donated by Merck & Co., Inc., as Mectizan® for the treatment of onchocerciasis and, more recently, lymphatic filariasis in Africa and Latin America. More than 200 million treatments have been distributed through the program. It is also approved as Stromectol® for the treatment of strongyloidiasis of the intestinal tract and onchocerciasis. Recently, approved human indications have been extended in France to include the treatment of scabies. The approved treatment regimens are as follows: 150 μg/kg once yearly for onchocerciasis, 200 μg/kg single dose for strongyloidiasis, and 150 to 200 μg/kg twice yearly or 300 to 400 μg/kg once yearly in endemic areas for lymphatic filariasis. The greatest experience with human use of ivermectin is in the dose ranges of 150 to 200 μg/kg.

Early pharmacokinetic studies conducted to support registration of the drug as a therapeutic agent against onchocerciasis demonstrated that plasma concentrations are approximately proportional to the dose, following oral administration of 6, 12, or 15 mg of ivermectin.[1] In two studies, after single 12 mg doses of ivermectin (2 × 6 mg) in fasting healthy volunteers (representing a mean dose of 165 μg/kg), the mean peak

plasma concentrations of the major component (H_2B_{1a}) were 46.6 ± 21.9 (range: 16.4-101.1) ng/ml and 30.6 ±15.6 (range: 13.9-68.4) ng/ml, respectively, at approximately 4 hours after dosing.[2] Ivermectin is metabolized in the liver, and ivermectin and/or its metabolites are excreted almost exclusively in the feces over an estimated 12 days, with < 1% of the administered dose excreted in the urine. Estimates of plasma half-life have varied from about 12 to 56 hours.[3-7]

Oral ivermectin has been considered as a possible treatment for head lice. In recent years, this condition has become a significant problem in developed countries, resulting in school absenteeism, social distress, and stigmatization. The economic loss to parents can also be substantial; informal estimates from the Centers for Disease Control and Prevention show that the cost of lost work time due to head lice infestations exceeds $1 billion annually.[8] Initial exploratory studies evaluated ivermectin doses of 100 to 200 μg/kg.[9-11] However, none of these early studies demonstrated eradication of head lice, suggesting that higher or more frequent doses may be necessary for this use.

Since the majority of safety and pharmacokinetic data on oral ivermectin are with single doses of 150 to 200 μg/kg, the primary objective of this study was to obtain additional information at higher and multiple doses. Doses up to 10 times the 200 μg/kg dose were evaluated to provide a substantial safety margin over the anticipated dosage range for head lice treatment. Specifically, for assessment of safety, signs observed in animal toxicity studies, as well as in documented human overdose cases, were chosen as safety endpoints. In particular, mydriasis was evaluated as the primary safety endpoint because it could be accurately measured with a previously validated method, pupillometry. The pharmacokinetic objectives were to evaluate the pharmacokinetics of ivermectin with higher doses, the extent of any ivermectin accumulated with multiple doses, and the effect of food and gender.

METHODS

Subjects

Both male and female subjects were considered eligible to participate if they were between 18 and 45 years of age and in good health on the basis of history, physical examination, and routine laboratory data. Female subjects of childbearing potential agreed to use an effective double-barrier birth control method from at least 1 month prior to the start of the study until 1 month after the completion of the study. Weight requirement for subjects varied with treatment panel: 50 to 90 kg for panels 1 and 2 and 60 to 90 kg for panels 3 and 4. All subjects must have been nonsmokers for ≥ 6 months.

Subjects were ineligible for enrollment if they had any ocular abnormality that might interfere with pupillometry assessment, including corrected visual acuity worse than 20/30 in both eyes (contact lenses acceptable), a current eye disorder requiring the attention of an ophthalmologist, or a history of intraocular surgery. Pregnant or breast-feeding women were excluded. Subjects with a history of neurologic or CNS disease; treated or untreated hypertension, asthma, or other pulmonary disease; major gastrointestinal abnormalities/peptic ulceration; cardiovascular, hepatic, or renal disease; drug allergy; drug or alcohol abuse; or any illness that, in the opinion of the investigator, might have confounded the results of the study or posed additional risk in administering ivermectin to the subject could not participate. Other exclusion criteria included donation of a unit of blood or participation in another clinical trial with an investigational agent within 4 weeks prior to commencement of the study, regular use of any illicit drugs, intake of excessive amounts of caffeinated coffee or beverages (> 8 cups/day), or use of prescription or nonprescription medicine that could not be discontinued 2 weeks before the start of the study. Subjects with a known hypersensitivity to any component of the ivermectin product or who had any condition that the investigator felt might interfere with participation were not eligible.

This study was conducted at Clinical Pharmacology Associates (Miami, FL) in conformance with applicable country or local requirements regarding ethical committee review, informed consent, and other statutes or regulations regarding the protection of the rights and welfare of human subjects participating in biomedical research. The study protocol and subject consent form were approved by a private, nonaffiliated institutional review committee (Southern Institutional Review Board, Inc., Miami, FL), which was properly constituted according to the applicable regulations. Written informed consent was obtained from each subject.

Study Design

This was a double-blind, placebo-controlled, multiple rising dose study in healthy adult men and women. Subjects were sequentially assigned to one of four treatment panels and were randomized to receive ivermectin or placebo within each panel (12 active, 4 placebo per panel) using a computer-generated allocation schedule. Subjects were also stratified by gender within each panel to ensure that equal numbers of sub-

Downloaded from jcp.sagepub.com at TEXAS A&M UNIV on September 19, 2011

FOI 26-3132 - Document 5

jects of each gender were assigned to each treatment regimen.

Ivermectin was administered as a fixed dose extending from 30 mg in panel 1 to 120 mg in panel 4. Doses consisted of ten to forty 3 mg tablets of ivermectin as necessary to achieve the stipulated dose. When considering the weight limitations of the protocol, this corresponded to the potential delivery of 333 μg/kg to 2000 μg/kg. Actual dose range delivered (μg/kg) in enrolled subjects in each dose group is indicated in the following descriptions of the dosing regimens. Panel 1 subjects received treatment A: ivermectin 30 mg (347-594 μg/kg) or placebo, three times a week (days 1, 4, 7), in the fasted state during study week 1. After a washout period of at least 1 week, they then received treatment E: ivermectin 30 mg (347-541 μg/kg) or placebo, single dose, in the fed state during study week 3. Panel 2 received treatment B: ivermectin 60 mg (713-1091 μg/kg) or placebo, three times a week (days 1, 4, 7), in the fasted state during study week 5. Panel 3 received treatment C: ivermectin 90 mg (1031-1466 μg/kg) or placebo, single dose, in the fasted state during study week 9. Panel 4 received treatment D: ivermectin 120 mg (1404-2000 μg/kg) or placebo, single dose, in the fasted state during study week 11.

The treatment regimens were selected based on the possibility that doses higher than 200 μg/kg would be needed to eradicate head lice. The 30 and 60 mg doses were administered to evaluate safety in potential therapeutic dose ranges for head lice treatment, spanning 347 to 1091 μg/kg for the participants in this study. The regimen for these dose levels was the maximum frequency anticipated for head lice treatment (three doses in 7 days) and allowed for assessment of possible accumulation. The 90 and 120 mg doses were evaluated only to assess toxicity and provide an additional margin of safety; therefore, these treatments were administered as single doses.

Confirmation of quantifiable pupillometry was not initially an entrance criterion for the study. However, after completion of the original 16 subjects in panel 1, it was observed that pupillometry measurements for 5 subjects were difficult to quantify due to the unexpected extreme pigmentation of the iris in this particular study population. For one of these subjects, accurate pupil measurements could not be obtained. Therefore, the protocol was amended to add an entry criterion specifying that subjects must have a quantifiable pupil measurement at the prestudy visit (1-2 weeks prior to study start). Pupillometry was added to the prestudy visit procedures to accommodate this requirement. In addition, since testing of the primary hypothesis for this study was dependent on the pupillometry measurements from this subject panel, the protocol amendment also enrolled 4 additional subjects to panel 1 to compensate for the missing data. These 4 subjects received treatment A only (30 mg or placebo, days 1, 4, 7, fasted) and were dosed concurrently with panel 2. They were not administered treatment E (30 mg or placebo, single dose, fed) because the primary hypothesis related to treatment A only. A group of 4 subjects was considered appropriate because a blocking factor of 4 was used for the allocation schedule (3 active: 1 placebo). In addition, at the time of the amendment, it was unknown if more than 1 subject would have missing data.

All treatment doses were administered in the Clinical Research Unit (CRU) under medical supervision. Before each treatment period, subjects reported to the CRU at a predetermined time the evening prior to dosing on day 1. Subjects were required to fast from all food and liquid, except water, from midnight before all treatment days. Study drug was provided as ivermectin 3 mg tablets and matching placebo tablets and was administered with a total of 16 ounces of water to accommodate the large numbers of tablets administered at the higher doses. For consistency, the same amount of water was administered for all dose levels. For treatment E, subjects consumed a standard high-fat breakfast (31.3 g protein, 57.16 g carbohydrates, 48.6 g fat, 784 kcal) beginning 20 minutes before dosing. The dose was administered within 5 minutes after completion of the meal. For all other treatments, fasting (except for water) continued on all treatment days until the 4-hour plasma sample was collected, after which subjects consumed a meal of approximately 500 calories. Subjects resumed regular meals after the 8-hour plasma sample had been collected. Standardized meals were provided in the CRU at scheduled times.

Safety monitoring included careful clinical observation for adverse experiences as well as physical examinations (1-2 weeks prestudy [PS] and 5-7 days posttreatment [PT]), neurological examinations (PS; –1, 4, and 12 h; and PT), pupillometry (PS; –1, 4, 6, and 24 h; and PT), vital signs (PS; –1, 0, 1, 2, 4, 8, and 24 h; and PT), electrocardiograms (PS, –1 and 4 h, and PT), and clinical laboratory tests consisting of a CBC, blood chemistry, and urinalysis (PS, –1 h, and PT). In the neurological exam, tests to detect signs of ivermectin toxicity were emphasized and accurately quantitated when possible (e.g., heel-toe to evaluate ataxia). Details of pupillometry are described in the next section. All adverse events were recorded. The investigator paid par-

Downloaded from jcp.sagepub.com at TEXAS A&M UNIV on September 19, 2011

ticular attention to any evidence of CNS toxicity, such as vomiting, mydriasis, or gait disturbance.

Treatment panels were dosed sequentially so that safety was established at a lower dose level (given in the fasted state) before proceeding to the next higher dose level. Safety parameters were chosen based on experience with human overdose and animal toxicity. For an individual subject, the investigator was instructed to discontinue a subject's test drug if any of the following signs or symptoms were observed postdose: one or more episodes of drug-related vomiting (excluding episodes occurring within 1 h of dosing), mydriasis (defined as absence of change in pupil size upon transition from low-light to high-light conditions during pupillometry), or gait disturbance (defined as a confirmed abnormal result from heel-toe test as compared with baseline prestudy assessment). For a dosage panel, the investigator was instructed to discontinue advancement to the next dose level if any of the following situations occurred: mydriasis or gait disturbance (as defined above for an individual subject) was observed in 1 or more subjects, a ≥ 2 mm increase in pupil diameter over baseline (predose) was observed in 2 or more subjects, or drug-related vomiting (excluding episodes occurring within 1 h of dosing) was observed in 3 or more subjects in a panel. In addition, the incidence of one or more drug-related serious adverse experiences or two or more drug-related severe adverse experiences in a panel would have warranted consideration of discontinuing dose-level advancement.

For pharmacokinetic analysis, plasma samples were collected at predefined intervals on days 1, 4, and 7 for treatments A and B and on day 1 only for treatments C, D, and E and analyzed for ivermectin concentration. The predefined intervals were predose (0 h) and at 0.5, 1, 2, 3, 4, 5, 6, 8, 10, 12, 16, 24, 36, 48, and 60 hours postdose on days 1 and 7 and predose only on day 4.

For treatments A and B, subjects remained in the CRU until the final day 7 blood sample was obtained (60 h after the day 7 dose). For treatments C, D, and E, subjects remained in the CRU until the final day 1 blood sample was obtained (60 h after the day 1 dose). Subjects returned for a posttreatment assessment 5 to 7 days following the last dose of study drug in a treatment period.

Pupillometry

To monitor for any evidence of mydriasis, this study used a method of pupillometry that had been validated internally and successfully used in a previous study of a mydriatic agent. The method accurately and reproducibly measures pupil diameter by photograph under standard lighting conditions. Photographic equipment consisted of a single-lens reflex camera (Nikon F70 camera body and Nikon 105 micro lens) with flash unit (Nikon SB23 with remote link), mounted on a support device in front of and facing the subject with the camera lens projecting through a reflective lighting screen. The subject's head was positioned on a head rest (similar to those found in a slit lamp unit). To reduce the influence of accommodation movement on the pupil, subjects focused through a hole in the reflective screen on an object 3 m beyond the camera.

All pupil measurements were made in a room equipped with black-out shades. Standard lighting conditions were created using two banks of four low-voltage tungsten lamps, projected from behind the subject onto a white screen located approximately 0.5 m in front of the subject. Dimmer switches attached to each bank of lights enabled the lamp units to be adjusted to either low-light (10-foot candles) or high-light (200-foot candles) conditions. A calibrated light meter (Gossen) placed at the temple of the subject's head, adjacent to the eye, was used to confirm that the proper light levels reached the subject's corneal plane. The left eye was photographed under both standard lighting conditions, in duplicate, at each time point prescribed by the protocol. In cases where a subject's corrected visual acuity was worse than 20/30 in the left eye, the right eye was photographed. Measurements of the maximal horizontal diameter of the pupillary area were obtained via image analysis of the developed transparencies (MCID M1 image analysis system, Imaging Research Inc., Ontario) and recorded in millimeters for statistical analysis. Photographs taken of a measuring scale (graph paper), placed at the same eye-to-camera distance used for pupil measurement, were used for calibration.

Prior to enrolling subjects into this study, pupil measurement standards and reproducibility were established at the study site. The method was tested under the same lighting conditions and in the same examination room subsequently used in performing the pupil measurements for the clinical study. Prestudy testing of the photographic measurement methodology was conducted by the same study personnel who performed pupil measurements during the study.

In addition, visual accommodation was measured predose for all subjects to obtain a baseline value (before the first dose of study drug only). Subsequently, if mydriasis was observed in a subject at any time during the study, accommodation was to be measured (as soon as possible after observation of mydriasis) to determine if there was accompanying cycloplegia.

FOI 26-3132 - Document 5

Ivermectin Assay

Plasma was separated by centrifugation from blood samples collected from the original 48 subjects on active treatment, at the time points specified above, and analyzed for ivermectin H_2B_{1a}. The additional 4 subjects added per protocol amendment were for safety assessment only, and samples from these subjects were to be assayed only in the event of a drug-related or serious adverse experience. Assay of plasma samples for ivermectin H_2B_{1a} concentration was performed by the Drug Metabolism Department, Merck Research Laboratories (West Point, PA), using a high-performance liquid chromatography (HPLC) method with fluorescence detection. The protein was removed from plasma samples by precipitation with acetonitrile. Ivermectin and the internal standard were then recovered from the matrix by liquid/solid-phase extraction on ChemElut cartridges. Reconstituted extracts were online derivatized and separated by reverse-phase HPLC and quantitated by fluorescence detection.

A standard curve of 0.5, 1, 2.5, 5, 10, 20, and 40 ng/ml ivermectin spiked into human control plasma was analyzed daily along with clinical samples. Accuracy ranged from 98.6% to 102% of nominal concentrations; precision ranged from 2.2% to 5.9% through the entire curve. Plasma quality control samples at low (1.25 ng/ml), medium (7.5 ng/ml), and high (25 ng/ml) concentrations were prepared prior to the start of the study and subjected to replicate within-day analyses (n = 5). Two high, two medium, and two low quality control samples were analyzed daily along with clinical samples to assess interday variability. Accuracy averaged 99.9%, 104.7%, and 102.6% for the low, medium, and high quality control samples, respectively. The corresponding values for precision were 7.9%, 6.1%, and 4.7%, respectively. The limit of reliable quantification for ivermectin H_2B_{1a} was 0.5 ng/ml.

Pharmacokinetic Calculations

The following pharmacokinetic parameters were evaluated: area under the plasma concentration-time curve from time 0 to infinity ($AUC_{0-\infty}$), maximum plasma concentration (C_{max}), time of occurrence for maximum (peak) plasma concentration (t_{max}), and half-life ($t_{½}$). $AUC_{0-\infty}$ was estimated by the trapezoidal method to the 60-hour point and extrapolated to infinity by the half-life estimated for that curve. C_{max} and t_{max} values were estimated by inspection of the plasma concentration-time curve. Half-life was estimated by the method of Kwan et al.[12] Accumulation ratios were approximated from ratios of $AUC_{0\text{-}60\ h}$ since these were the closest values available to the ratio of AUC_{τ} (τ = 72 h) for this study. Computed values of AUC and half-life were calculated in EXCEL (Microsoft Corporation, Redmond, WA).

Statistical Analysis

Safety

The primary parameter for the safety assessment of ivermectin was change in pupil size under high-light conditions between baseline (day 1 predose) and the approximate time of maximum drug concentration (C_{max}) on day 7 (maximum of the 4- and 6-h time points). The primary hypothesis was that oral administration of ivermectin in the fasted state, at a regimen of 30 mg for three doses over 1 week (days 1, 4, 7), does not affect the maximum pupil diameter change from baseline at high-light conditions on day 7 as compared to placebo; a mean difference of 1 mm between the 30 mg ivermectin and placebo groups was considered significant. The difference in maximum (of the 4- and 6-h time points) pupil diameter change from baseline (day 1 predose) at high-light conditions on day 7 between the groups receiving 30 mg ivermectin (in the fasted state) and placebo (pooled from treatments A and B) was assessed using an analysis of variance (ANOVA) model with gender, treatment, and gender-by-treatment interaction as factors. A 90% confidence interval for the mean difference (30 mg ivermectin [in the fasted state] vs. placebo) in maximum (of the 4- and 6-h postdose time points) pupil diameter change from baseline (day 1 predose) at high-light conditions on day 7 was calculated using the MSE from the ANOVA referencing a t-distribution. Whether or not to combine the results from males and females within each treatment was determined by assessing the gender-by-treatment interaction. The assumption of normality was tested using the Shapiro-Wilk statistic.

Given a parallel study with 12 subjects in one group (30 mg fasted) and 8 in the other (placebo) and similar between-subject variation (mean square error = 0.0361) as estimated from historical data, there is a > 99% probability that the observed 90% confidence interval for the mean difference in maximum pupil diameter change from baseline (day 1 predose) between the 30 mg ivermectin (in the fasted state) group and the placebo group would fall within the equivalence interval of (–1.0, 1.0), if the true difference was 0. Probabilities were calculated using SAS 6.12 (SAS Institute, Cary, NC).

Downloaded from jcp.sagepub.com at TEXAS A&M UNIV on September 19, 2011

Although not specified in the primary hypothesis, an analysis of the pupil diameter changes for the other 30 mg time points (days 1 and 4, high light; days 1, 4, and 7, low light) and for the other dose groups was done using the same criteria as for the primary analysis.

General safety and tolerability were assessed by examining adverse experiences and laboratory data. Adverse experiences were tabulated and summarized.

Pharmacokinetics

Estimation of the pharmacokinetic parameters of ivermectin in this four-panel, escalating dose study was accomplished by using an ANOVA model with gender, dose, and gender-by-dose interaction as factors. The analysis of the day 1 data included data from treatments A, B, C, and D. The day 7 analysis included data from only treatments A and B. Whether or not to combine the results from males and females within each treatment was determined by assessing the gender-by-dose interaction. The assumption of normality was tested using the Shapiro-Wilk statistic.

The effect of food on the pharmacokinetics of ivermectin on day 1 was estimated by comparing the natural log-transformed $AUC_{0-\infty}$ values for the 30 mg dose of ivermectin in the fed and fasted states (treatment E vs. treatment A). An ANOVA model, including treatments A and E with subject and treatment as factors, was used. A 95% confidence interval for the AUC geometric mean ratio (30 mg ivermectin fed [treatment E]/30 mg ivermectin fasted [treatment A]) was calculated using the MSE from the ANOVA referencing a *t*-distribution.

Ivermectin accumulation was assessed in the following manner: an ANOVA model including treatments A and B with dose, day, and dose-by-day interaction as factors was used to analyze the natural log-transformed $AUC_{0\text{-}60\ h}$ values. Ninety-five percent confidence intervals for the AUC geometric mean ratio (day 7, last dose/day 1, first dose) were calculated using the MSE from the ANOVA referencing a *t*-distribution for the 30 mg ivermectin fasted (treatment A) and 60 mg ivermectin (treatment B) treatment groups.

RESULTS

Subjects

Sixty-eight subjects (51 ivermectin, 17 placebo) entered the study and were sequentially assigned to one of four treatment panels. The subjects' ages ranged from 21 to 45 years, with a median of 34.5 years. Thirty-five subjects (51.5%) were male and 33 subjects (48.5%) were female. Subjects were 89.7% Hispanic, 4.4% Caucasian, 4.4% Black, and 1.5% Asian. The distribution of age, gender, and racial origin appeared to be similar across the treatment groups. Overall, the study population was generally healthy with few medical problems. Secondary diagnoses were similar across the treatment groups, consisting primarily of a history of cesarean section or tubal ligation.

Safety

Pupillometry

Table I summarizes pupil diameter changes from baseline (day 1 predose) in all study groups postdose (days 1, 4, and 7, when measured) at both low-light and high-light conditions. The mean pupil diameter in the ivermectin 30 mg (fasted) treatment regimen decreased slightly from baseline for both males (–0.119 mm) and females (–0.107 mm). The mean pupil diameter in the placebo regimen remained virtually unchanged from baseline for both males (–0.002 mm) and females (0.035 mm). Gender effect was not significant at the 95% confidence level from an analysis of variance (ANOVA) model with gender, treatment, and gender-by-treatment interaction as factors.

The difference in pupil diameter change from baseline (day 1 predose) at high-light conditions on day 7 between the groups receiving 30 mg ivermectin in the fasted state and placebo (pooled from treatments A and B) was –0.013. The 90% confidence interval (–0.239, –0.021) for the difference falls within the equivalence interval (–1.0, 1.0), indicating that the ivermectin 30 mg regimen in the fasted state had an equivalent mydriatic effect as compared with placebo, according to prespecified criteria. Exploratory examination of pupil size of all other groups on days 1, 4, and 7 at both high-light and low-light conditions confirmed that there was no evidence of a mydriatic effect.

Adverse Events

Clinical adverse experiences reported during the study are presented in Table II. Of the 51 subjects who received ivermectin, 12 subjects (24%) reported at least one clinical adverse experience. This rate was similar to that observed in the placebo group (6 subjects, 35%). In addition, there was no consistent trend in the incidence of adverse experiences indicative of a dose response. All clinical adverse experiences were transient and mild, and no adverse experience recurred with repeated dosing. The most commonly reported adverse experiences were headache, nausea, dizziness, and rash, occurring in both ivermectin- and placebo-treated

a. Excluding 1 subject from panel 1 whose pupillometry measurements were not quantifiable. For day 1, pooled from treatments A, B, C, and D, $n = 16$; for days 4 and 7, pooled from treatments A and B, $n = 8$.

b. One subject discontinued prior to receiving fed treatment and did not contribute to the corresponding analysis.

c. The 90% confidence interval (CI) for the primary endpoint (difference in mean change between ivermectin 30 mg, fasted and placebo at high-light conditions on day 7). The 90% CI falls within the predetermined equivalence interval of (–1.0, 1.0) mm.

subjects. Seven ivermectin-treated subjects (14%) and 3 placebo-treated subjects (18%) had drug-related clinical adverse experiences. None of the subjects discontinued due to clinical adverse experiences. None of the clinical adverse experiences was serious.

Two subjects experienced laboratory adverse experiences, both in the 30 mg ivermectin group. A 37-year-old female developed increased alanine transaminase (ALT) to approximately 2.5 times normal on day 14 and elevated gamma-glutamyl transferase (GGT) to approximately 4 times normal on day 18. ALT returned to normal on day 23, but GGT remained mildly elevated (no baseline values obtained). Further hepatic evaluation revealed cholelithiasis (a gallbladder filled with stones). The investigator rated both laboratory adverse experiences as possibly related to study drug. The second subject, a 25-year-old male, developed hematuria that resolved after passing a kidney stone, and the event was evaluated as definitely not related to study drug.

Two subjects developed elevated liver function tests (LFTs) at least two times the upper limit of normal. The first subject was in the 30 mg ivermectin group and developed increased ALT and GGT levels, which were reported as laboratory adverse experiences (described above). The second subject, a 38-year-old male on placebo treatment, developed increased aspartate transaminase (AST) and ALT levels to approximately two times normal on day 7. The investigator considered these elevations to be not clinically significant.

Two subjects discontinued the study. One subject in the 30 mg ivermectin group discontinued due to a laboratory adverse experience (37-year-old female described above). One subject in the placebo group was lost to follow-up.

Pharmacokinetics

General

Pharmacokinetic results ($AUC_{0-\infty}$, C_{max}, t_{max}, and half-life) are shown in Table III. In addition, box plots of $AUC_{0-\infty}$ by ivermectin dose (day 1, fasted only) are displayed in Figure 1. For single doses of 30 to 120 mg administered in the fasted state, the AUC and C_{max} of ivermectin increase with increasing dose and appear generally dose proportional in this range. A high variability in absorption is apparent from examination of

Although a subject may have had two or more adverse experiences, the subject is counted only once within a category. The same subject may appear in different categories. All body systems are listed in which at least 1 subject had an adverse experience.

standard deviations and from the overall trends in AUC and C_{max} with increasing dose. Specifically, AUC and C_{max} do not appear to increase between the doses of 60 and 90 mg. However, a nearly proportional increase is seen with the 120 mg dose, indicating that absorption is not saturated in this range. t_{max} and half-life were generally invariant across the dose range, as would be expected from linear kinetics. There was no significant trend indicative of a gender effect.

Accumulation

The mean plasma concentration profiles on days 1 and 7 following multiple doses of 30 and 60 mg ivermectin given in the fasted state are shown in Figure 2. The geometric mean ratio (GMR) of the $AUC_{0\text{-}60\ h}$ of ivermectin on day 7 to the $AUC_{0\text{-}60\ h}$ on day 1 was calculated for assessing accumulation. GMRs (day 7/day 1) were 1.24 and 1.40 for the ivermectin 30 and 60 mg doses, respectively. This result suggests minimal accumulation of drug with day 1, 4, and 7 dosing, consistent with a short half-life relative to the dosing interval (72 h). The 95% confidence interval was (0.80, 1.92) and (0.91, 2.18) for the 30 mg (in the fasted state) level and the 60 mg level, respectively.

Food Effect

The effect of food on the pharmacokinetics of ivermectin was estimated by comparing the mean natural log-transformed $AUC_{0\text{-}\infty}$ values for the 30 mg dose of ivermectin in the fed and fasted states (treatment E vs. A). The mean plasma concentration profiles in the fed and fasted states are presented in Figure 3. The geo-

a. As prespecified in the protocol amendment, the plasma samples from the 3 additional subjects receiving 30 mg ivermectin treatment were not analyzed and did not contribute to the pharmacokinetic analyses.
b. One subject discontinued prior to receiving fed treatment and did not contribute to the corresponding analysis.
c. Arithmetic mean (standard deviation).
d. Geometric mean.
e. Harmonic mean.

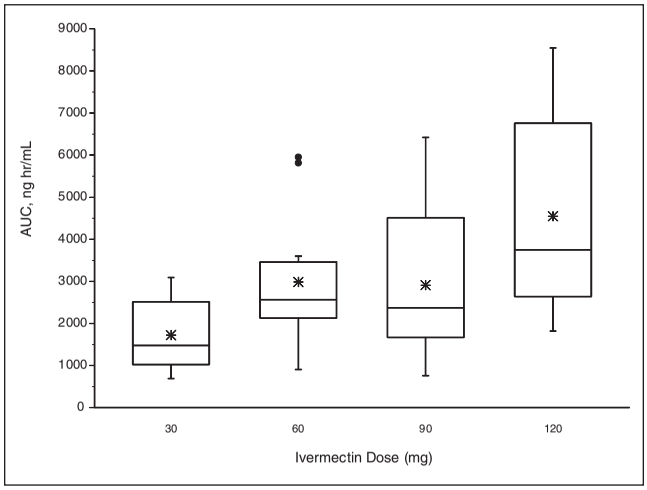

Figure 1. Box plots of AUC by ivermectin dose (day 1, fasted only). The box represents the middle half of the data with the bottom and top of the box representing the 25th and 75th percentiles. The median is portrayed by a horizontal line segment within the box, and the mean is represented by an asterisk. The height of the box is multiplied by 1.5 to determine the height of the "step." The upper vertical line extends up to the highest data value within the step, and the lower vertical line extends down to the lowest data value within the step. Circles represent data values that exceed the 25th and 75th percentiles by more than the height of the step. Mean AUC does not appear to increase between the doses of 60 and 90 mg, largely due to the influence of the two outliers in the 60 mg dose group. A nearly proportional increase is seen with the 120 mg dose, indicating that absorption is not saturated in this range.

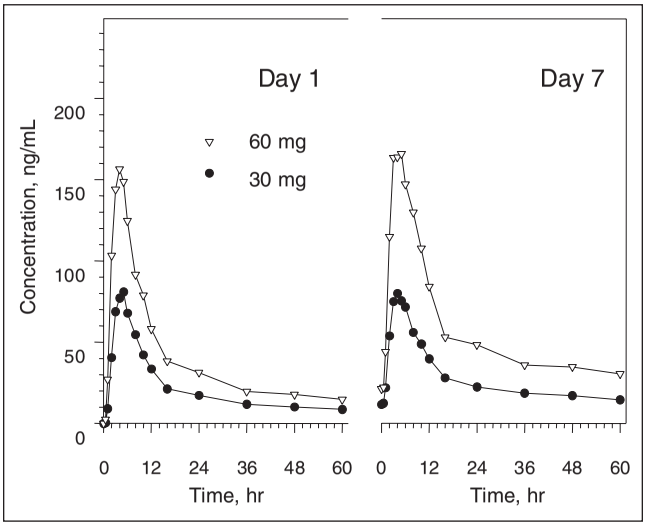

Figure 2. Mean plasma concentration (ng/ml) profiles of ivermectin on days 1 and 7 following multiple oral doses of 30 and 60 mg given fasted on days 1, 4, and 7.

metric mean ratio of $AUC_{0-\infty}$ values (fed/fasted) was 2.57. The 95% confidence interval was (2.16, 3.05).

DISCUSSION

This study was designed primarily to evaluate the safety and tolerability of oral ivermectin to support its

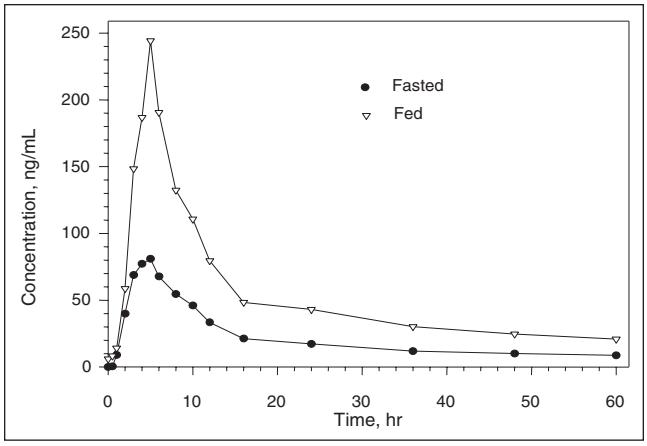

Figure 3. Mean plasma concentration (ng/ml) profiles of ivermectin following single oral doses of 30 mg (fed and fasted administration).

use for the treatment of head lice infestation. Head lice predominantly affect school-age children. However, for both ethical and practical reasons, it was felt appropriate to conduct this study in healthy adult subjects. Extensive safety data are available for ivermectin, primarily at dose levels of 150 to 200 µg/kg. There also are published studies conducted at doses higher than 200 µg/kg for the treatment of internal parasites.[13-21] The present study expanded the safety data available for ivermectin at higher doses in subjects without internal parasitic infestations. The safety and tolerability of ivermectin were evaluated from two perspectives in this study: (1) assessment of CNS effect, the sole target of previously documented ivermectin toxicity, and (2) assessment of the general toxicity of ivermectin. No CNS toxicity was detected in the study, and ivermectin was generally well tolerated. Therefore, this study demonstrates that ivermectin is well tolerated in healthy subjects and provides additional evidence that the more severe reactions observed in the treatment of onchocerciasis and lymphatic filariasis are most likely due to the death of the organisms.[22]

A second purpose of the study was to collect additional pharmacokinetic data on ivermectin. Specifically, the study was designed to extend the kinetic understanding of this drug beyond the doses (up to 15 mg) examined previously, to document its behavior when administered in repeated doses in the manner contemplated for use against head lice, and to examine the effect of a high-fat meal on absorption.

Safety and Tolerability

Specific signs or symptoms of CNS toxicity were based on those determined in previous high-dose animal studies and observations of human overdose and included emesis, mydriasis, and ataxia. Mydriasis was chosen as the endpoint for the primary hypothesis since it can be accurately quantitated through pupillometry. Pupillometry is a simple, accurate, and reproducible method to measure pupil diameter quantitatively, which was validated internally prior to use in this study. It was observed in the first treatment panel that measurement of pupil diameter was difficult in persons with extremely dark iris color. However, with the addition of a screening evaluation at the prestudy visit, this difficulty was resolved.

No indication of CNS toxicity associated with oral ivermectin was observed for any of the doses administered in this study. This was most strongly supported by the absence of a mydriatic effect using quantitative pupillometry. The primary analysis of the pupillometry data was in the 30 mg ivermectin treatment group since this fixed dose spanned the range (in µg/kg) most likely to be employed in head lice therapy. Comparison of pupil size to baseline was made after the third dose, when maximum drug concentration was likely to be present if any accumulation occurred. Considering this criterion, the change in pupil size following 30 mg ivermectin administration was not different from that observed with placebo. Escalation to a single dose of up to 2 mg/kg, 10 times the approved dose, was also unassociated with any mydriatic effect. This supports the safety of ivermectin in the anticipated dosage range for head lice and provides a significant margin of safety.

Ivermectin was generally well tolerated. There were no serious clinical or laboratory adverse experiences. Clinical adverse experiences were similar between the ivermectin and placebo groups.

Specific adverse experiences to consider are those within the gastrointestinal and nervous systems since emesis, ataxia, and mydriasis are cardinal signs of ivermectin toxicity. Three of 51 subjects in the ivermectin-treated groups (1 fecal abnormality, 1 nausea, 1 vomiting) and 1 of 17 subjects in the placebo groups (1 nausea) experienced gastrointestinal adverse experiences. The adverse experience of vomiting occurred in a subject administered 60 mg of ivermectin on day 4. The event was evaluated as not related to ivermectin and did not occur after the day 1 dose, nor

Downloaded from jcp.sagepub.com at TEXAS A&M UNIV on September 19, 2011

FOI 26-3132 - Document 5

did it recur with the day 7 dose. Six of the 51 subjects in the ivermectin-treated groups (4 headache, 1 anxiety, 1 dizziness) and 3 of the 17 subjects in the placebo groups (2 headache, 1 dizziness and headache) experienced nervous system adverse experiences. No increase in any adverse experiences was noted with dose escalation, and no adverse experience recurred with repeated dosing. Of note, no adverse experiences were reported in the subjects who received 120 mg of ivermectin.

Two subjects developed increases in LFTs during the study, 1 on ivermectin 30 mg and 1 on placebo. The subject on active drug was subsequently identified as having cholelithiasis, which was unlikely to be related to acute treatment with ivermectin. No other clinically significant LFT abnormalities occurred despite dose escalation to 120 mg. These data, together with extensive animal and human exposure, suggest that routine monitoring of laboratory values is unnecessary at the dose levels anticipated for head lice treatment.

Pharmacokinetics

Pharmacokinetic parameters of ivermectin following single doses were consistent with previous observations[1] and with linear behavior up to single doses of 120 mg. Substantial variability in absorption was apparent across doses, but this phenomenon was attributable to absorption rates of < 50% in the fasted state and to the parallel panel design of the study.

Absorption of ivermectin was significantly higher when administered following a high-fat meal, approximately 2.5 times that in the fasted state. Although the effect of food on absorption of ivermectin had not been previously studied, this result was not unexpected. When the drug was administered in a hydroalcoholic solution,[1] a similar increase in bioavailability was observed (compared to administration as a tablet). The extent of agreement between these results suggests that the poor solubility in water of the lipophilic ivermectin molecule limits absorption, but agents that help to solubilize the molecule (such as alcohol or bile) increase absorption of the drug. However, the standard high-fat meal is not representative of typical food ingestion. Furthermore, it is reassuring that despite a substantial increase in the AUC of ivermectin with administration of a high-fat meal, no toxicity was noted.

The apparent half-life for ivermectin identified in the product label is 16 hours or longer. The overall estimate from this study (approximately 18 h) is slightly longer. Half-life estimates varied somewhat with dose and means of administration from approximately 15 hours in fed subjects given 30 mg ivermectin doses to approximately 20 hours in the same group following administration of 30 mg ivermectin in the fasted state. Since the bioavailability is substantially higher when the drug is administered in the fed state, and a shorter half-life was observed in this state, it is possible that the half-life observed following oral administration is influenced by slow absorption of the drug, rather than being a true estimate of elimination half-life.

The accumulation observed following administration of drug every fourth day was rather modest and consistent with a moderate elimination half-life. The apparent change observed between the 30 and 60 mg dose regimens is likely attributable to the significant variability in absorption and the small number of subjects studied. In fact, accumulation ratios for both doses were statistically indistinguishable from 1. No significant pharmacokinetic differences were observed between men and women. No information has been gathered on the pharmacokinetics of ivermectin in children, but given the generally consistent kinetic behavior among many different species of widely distributed body sizes, it is expected that the pharmacokinetics in children will be consistent with those in adults.

In summary, the safety profile generated in this study supports the use of oral ivermectin at the approved dose levels and at dose levels being considered for the treatment of head lice. Furthermore, a significant safety margin is demonstrated. However, studies in the pediatric population are necessary to confirm safety in children at higher dose levels. The pharmacokinetic parameters are consistent with those previously established, with the exception of a slightly longer half-life. A significant food interaction was demonstrated.

We would like to acknowledge the following individuals for their considerable contributions to this study: Mr. Manuel Pinto and the staff of Clinical Pharmacology Associates for their invaluable help with study conduct and patient recruitment, Ms. Geraldine Bolden of Merck Research Laboratories for her excellent work in conducting the image analysis of the pupillometry transparencies, Ms. Mitra Asgary of Merck Research Laboratories for her contribution in analyzing the pharmacokinetic samples, and Dr. Stephanie Larouche, formerly of Merck Research Laboratories, for her encouragement and scientific guidance.

Summary

Ivermectin is an FDA-approved drug for a parasitic disease that has broad antiviral activity. This study aims to analyse the efficacy of ivermectin in improving the Covid-19 outcomes. We systematically searched the PubMed, Europe PMC and ClinicalTrials.gov database using specific keywords related to our aims until 10th May 2021. All published randomized clinical trial studies on Covid-19 and ivermectin were retrieved. The quality of the study was assessed using Jadad scale assessment tool for clinical trial studies. Statistical analysis was done using Review Manager 5.4 software. A total of 19 studies with 2768 Covid-19 patients were included in this meta-analysis. This meta-analysis showed that ivermectin was associated with reduction in severity of Covid-19 (RR 0.43 [95% CI 0.23–0.81], $p = 0.008$), reduction of mortality (RR 0.31 [95% CI 0.15–0.62], $p = 0.001$), higher negative RT-PCR test results rate (RR 1.23 [95% CI 1.01–1.51], $p = 0.04$), shorter time to negative RT-PCR test results (mean difference [MD] −3.29 [95% CI −5.69, −0.89], $p = 0.007$), higher symptoms alleviations rate (RR 1.23 [95% CI 1.03–1.46], $p = 0.02$), shorter time to symptoms alleviations (MD −0.68 [95% CI −1.07, −0.29], $p = 0.0007$) and shorter time to hospital discharge (MD −2.66 [95% CI −4.49, −0.82], $p = 0.004$). Our study suggests that ivermectin may offer beneficial effects towards Covid-19 outcomes. More randomized clinical trial studies are still needed to confirm the results of our study.

KEYWORDS
covid-19, ivermectin, treatment

Abbreviations: CI, confidence intervals; Covid-19, coronavirus disease 2019; FDA, The United States Food and Drug Administration; FiO2, fractional concentration of oxygen inspired air; ICU, intensive care unit; IgE, immunoglobulin E; IgG1, immunoglobulin G1; IL-1, interleukin 1; IL-6, interleukin 6; IL-8, interleukin 8; IL-10, interleukin 10; LPS, lipopolysaccharide; NCP, nucleocapsid protein; NF-kB, nuclear factor-kappa B; PaO2, partial pressure of arterial oxygen; PRISMA, Preferred Reporting Items for Systematic Reviews and Meta-Analyses; RR, risk ratio; RT-PCR, reverse transcriptase-polymerase chain reaction; SARS, severe acute respiratory syndrome; SARS-CoV-2, SARS-coronavirus-2; SD, standard deviations; TNF-α, tumour necrosis factor-α.

1 | INTRODUCTION

At the end of 2019, the first cases of a newly discovered acute respiratory illness, named coronavirus disease 2019 (Covid-19), were reported in Wuhan, China. As of 22 December 2020, a total of about 75.1 million cases and 1,680,794 deaths were identified across the world.[1] Covid-19 has various clinical manifestations, ranging from mild respiratory manifestations such as fever, cough, anosmia to severe or life-threatening conditions such as shock, respiratory distress, arrhythmia, sepsis, loss of consciousness.[2–5] Previous published meta-analysis studies have identified several comorbidities,[6–10] home medications[11,12] and laboratory values[13,14] which are associated with severe outcomes and the risk of dying from Covid-19. To reduce the severity and mortality rate of Covid-19, many attempts have been undertaken, including to discover the potential therapy. There were many therapeutic agents evaluated in clinical trials and suggested for Covid-19 therapy, such as remdesivir, dexamethasone, colchicine and tocilizumab.[15–17] These drugs may be beneficial for Covid-19 treatment because of their effects on the cytokine storm syndrome which may cause progression of the disease into more severe outcome.[18] Ivermectin is a drug that is used to manage parasitic infections with broad-spectrum effectivity and has been approved by The United States Food and Drug Administration (FDA). It has been long known for the treatment of onchocerciasis, strongyloidiasis, lymphatic filariasis and/or scabies.[19] Besides its potential as anti-parasitic agents, several articles have demonstrated the antiviral activity of ivermectin against various viruses.[20–22] Ivermectin has also been suggested to offer benefit in improving the outcomes from Covid-19 because of its action on prevention of severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2) proteins from entering the host cell nucleus in vitro.[23] Nonetheless, the evidence concerning the advantage of ivermectin, specifically in patients with SARS-CoV-2 infections, remains unclear. The objective of this meta-analysis is to explore the potential advantage of ivermectin to improve the outcomes of Covid-19 based on available randomized clinical trial studies.

2 | MATERIALS AND METHODS

2.1 | Eligibility criteria

The protocol of this study has been registered in PROSPERO (CRD42021230652). Included articles in this study are selected as potentially fulfilling the entry criteria: comply with the PICO framework (P: Population—Covid-19 patients; I: Intervention—ivermectin medications; C: Comparison or Control—a group of patients who did not receive ivermectin, only receive standard of care therapy or any other medications as control/placebo; O: Outcome—severe Covid-19, mortality, negative RT-PCR test results rate, time to negative RT-PCR test results, symptoms alleviations rate, time to symptoms alleviations and time to hospital discharge), randomized clinical trial articles were included, with the condition that the full-text paper was published. The exclusion criteria are any studies other than randomized clinical trials, studies reported other than in English language, studies focussing on the populations of young age (below 18 years old) and women during their pregnancy.

2.2 | Search strategy and study selection

The papers were searched systemically and obtained from PubMed, Europe PMC and ClinicalTrials.gov. Search terms used include 'ivermectin' OR 'stromectol' OR 'stromectal' OR 'sklice' OR 'ivomec' OR 'mectizan' AND 'SARS-CoV-2', OR 'coronavirus disease 2019' OR 'Covid-19' in a time range from 20th December 2019 until the present time (10th May 2021) with English-language restriction. The details regarding the search strategy used in this study are listed in Table 1. Studies evaluating the use of ivermectin therapy in patients with Covid-19, with a valid outcome of interest definition, were included in this study. Potential eligible articles searching was done by analysing the papers cited by authors of all identified studies. The search strategy was presented in the Preferred Reporting Items for Systematic Reviews and Meta-Analyses diagram.

2.3 | Data extraction and quality assessment

Two authors performed the data extraction process. An extraction form was developed to list the essential information about the study and its population characteristic, ivermectin dose, time to ivermectin administration, control group medications, the number of patients receiving ivermectin and the control group, also each outcome of Covid-19 patients' proportion.

This study's outcomes of interest are rate of negative RT-PCR test results, rate of symptoms alleviations, time to negative RT-PCR test results, time to symptoms alleviations, time to hospital discharge, severe Covid-19 and mortality. The rate of negative RT-PCR test results was described by the number of patients who were converted from positive to negative RT-PCR test results at the end of follow-up. The rate of symptoms alleviations was described by the number of patients who have symptoms improvement or who are symptoms-free at the end of follow-up. Time to negative RT-PCR test results was defined by the time needed for the conversion from positive RT-PCR to negative RT-PCR test results. Time to symptoms alleviations was defined by the time needed for the patients' symptoms to be disappeared. Time to hospital discharge was defined by the duration needed for patients to be discharged from the hospital. Severe Covid-19 manifestation was the one having either of the mentioned features at the time of, or after, admission: (1) respiratory distress (≥30 breaths per min); (2) oxygen saturation at rest ≤93%; (3) ratio of the partial pressure of arterial oxygen (PaO2) to a fractional concentration of oxygen inspired air (FiO2) ≤300 mmHg; or (4) critical complication (respiratory failure, septic shock and or multiple

drop-outs of each study were evaluated. Then, studies were scored from zero to seven. A study ranked as a high-quality study if the score was >4.[25]

2.4 | Statistical analysis

Review Manager 5.4 (Cochrane Collaboration) software was used to perform the meta-analysis. Mantel–Haenszel's formula was done to obtain risk ratios (RR) and its 95% confidence interval (CI), while Inverse Variance method was used to obtain mean difference (MD) and its standard deviations (SD). The heterogeneity was assessed by using the I^2 statistic with a value of <25%, 26%–50% and >50% were considered as low, moderate and high degrees of heterogeneity, respectively. The results were considered significant when the two-tailed p-value was ≤0.05. The formula by Wan X et al. was used for meta-analytical pooling, if the available data were in medians and interquartile ranges to be converted to mean and SD.[26] The qualitative risk of publication bias was assessed with Begg's funnel plot analysis.

3 | RESULTS

3.1 | Study selection and characteristics

In electronic databases, 1612 studies were found. A total of 1237 records remained following the elimination of duplicates. By screening the titles/abstracts and matching the inclusion and exclusion criteria, 1142 studies were removed. Among the 95 evaluated full-text articles for its eligibility, 47 articles were excluded due to unposted results (still recruiting or withdrawn), 20 articles because the study designs are not randomized clinical trial study (non-randomized clinical trial, cross-sectional, observational studies, case-series), 5 articles because of no control/comparison group in the studies, 3 articles because of they do not mention the criteria of our outcome of interest and 1 article because the article was not in English. At last, the meta-analysis included 19 randomized clinical trial studies[27–45] with a total of 2768 Covid-19 patients (Figure 1). Amongst them, 10 were open-label randomized clinical trial studies, while the rest nine studies were double-blind randomized clinical trial studies. Table 2 presents the characteristic of the studies.

3.2 | Quality of study assessment

Jadad scale assessments were used to assess clinical trial studies (Table 3). Seven out of 19 included studies were graded 'high quality', while the other 12 studies were graded 'moderate quality'. To sum up, all papers were decent to be further analysed using meta-analysis.

FOI 26-3132 - Document 5

TABLE 3 Quality appraisal of studies included in the meta-analysis using Jadad scale assessment

Pott-Junior H et al. 2021[42]	2	2	0	1	5	High quality
Ravikirti et al. 2021[43]	2	2	1	1	6	High quality
Shahbaznejad L et al. 2021[44]	0	1	1	1	3	Moderate quality
Shouman W et al. 2020[45]	1	1	0	1	3	Moderate quality

Note: We used Jadad scale to assess the included studies. Points were determined as follows: (I) Random allocation: computer-generated random numbers, 2 points; not described, 1 point; inappropriate method, 0 point. (II) Allocation concealment: central randomization, sealed envelopes or similar, 2 points; not described, 1 point; inappropriate or unused, 0 point. (III) Blindness: identical placebo tablets or similar, 2 point; inadequate or not described, 1 point; inappropriate or no double blinding, 0 point. (IV) Withdrawals and drop-outs: numbers and reasons are described, 1 point; not described, 0 point. The Jadad scale score ranges from 1 to 7; higher score indicates better RCT quality. If a study had a modified Jadad score >4 points, it was considered to be of high quality; if the score was 3–4 points, it was moderate quality; and if the score was <3 points, it was low quality.

3.3 | Ivermectin and outcomes

3.3.1 | Severe Covid-19

Eight studies (n = 1638) reported on the severe Covid-19 outcome. Our pooled analysis showed that ivermectin administration was associated with reduction of severe Covid-19 outcome (RR 0.43 [95% CI 0.23–0.81], $p = 0.008$, $I^2 = 65\%$, random-effect modelling; Figure 2a).

3.3.2 | Mortality

Eight studies (n = 1726) reported on the mortality outcome. Our pooled analysis showed that ivermectin administration was associated with reduction of mortality from Covid-19 (RR 0.31 [95% CI 0.15–0.62], $p = 0.001$, $I^2 = 40\%$, random-effect modelling; Figure 2b).

3.3.3 | Negative RT-PCR test results rate

Nine studies (n = 1205) reported on the negative RT-PCR test results rate outcome. Our pooled analysis showed that ivermectin administration was associated with higher rate of negative Covid-19 RT-PCR test results (RR 1.23 [95% CI 1.01–1.51], $p = 0.04$, $I^2 = 91\%$, random-effect modelling; Figure 2c).

3.3.4 | Time to negative RT-PCR test results

Six studies (n = 782) reported on the time to negative RT-PCR test results outcome. Our pooled analysis showed that ivermectin administration was associated with shorter time to negative Covid-19 RT-PCR test results (MD −3.29 (95% CI −5.69, −0.89), $p = 0.007$, $I^2 = 96\%$, random-effect modelling; Figure 2d).

3.3.5 | Symptoms alleviations rate

Eight studies (n = 1535) reported on the symptoms alleviations rate outcome. Our pooled analysis showed that ivermectin administration was associated with higher rate of symptoms alleviations (RR 1.23 [95% CI 1.03–1.46], $p = 0.02$, $I^2 = 85\%$, random-effect modelling; Figure 2e).

FOI 26-3132 - Document 5

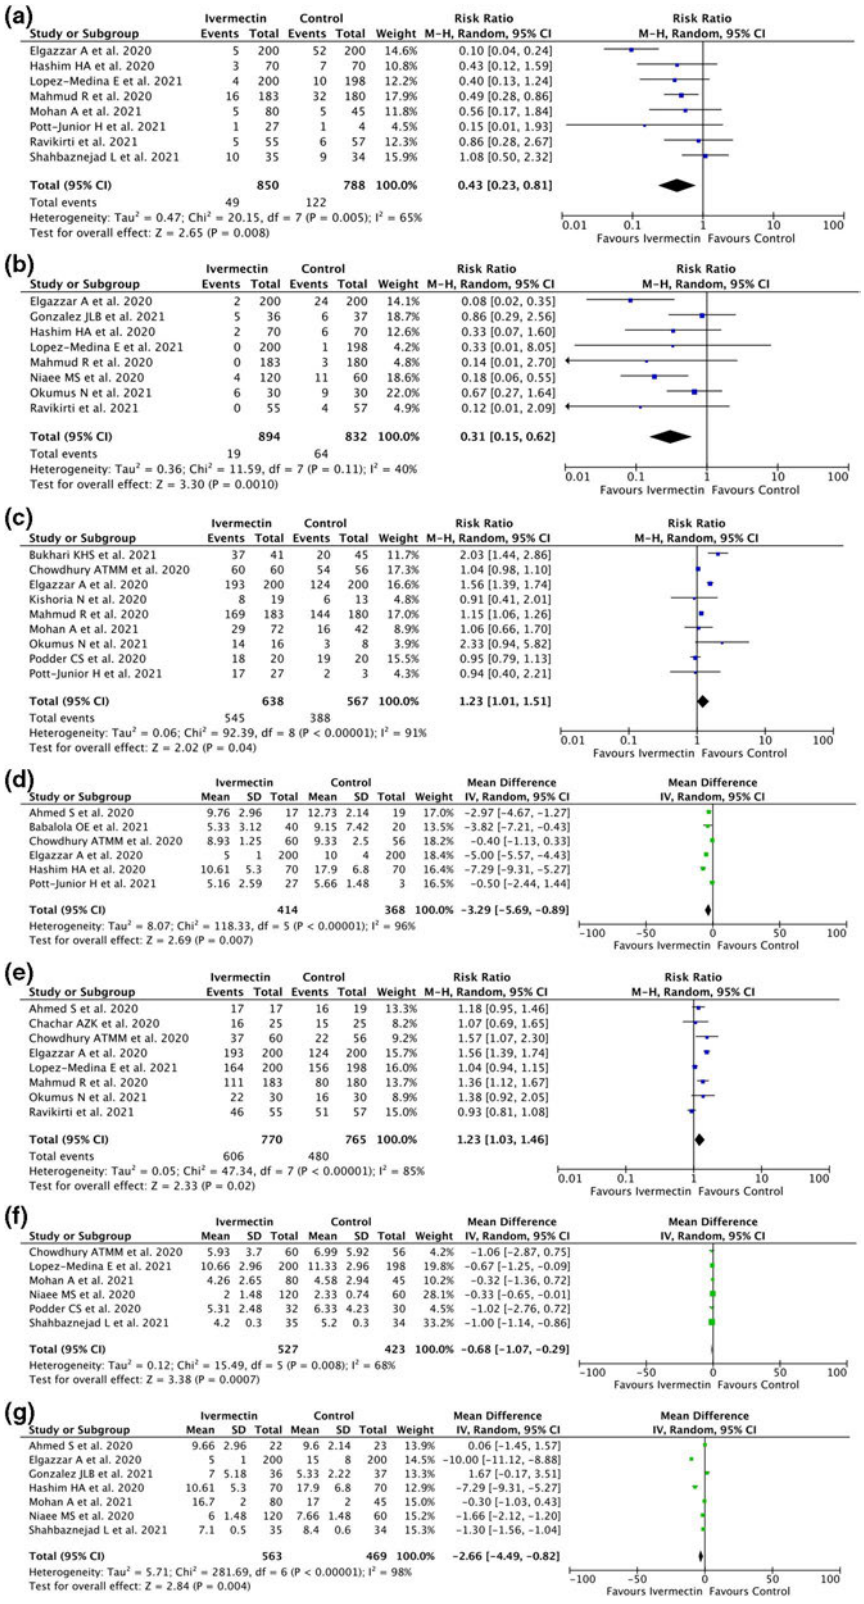

FIGURE 2 Forest plot that demonstrates the association of ivermectin administration with severe Covid-19 (a), mortality (b), negative RT-PCR test results rate (c), time to negative RT-PCR test results (d), symptoms alleviations rate (e), time to symptoms alleviations (f) and time to hospital discharge (g) outcomes

FOI 26-3132 - Document 5

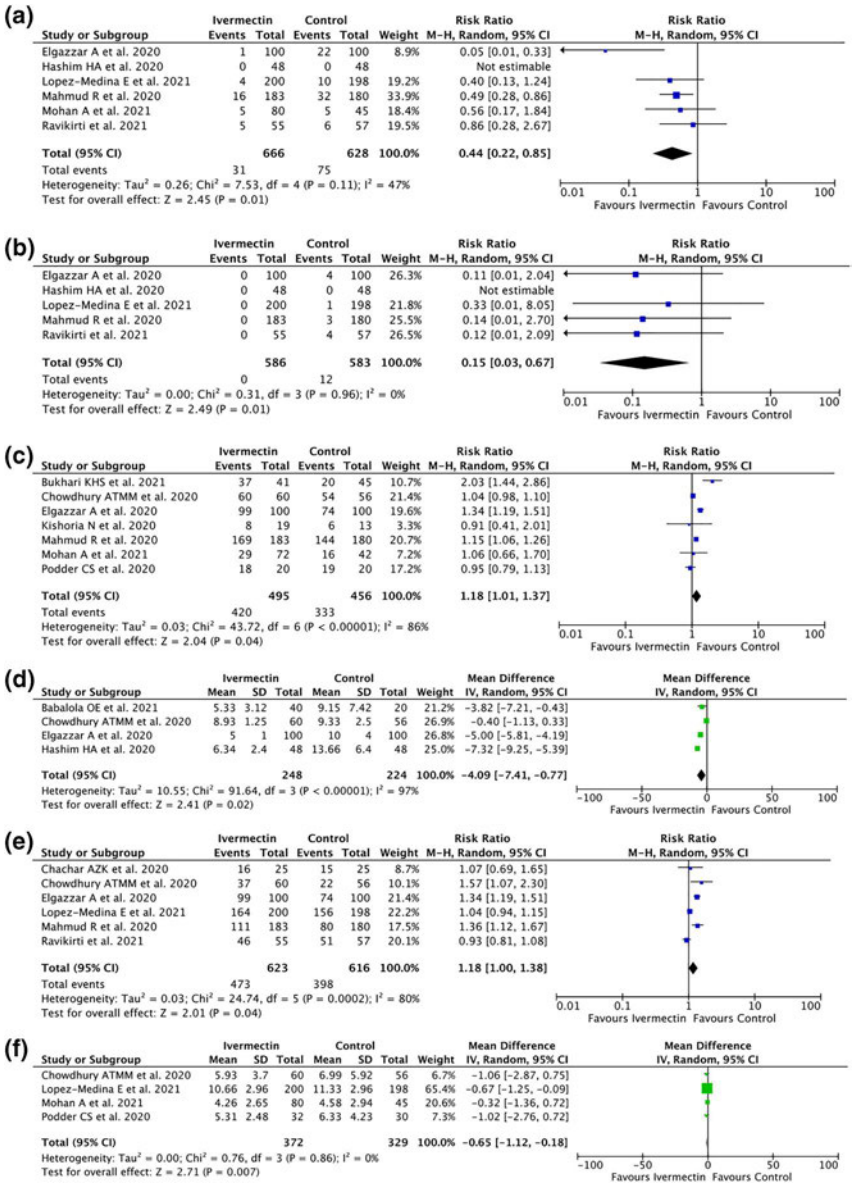

FIGURE 3 Subgroup analysis in mild to moderate patients that demonstrates the association of ivermectin administration with severe Covid-19 (a), mortality (b), negative RT-PCR test results rate (c), time to negative RT-PCR test results (d), symptoms alleviations rate (e) and time to symptoms alleviations (f) outcomes

3.3.6 | Time to symptoms alleviations

Six studies (n = 950) reported on the time to symptoms alleviations outcome. Our pooled analysis showed that ivermectin administration was associated with shorter time to symptoms alleviations (MD −0.68 (95% CI −1.07, −0.29), p = 0.0007, I^2 = 68%, random-effect modelling; Figure 2f).

3.3.7 | Time to hospital discharge

Seven studies (n = 1,032) reported on the time to hospital discharge outcome. Our pooled analysis showed that ivermectin administration was associated with shorter time to hospital discharge (MD −2.66 (95% CI −4.49, −0.82), p = 0.004, I^2 = 98%, random-effect modelling; Figure 2g).

3.4 | Subgroup analysis

Subgroup analysis revealed that ivermectin administration in mild to moderate patients showed a lower RR, therefore was associated with lower severity (n = 1294; RR 0.44 [95% CI 0.22–0.85], p = 0.01, I^2 = 47%, random-effect modelling; Figure 3a) and mortality (n = 1169; RR 0.15 [95% CI 0.03–0.67], p = 0.01, I^2 = 0%, random-effect modelling; Figure 3b) outcomes when compared with severity (n = 313; RR 0.41 [95% CI 0.10–1.59], p = 0.20, I^2 = 83%, random-effect modelling; Figure 4a) and mortality (n = 377; RR 0.41 [95% CI 0.16–1.04], p = 0.06, I^2 = 58%, random-effect modelling) outcomes (Figure 4b) in severe patients.

On the other side, subgroup analysis also revealed that ivermectin administration in severe patients showed a higher RR and higher MD in terms of negative RT-PCR test results rate (n = 224; RR 1.90 [95% CI 1.56–2.31], p < 0.00001, I^2 = 0%, random-effect

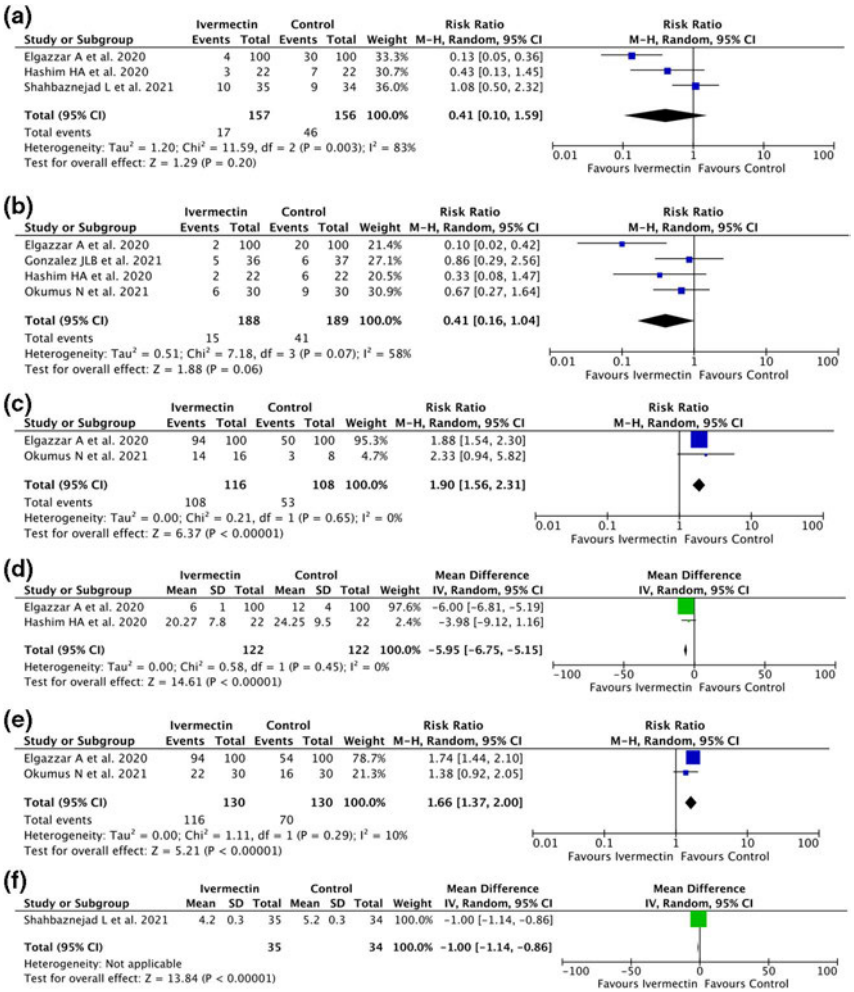

FIGURE 4 Subgroup analysis in severe patients that demonstrates the association of ivermectin administration with severe Covid-19 (a), mortality (b), negative RT-PCR test results rate (c), time to negative RT-PCR test results (d), symptoms alleviations rate (e) and time to symptoms alleviations (f) outcomes

modelling; Figure 4c), time to negative RT-PCR test results (n = 244; MD −5.95 (95% CI −6.75, −5.15), p < 0.00001, I^2 = 0%, random-effect modelling; Figure 4d), symptoms alleviations rate (n = 260; RR 1.66 [95% CI 1.37–2.00], p < 0.0001, I^2 = 10%, random-effect modelling; Figure 4e) and time to symptoms alleviations (n = 69; MD −1.00 [95% CI −1.14, −0.86), p < 0.00001, I^2 = 0%, random-effect modelling; Figure 4f) when compared with those outcomes in mild to moderate patients (negative RT-PCR test results rate, n = 951 [RR 1.18 (95% CI 1.01–1.37), p = 0.04, I^2 = 86%, random-effect modelling; Figure 3c], time to negative RT-PCR test results, [n = 472; MD −4.09 (95% CI −7.41, −0.77), p = 0.02, I^2 = 97%, random-effect modelling; Figure 3d], symptoms alleviations rate [n = 1239; RR 1.18 (95% CI 1.00–1.38), p = 0.04, I^2 = 80%, random-effect modelling; Figure 3e] and time to symptoms alleviations [n = 701; MD −0.65 (95% CI −1.12, −0.18), p = 0.007, I^2 = 0%, random-effect modelling; Figure 3f]).

3.5 | Publication bias

Funnel plot analysis showed a relatively symmetrical inverted-plot for the negative RT-PCR test results rate (Figure 5c), time to negative RT-PCR test results (Figure 5d), symptoms alleviations rate (Figure 5e), time to symptoms alleviations (Figure 5f) and time to hospital discharge (Figure 5g), showing no indication of publication bias. Funnel plot analysis showed an asymmetrical inverted-plot for the severe Covid-19 (Figure 5a) and mortality outcome (Figure 5b), showing some indication of publication bias. However, because the number of included studies in each outcomes are fewer than 10 studies, the funnel plots and statistical tests for detecting publication bias are not much reliable when compared with whenever there are more than 10 included studies in each outcomes.[46,47]

4 | DISCUSSION

According to our pooled analysis, ivermectin was discovered to have an association with a higher negative RT-PCR test results rate, shorter time to negative RT-PCR test results, higher symptoms alleviations rate, shorter time to symptoms alleviations, shorter time to hospital discharge and reduction in the severity and mortality from Covid-19. Our subgroup analysis also showed that the benefits of ivermectin therapy in reducing the severity and mortality outcomes from Covid-19 were more prominent when administered into mild to

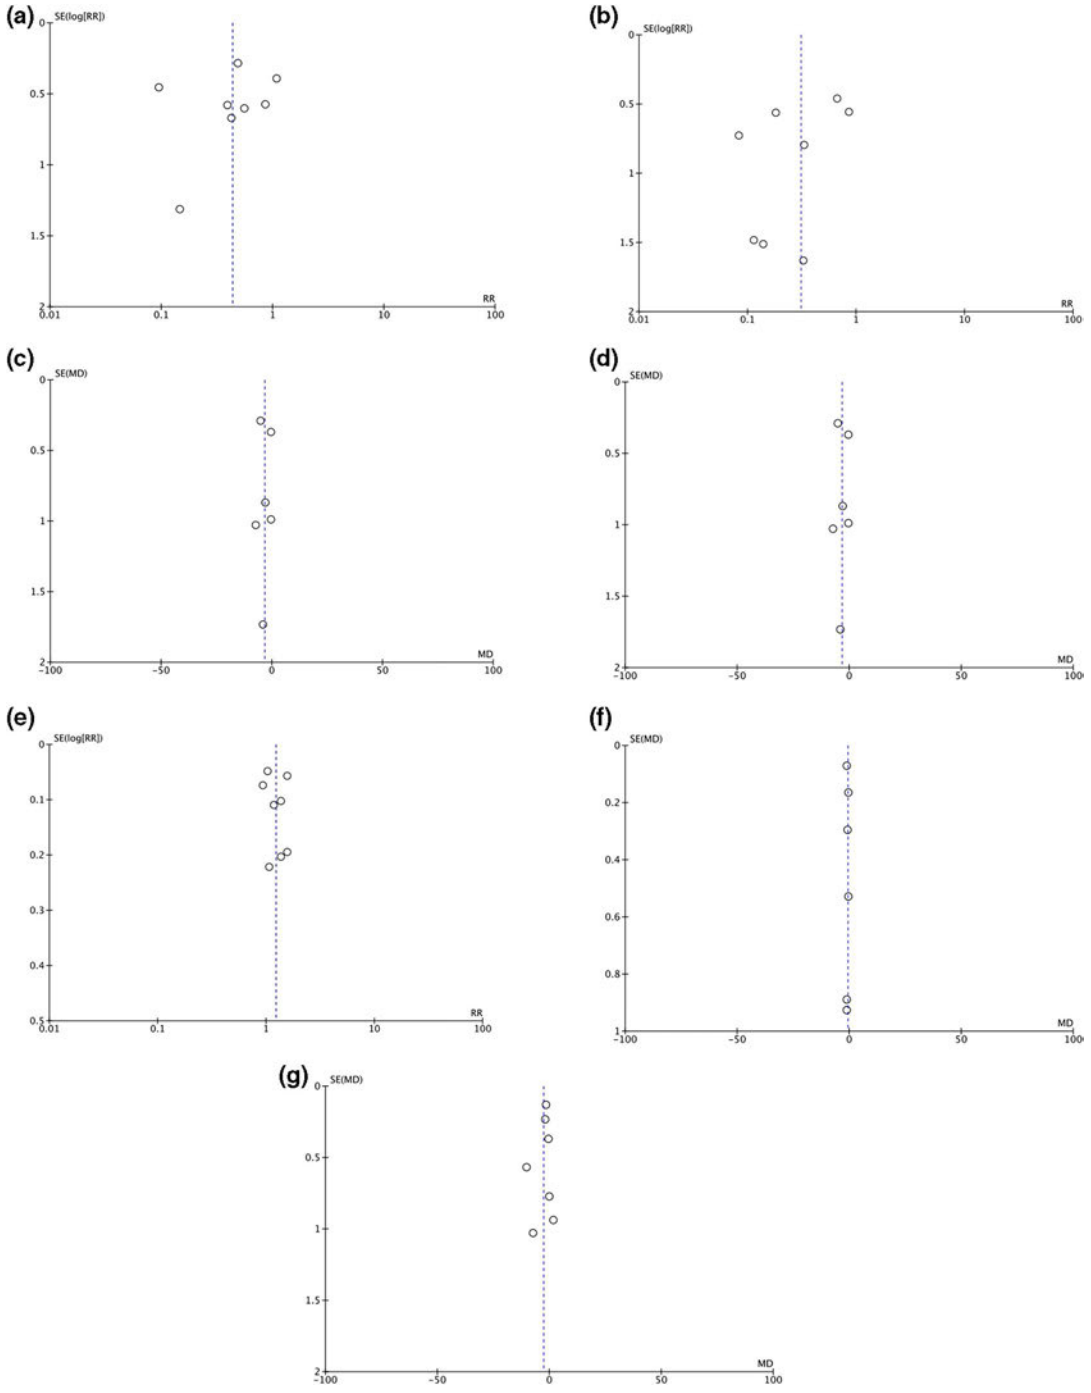

FIGURE 5 Funnel plot analysis for the association of ivermectin administration with severe Covid-19 (a), mortality (b), negative RT-PCR test results rate (c), time to negative RT-PCR test results (d), symptoms alleviations rate (e), time to symptoms alleviations (f), and time to hospital discharge (g) outcomes

moderate patients, compared with in severe patients. On the other side, the benefits of ivermectin therapy in increasing negative RT-PCR test results rate, shortening time to negative RT-PCR test results, increasing symptoms alleviations rate and shortening time to symptoms alleviations were more apparent in severe patients when compared with in mild to moderate patients.

A few arguments might explain these findings. The sequestration of the SARS-CoV-2 viral nucleocapsid protein (NCP) into the host nucleus through the nuclear-pore-complex is a vital step in viral pathogenesis and defence against host immune response.[48] Ivermectin can selectively inhibit the host importin α/β transporter protein which decreases translocation (shuttling) of SARS-CoV-2 NCP from the cytoplasm to the nucleus, alteration of NCP distribution will lead to viral propagation disruption and survival.[23] The in vitro study by Caly et al.[23] has proved that giving ivermectin in one dose was able to reduce the viral RNA load by 99.98% at 48 h and

replication of an Australian isolate of SARS-CoV-2 in Vero/hSLAM cells by 5000-folds. Therefore, it has potent effects in altering disease progression and spread. These in vitro findings were further supported with the results from a double-blind, placebo-controlled, randomized clinical trial study, showing that patients who received ivermectin 400 μg/kg single dose have a lower median viral load at Day 4 (161,000 vs. 493,500 copies/ml) and Day 7 post-treatment (1018 vs. 23,550 copies/ml). The differences were found, rising from a threefold decrease on the fourth day to about 18-fold lower on the seventh day when compared with placebo.[49] Second, the pathophysiologic process which underlies severe Covid-19 involves hyperinflammatory response and accumulation of cytokines, called a cytokine storm. A meta-analysis study has demonstrated that severe Covid-19 patients tend to produce higher cytokine levels such as interleukin-6 (IL-6), IL-8, IL-10 and tumour necrosis factor-α (TNF-α), in comparison to non-severe cases.[50] On the other side, an anti-inflammatory effect was also demonstrated in ivermectin, both in vivo and in vitro studies. Ivermectin can reduce the IL-1, IL-6, TNF-α production and suppressing lipopolysaccharide-induced nuclear factor-kappa B translocation.[51] The suppression of mucus due to hypersecretion in the respiratory tract, the reduction of immune cell recruitment, and a decrease in the production of cytokines and immunoglobulin E/immunoglobulin G1 in bronchoalveolar lavage of experimental mice, were found as a consequence of 2 mg/kg of ivermectin administration.[52] These findings suggest that ivermectin has an anti-inflammatory effect on the lung tissue, besides at the systemic level, which might help to reduce the severity and prevent mortality from Covid-19.

This study has several limitations. First, significant heterogeneities were found on most of the outcomes of interests included in this study. This was probably caused by the difference in the given ivermectin doses and the medications used as a standard of care or placebo. Second, the total number of patients included in this study was relatively small because at this time, ivermectin is still considered as new repurposed drug for Covid-19 where early trials still show conflicting results and there is still no meta-analysis study to support its efficacy, therefore it may be difficult to collect the participants and receiving their consent to participate in the trials. Third, we include some pre-print studies to minimize the risk of publication bias; however, the authors have made exhaustive efforts to ensure that only sound studies were included, and we expect that most of those studies currently available in pre-print form will eventually be published and that we will identify them through ongoing electronic literature surveillances. We hope that this study can give further insight into the management of Covid-19 patients.

5 | CONCLUSION

Our meta-analysis of randomized clinical trial studies indicates that ivermectin administration had an association with favourable outcomes of Covid-19, compromising of higher rate of negative RT-PCR test results, shorter time to negative RT-PCR test results, higher rate of symptoms alleviations, shorter time to symptoms alleviations, shorter time to hospital discharge, reduction in the severity and mortality rate from Covid-19. This study suggests that ivermectin may be the potential therapeutic agents for the managements of Covid-19 to give better outcomes for the patients. However, more randomized clinical trial studies are still necessary and encouraged to be done for confirming the results of our study. Finally, ivermectin should be considered as an essential drug for future Covid-19 therapy models.

Abstract

Objectives: COVID-19 patients suffer from the lack of curative therapy. Hence, there is an urgent need to try repurposed old drugs on COVID-19. **Methods**: Randomized controlled study on 70 COVID-19 patients (48 mild-moderate, 11 severe, and 11 critical patients) treated with 200ug/kg PO of Ivermectin per day for 2-3 days along with 100mg PO doxycycline twice per day for 5-10 days plus standard therapy; the second arm is 70 COVID-19 patients (48 mild-moderate and 22 severe and zero critical patients) on standard therapy. The time to recovery, the progression of the disease, and the mortality rate were the outcome-assessing parameters. **Results:** among all patients and among severe patients, 3/70 (4.28%) and 1/11 (9%), respectively progressed to a more advanced stage of the disease in the Ivermectin-Doxycycline group versus 7/70 (10%) and 7/22 (31.81%), respectively in the control group ($P>0.05$). The mortality rate was 0/48 (0%), 0/11 (0%), and 2/11 (18.2%) in mild-moderate, severe, and critical COVID-19 patients, respectively in Ivermectin-Doxycycline group versus 0/48 (0%), and 6/22 (27.27%) in mild-moderate and severe COVID-19 patients, respectively in standard therapy group ($p=0.052$). Moreover, the mean time to recovery was 6.34, 20.27, and 24.13 days in mild-moderate, severe, and critical COVID-19 patients, respectively in Ivermectin-Doxycycline group versus 13.66 and 24.25 days in mild-moderate and severe COVID-19 patients, respectively

in standard therapy group (P<0.01). **Conclusions:** Ivermectin with doxycycline reduced the time to recovery and the percentage of patients who progress to more advanced stage of disease; in addition, Ivermectin with doxycycline reduced mortality rate in severe patients from 22.72% to 0%; however, 18.2% of critically ill patients died with Ivermectin and doxycycline therapy. Taken together, the earlier administered Ivermectin with doxycycline, the higher rate of successful therapy.

Keywords: Ivermectin, Doxycycline, COVID-19, Coronavirus, SARS-CoV-2

Introduction

Since December 2019, the world has been facing unprecedented health caused by global spread of a novel coronavirus, SRARS-CoV-2 which causes respiratory, and multi-organ viral infection, called COVID-19. The pandemic of COVID-19 resulted in 35 million infections and more than one million deaths till the date of writing this article [1]. Almost all patients start as mild-moderate disease; however, about 15% of them progress within 5-14 days post infection to a more advanced stage of the disease, being severe and critical patients [2]. The highest risk patients have been shown to be elderly, obese, diabetic, immunosuppressed, or those with cardiovascular diseases [3, 4].

The main problem of COVID-19, there is no curative therapy till now. And the vaccine development takes time. Even after developing a successful vaccine, SARS-CoV-2 seems to induce a short lasting humeral immunity, 3-12 months only. Therefore, in the coming years when COVID-19 will be converted to seasonal endemic viral infection, a reliable therapy is still needed along with working vaccines [5].

From December 2019 till September 2020, no single drug was found to be a silver bullet for COVID-19. COVID-19 starts as respiratory viral infection but in some patients progress to severe viral pneumonia and very dangerous immune deregulation condition called cytokine storm which if is not promptly treated, it might result in acute respiratory distress syndrome (ARDS), multi-organ failure, lethal

coagulopathies and death [2, 4, 6]. Therefore, potent antiviral therapy and immunomodulatory therapy for COVID-19 patients are desperately needed.

Ivermectin reduced viral load of SARS-CoV-2 *in vitro* by 5000 folds within 48h [7]. Moreover, several previous reports revealed antiviral activity of Ivermectin on Dengue HIV, Yellow fever, West Nile, Hendra, Newcastle, and Zika viruses [8-10]. Furthermore, several observational studies and real-world clinical practice showed that Ivermectin is effective in treating COVID-19 patients at both mild-moderate and severe phases of the disease [11-14]; accordingly, it is thought that Ivermectin might possess antiviral as well as immunomodulatory activity [12-14]. Ivermectin is most probably a host-specific antiviral drug and it acts as a specific inhibitor of importin α/β-mediated nuclear import inhibiting replication of several viruses such as HIV-1, Zika and dengue viruses [10]. It is thought that Ivermectin might inhibit SARS-CoV-2 using the same mechanism [7]. In addition, there have been several reports revealed that Ivermectin acts as anti-inflammatory and immunomodulatory agent and it can curb over-reacting innate and cellular immune responses [8, 15]. This explains how Ivermectin could alleviate symptoms of COVID-19 patients at viral replication phase (the first 7-10 days of infection) as well as the later hyperinflammatory phase [7-10].

Doxycycline is a broad spectrum antibiotic with reported antiviral activities on several viruses including SARS-CoV-2 [16-18]. The mechanism of the antiviral effects of tetracycline derivatives might be due to transcriptional upregulation of intracellular zinc finger antiviral protein which serves for encoding genes in host cells [19]. Doxycycline acts as an ionophore for zinc facilitating zinc entry into human cells and increasing cytoplasmic zinc concentration; high intracellular zinc levels are inhibitory to the replication of RNA viruses in cytoplasm of the cells by inhibiting RNA-depndent RNA polymerase enzyme [20]. Moreover, doxycycline has immune dampening effect making it useful to ease over-reacting immune systems [21].

In an attempt to find an effective therapy to COVID-19 patients, the current clinical trial was set up to test the combinational therapy of Ivermectin and Doxycycline in treating COVID-19 patients at different stages of the disease.

Patients and methods

Patients

One hundred forty (140) COVID-19 patients at different stages of the disease were included in this study. Half of them (70 patients) received Ivermectin with Doxycycline and standard care while the other half (70 patients) received the standard care only. The patients were recruited in Alkarkh and Alforat hospitals in Baghdad city in the duration from July 1st to September 30th. The recruited patients were either outpatients or inpatients, according to the severity of the disease. Mild-moderate patients were outpatients while severe and critical patients were all inpatients. All of the recruited COVID-19 patients were diagnosed by clinical, radiological and laboratory PCR testing. Alike, recovery of COVID-19 patients was based on the disappearance of symptoms, clearance of radiological chest x-ray or Ct-scans, and getting negative PCR results.

The classification of COVID-19 patients to mild-moderate, severe, and critical was carried out according to the WHO guidelines. Ivermectin-Doxycycline group consisted of 48 mild-moderate, 11 severe and 11 critical patients while the control group consisted of 48 mild-moderate and 22 severe patients. For ethical basis, no critical patient recruited in this study was allocated to the control group; all of critical patients were allocated to the Ivermectin-Doxycycline group. The classification of the recruited patients was based on the stage of the disease at the first day of recruitment; the designated therapy of the current study was initiated at the first day of recruitment. Inclusion criteria of the patients enrolled in the clinical trial were those who were symptomatic for no more than three days for mild-moderate cases, no more than two days after being severe cases, and no more than one day after being critical cases. The purpose behind this was to assess Ivermectin-Doxycycline therapy versus standard care therapy at the beginning of each stage of the disease. The recruited patients were monitored till recovery or death.

The present study was approved by the ethical and scientific committee in Baghdad-Alkarkh General Directorate of under the approval number BKH-CT-016.

Randomization of patients

COVID-19 patients were randomly allocated to one of the study groups depending on a simple method. Patients recruited at dates with odd number were allocated to

medRxiv preprint doi: https://doi.org/10.1101/2020.10.26.20219345; this version posted October 27, 2020. The copyright holder for this preprint

Ivermectin-Doxycycline group while other patients were allocated to the control group. Inside each group, maximal limit of 48 mild-moderate patients and 22 severe and/or critical patients were allowed. The randomization process as well as the patients records for disease progression, recovery, and clinical or laboratory testing were supervised by the health authority of Alkarkh Health General Directorate in Baghdad city.

Protocols of therapy

Ivermectin-Doxycycline group

Ivermectin 200ug/kg PO per day for two days, and in some patients who needed more time to recover, a third dose 200ug/kg PO per day was given 7 days after the first dose. Doxycycline 100mg capsule PO every 12h per day was given for 5-10 days, based on the clinical improvement of patients. In addition, standard care was given to the patients of Ivermectin-Doxycycline group based on the clinical condition of each patient.

Control group: The patients in this group received only standard care which included all or some of the following, according to the clinical condition of each patient.

Standard care

- Acetaminophen 500mg on need
- Vitamin C 1000mg twice/ day
- Zinc 75-125 mg/day
- Vitamin D3 5000IU/day
- Azithromycin 250mg/day for 5 days
- Oxygen therapy/ C-Pap if needed
- Dexamethazone 6 mg/day or methylprednisolone 40mg twice per day, if needed
- Mechanical ventilation, if needed

Outcome-assessing parameters of the disease progression or recovery

medRxiv preprint doi: https://doi.org/10.1101/2020.10.26.20219345; this version posted October 27, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

FOI 26-3132 - Document 5

Three parameters used in the present study were to assess the disease progression or recovery in COVID-19 patients who received standard care only compared to patients who received standard care with Ivermectin and Doxycycline therapy. These three parameters are:

1. Time to recovery, if any. It is the time between taking therapy till recovery.
2. Percentage of patients who progress to a more advanced stage of the disease after at least 3 days of giving therapy. For example, a patient was recruited as mild-moderate; after 3 days from starting therapy, the patient progressed to severe stage; such patient is considered a progressing patient even though she or he was under treatment.
3. Mortality rate among mild-moderate, severe, or critical patients in Ivermectin-Doxycycline group versus those in control group.

Statistical analysis

Data was processed according to the normality tests results; parametric data were represented with mean values and non-parametric data were represented with median values. Percentage of mortality rate was calculated for each group of the study. Odds ratio and chi-square were used to test the strength and significance of association. P values less than 0.05 was considered significant

Results

Patients characteristics

Mean age of the recruited patients was 48.7±8.6 year with range 16 to 86 year; patients in Ivermectin-Doxycycline and control groups were age- and sex- matched. Mean age of Ivermectin-Doxycycline group was 50.1±9.3 year with 53% males and 47% females while mean age of control group patints was 47.2±7.8 year with 51% male and 49% females ($P>0.05$). In both groups, the median post-infection day for starting therapy was 3 days in mild-moderate, 7 days in severe, and 8.5 days in critical cases. The mean weight of Ivermectin-Doxycycline and control patients was 79.6±13.2 kg and 71.5±11.9 Kg, respectively ($P>0.05$).

Time to recovery

medRxiv preprint doi: https://doi.org/10.1101/2020.10.26.20219345; this version posted October 27, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

FOI 26-3132 - Document 5

The time to recovery was shown to be significantly reduced in the Ivermectin-Doxycycline compared to the control group; mean recovery time in Ivermectin-Doxycycline group was 10.61± 5.3 days versus mean recovery time in control group, 17.9±6.8 days ($P<0.05$). Hence, using Ivermectin along with Doxycycline reduced mean time to recovery up to 7 days. By analyzing the mean time to recovery in mild-moderate, severe, or critical patients in each group, it was shown that the mean time to recovery in Ivermectin-Doxycycline group was 6.34±2.4, 20.27±7.8, 19.77±9.2 days, respectively versus 13.66±6.4, 24.25±9.5 days, in control group, respectively ($P<0.01$). Accordingly, Ivermectin-Doxycycline reduced recovery time about 7.32 days in mild-moderate, and 3.98 or roughly 4 days in severe patients (Table 1).

Progression of the disease

The rate of progression of the disease, or the deterioration of the clinical condition of the patients despite of taking standard care with/without Ivermectin-doxycycline therapy, was shown to be varied between the two groups studied. At beginning, no single mild-moderate patient in both groups progressed to a more advanced stage of the disease. For severe COVID-19 patients, 1/11 (9%) in Ivermectin-Doxycycline group versus 7/22 (31.81%) in control group progressed to more advanced stage of the disease, namely being classified as critical cases ($P>0.05$). Thus, Ivermectin-Doxycycline protocol was shown to lower progression of the disease in severe patients if given within the first two days of the severe stage of the disease. For critical patients, ethically, critical patients were not included in the control group as critical patients need to receive all possible medications for saving their lives; hence, it was not possible to compare the rate of progression of the disease in critical patients between the two studied groups (Table 1).

Mortality rate

The mortality rate was shown to be 0/48 (0%) in mild-moderate patients in both groups. Nevertheless, the mortality rate was diminished to 0/11 (0%) in Ivermectin-Doxycycline group compared to 6/22 (27.27%) ($P=0.052$). For critical patients, Ivermectin-Doxycycline did not prevent death in those patients as mortality rate was shown to be 2/11 (18.2%), (Table 1). No critical patients were included in the control group to compare with; however, it is obvious that 18.2% of death in critical COVID-19 patients received Ivermectin-Doxycycline is much lower than the death rate in

critical cases of COVID-19 in Iraq that might reach above 50% (based on real-world data not official published data).

Table 1: Parameters of the study outcomes between Ivermectin-Doxycycline and control groups

Outcome parameter	Subgroup of patients	Ivermectin-Doxycycline	Control	P value
Time to recovery (day)	Total	10.61± 5.3	17.9±6.8	<0.0001
	Mild-moderate	6.34±2.4	13.66±6.4	<0.0001
	severe	20.27±7.8	24.25±9.5	0.29
	critical	19.77±9.2	/	
Rate of progression of disease number/total (%)	Total	3/70 (4.28%)	7/70 (10%)	0.19 (OR*=0.4, P=0.2)
	Mild-moderate	0/48 (0%)	0/48 (0%)	1
	severe	1/11 (9%)	7/22 (31.81%)	0.15 (OR=0.21, P=0.17)
	critical	2/11 (18.2%)	/	
Mortality rate	Total	2/70 (2.85%)	6/70 (7.14)	0.14 (OR=0.31, P=0.16)
	Mild-moderate	0/48 (0%)	0/48 (0%)	1
	severe	0/11 (0%)	6/22 (27.27%)	0.052 (OR=0.11, P=0.14)
	critical	2/11 (18.2%)	/	

OR*: Odds ratio

Discussion

Finding an effective therapy for COVID-19 is an ultimate goal for health bodies all over the world. The problem of the standard care for COVID-19 patient is not curative; however, the current situation is much better than the first months of the pandemic , after introducing steroid therapy for severe/critical patients and high doses of vitamin D3, vitamin C and Zinc for mild-moderate cases [22]. COVID-19 is a multiphasic disease starting with virus replicative phase lasting for 7-10 days then, in some patents, is followed with hyperinflammatory phase and cytokine storm where the most fatalities occur [2, 4]. If the viral and hyperinflammatory phases of the disease were not addressed early and properly, the patient might progress to ARDS

which is almost fatal [2,6]. Hence, antiviral, anti-inflammatory, and immunomodulatory medications are necessary to stop the vicious progression of COVID-19 from mild-moderate to severe and to stop the clinical deterioration of the already severe patients.

Accordingly, Ivermectin and Doxycycline were used in this study because both drugs have shown antiviral and immunomodulatory activities [8-15]. Moreover, Doxycycline is a broad spectrum antibiotic which tackles the problem of secondary bacterial infection in COVID-19 patients [16-20]. Both drugs are FDA approved and have a high historical safety record [8,10,16, 19]; moreover, no interaction is known between Ivermectin and Doxycycline or between Ivermectin-Doxycycline and any of the medications given in the standard care. By contrary, for example, Azithromycin with Hydroxychloroquine are known to interact adversely for prolonging QT interval of cardiogram which might lead to serious complications [23].

Using FDA approved and safe antiviral and immunomodulatory medications for COVID-19 is scientifically justified for untreatable disease like COVID-19. It has been found that most of COVID-19 patients who progress to severe/critical disease have high viral load of SARS-CoV-2 and over-reacting immune response [24]. Therefore, reducing the viral load and dampening the immune response and inflammatory cytokines are necessary to save patients' lives.

The findings of the current trial showed that Ivermectin-Doxycycline reduced the mean time to recovery from 17.9 to 10.61 days in the recruited COVID-19 patients. Alike, for mild moderate patients, Ivermectin-Doxycycline reduced mean time to recovery from 13.66 to just 6.34 days with reduction in time up to 7.32 days. Nevertheless, Ivermectin-Doxycycline reduced the mean time to recovery in severe patients only 4 days, from 24 to 20 days. Based on these findings, Ivermectin and Doxycycline protocol proves to be effective in speeding up recovery in both mild-moderate outpatients and severe inpatients. This has a tremendous effect on lowering the burden of the disease, minimizing chances of developing immune deregulation, and freeing as quickly as possible hospital beds to other patients. This adds further evidence that Ivermectin-Doxycycline could exert both antiviral and immunomodulatory actives. Several observational studies showed that Ivermectin

medRxiv preprint doi: https://doi.org/10.1101/2020.10.26.20219345; this version posted October 27, 2020. The copyright holder for this preprint

FOI 26-3132 - Document 5

with/without Doxycycline shortens the time needed to recover COVID-19 patients and Ivermectin is beneficial for mild-moderate as well as severe patients [8-15].

In the current study, Ivermectin-Doxycycline arm lowered the rate of progression of the severe patients from 31.81% to as low as 9%. More interestingly Ivermectin-Doxycycline abolished death in severe patients, 0% mortality rate, compared to control arm, 27.27%. It is noteworthy to mention that the non-progression of the disease and the zero mortality in mild-moderate patients in both arms of the study might be attributed to the early diagnosis and therapy; moreover, the current standard care has become more effective than that used in the early months of the pandemic. However, larger study population is required to trace differences in the disease progression or the mortality rate of mild-moderate patients of COVID-19 taking Ivermectin-Doxycycline compared to patients taking standard care.

Accordingly, the present clinical trial reveals that Ivermectin-Doxycycline might stop disease progression and reduce death rate in severe patients of COVID-19. An observational preprint study conducted in Florida showed that Ivermectin cuts mortality rate of severe COVID-19 patients from 80.7% to 38.8% [25]. Interestingly, both Ivermectin and Doxycycline concentrations in the tissue of the lung have been estimated 2 times more than that in plasma [26, 27]. Therefore, their antiviral and anti-inflammatory effect on pulmonary tissues is expected to be prominent. These findings provide evidence that Ivermectin might be a potent immunomodulatory in addition to being antiviral agent. Nevertheless, these observational findings still need confirmation by a large randomized controlled study.

In fact, the observed benefits of Ivermectin-Doxycycline on the enrolled COVID-19 patients cannot be separated from the effect of the standard care, including Vitamin D and C, Zinc, and steroids, which was given concomitantly. Therefore, giving Ivermectin-Doxycycline along with Zinc, Vitamins D and C, and steroids at the viral and/or the hyperinflammatory phase of the disease seems clinically of benefit. This might shape the future most-fit combinational therapy of COVID-19 patients to minimize as could as possible the death rate and to decrease the duration and the progression of the disease.

Aims: Ivermectin is a safe, inexpensive and effective early COVID-19 treatment validated in 20+ random, controlled trials. Having developed combination therapies for *Helicobacter pylori*, the authors present a highly effective COVID-19 therapeutic combination, stemming from clinical observations. **Patients & methods:** In 24 COVID-19 subjects refusing hospitalization with high-risk features, hypoxia and untreated moderate to severe symptoms averaging 9 days, the authors administered this novel combination of ivermectin, doxycycline, zinc and vitamins D and C. **Results & conclusions:** All subjects resolved symptoms (in 11 days on average), and oxygen saturation improved in 24 h (87.4% to 93.1%; $p = 0.001$). There were no hospitalizations or deaths, less than ($p < 0.002$ or 0.05, respectively) background-matched CDC database controls. Triple combination therapy is safe and effective even when used in outpatients with moderate to severe symptoms.

Clinical Trial Registration: NCT04482686 (ClinicalTrial.gov)

First draft submitted: 15 January 2022; Accepted for publication: 25 January 2022; Published online: 9 February 2022

Keywords: coronavirus • COVID • doxycycline • ivermectin • SARS-CoV-2 • zinc

There is currently a lack of effective treatments for early or ambulatory patients with COVID-19. Patients testing positive are sent home to isolate without specific treatment prescribed. However, there is growing evidence that certain repurposed drugs with good safety profiles, taken early, can significantly improve outcomes and even avoid or delay the need for immune-modulators, antiplatelet/antithrombotic therapy and the administration of oxygen [1].

Among the most extensively studied of such COVID-19 therapeutics is ivermectin (IVM), a drug that has been used safely in 3.7 billion doses worldwide since 1987 [2–4]. Recently, Dr Satoshi Omura, the 2015 Nobel Prize co-laureate for the discovery of IVM, and colleagues comprehensively reviewed studies to date on IVM activity against COVID-19, concluding that the evidence demonstrated such efficacy [4]. IVM used alone has been tested in more than 20 randomized, controlled trials (RCTs) for COVID-19 treatment, with statistically highly significant clinical benefits in almost all of these and an average of 62% reduction in risk of death [5]. Five such studies for IVM treatment of COVID-19 recently published in top-tier medical journals have all shown multiple clinical benefits for IVM versus controls, most of these with high statistical significance on the order of $p < 0.002$ [6–10]. At much greater than the standard single antiparasite dose of 200 μg/kg, IVM is well tolerated [11,12] and has been used in RCTs for COVID-19 treatment at cumulative doses of 1500 μg/kg [13] and 3000 μg/kg [14,15] over 4 or 5 days either without or with mild and transient adverse effects. Not surprisingly, IVM has become extensively used in the prevention and early disease management of COVID-19, particularly in non-Western countries.

Despite this strong evidence of clinical benefit in COVID-19 for IVM therapy, variation in therapeutic regimens, especially with respect to the addition of a broad-spectrum antibiotic and zinc, has led to confusion as to how best to manage acute infections. Indeed, the most impressive of the early ambulatory multidrug therapies, claiming

FOI 26-3132 - Document 5

87% and 75% reductions in hospitalization and deaths, respectively, both with a p-value of 0.001, in 869 high-risk subjects, left optimal management strategy unclear due to a mixed use of IVM and hydroxychloroquine (HCQ) [15]. There is an immediate need for an effective, safe and practically available combination therapy formulation based on the best available data.

At a cellular level, IVM modulates communication between the cytoplasm and nucleus, creating a hostile environment for assemblage of the virus while reducing cytokine-mediated inflammation. In addition, IVM inhibits pathology following infection with the COVID-19 virus, by specifically blocking the binding of the virus 'spike' protein to the ACE2 receptor. Finally, IVM has been associated with favorable changes in cellular innate immunity [16].

The authors' group has been systematically developing antiviral drug combinations for COVID-19 and found IVM to be particularly effective as a co-therapy for use early in COVID-19 to shorten the time to symptom resolution and to prevent hospitalization. IVM used alone can at times be only partially effective but not curative [1,6,17]. Thus, the authors chose a combination of safe and widely available medications, approved for other indications and without drug–drug interactions or QT prolongation and one that inhibits intracellular virus replication and possesses some anti-inflammatory properties.

The use of combination therapy for intracellular bacterial infections is not new and has been used successfully to treat tuberculosis, *Helicobacter pylori* (*H. pylori*) infections, leprosy and intracellular viral infections such as hepatitis B and C, in which a single component of the combination therapies is rarely curative. In some viral infections such as HIV, even combined multiple antiviral drugs cannot completely cure but suppress the viral load perpetually [18]. IVM is best known for its broad-spectrum efficacy for parasite infections, its high cure rate and its limited drug resistance when used in combination [19]. Although useful, IVM alone is not the 'magic bullet'. Combinations can help lower individual doses and reduce side effects. To cover all age group requirements, the authors combined IVM with doxycycline and zinc as active components and with vitamins D and C as replacement 'excipients' given to supplement common clinical deficiencies in the aged.

This study reports the use of the above combination therapy in consecutive, ambulatory, complex and at times profoundly hypoxic patients who insisted on avoiding hospitalization and whose oxygen saturation (SpO_2) was as low as 73%. Participants were treated by an experienced clinical trials team running a trial called Combination Therapy to Treat COVID-19 Infection.

Methods

Subjects

Subjects were identified from patients referred by physicians or word-of-mouth in Los Angeles, Ventura County, CA, and other states in the USA. These patients were referred to participate in clinical trials under clinicaltrial.gov ID NCT04482686 (which is a double-blind RCT). However, some did not qualify for this trial, as their SpO_2 was less than 90%, and were deemed too sick to enter a placebo-controlled trial. All subjects refused hospitalizations for different reasons, including not wanting to die in the hospital. Given subjects were excluded from other studies and refused to go to the hospital, they were treated off-label via telemedicine, during August 2020 and February 2021. Subjects were given the opportunity to participate in this open-label trial with institutional review board (IRB) oversight once the diagnosis was made via swab reverse transcription quantitative real-time PCR (RT-qPCR) testing. Inclusion criteria were as follows: positive PCR for COVID-19, informed consent, age $\geq$18 years old and agreement to practice two highly effective methods of birth control if of childbearing potential. Exclusion criteria were allergies or drug interactions with the combination therapy components; listed comorbidities, including seizure risk; and pregnancy.

Treatment

Treatment began as soon as practical, within 72 h of patients presenting to Ventura Clinical Trials. All screened subjects met the inclusion criteria and were enrolled consecutively. Treatment was defined as 'IVM Combination Therapy' (ICT) and consisted of 10 days of oral doxycycline (100 mg twice a day), IVM (12 mg on day 1, day 4 and day 8), zinc (25 mg twice a day), vitamin D3 (1500 IU twice a day) and vitamin C (1500 mg twice a day). ICT was given daily for 10 days only.

Two patients (#10 and #23) received an initial treatment on day 1 of 36 mg IVM (rather than 12 mg) due to particularly low SpO_2 or expected clinical need.

Monitoring

Subjects self-recorded symptoms in their daily logs (Supplementary Figure 1) for the first 10 days. Electrocardiograms (EKGs), blood pressure, temperature (reported in °F) and SpO_2 were collected via provided medical equipment at home. On days 1, 5, 10 and 30, SARS-CoV-2 testing swabs were self-collected by subjects and sent to pathology for testing. Pregnancy tests were performed as appropriate.

End points

End points were time from presentation to negative SARS-CoV-2 PCR, time from presentation to symptom resolution, progression to hospitalization and patient survival.

Externally controlled trial arm

Given the challenges for COVID-19 of enrolling high-risk, severely hypoxic patients in an open-label trial with an untreated control arm, the treated group arm survival was compared with the control group survival rate in the general population. This externally controlled trial (ECT), also known as a synthetic control arm, was calculated from the public CDC database of COVID-19 subjects [20]. Available information includes age range, presence of any chronic condition (COVID-19 vulnerability or otherwise, conditions not specified), date of infection and whether the COVID-19 diagnosis was laboratory confirmed. The authors used information from all subjects who met the following criteria: age 50+ years old; laboratory-confirmed COVID-19 diagnosis; death/survival, race and sex status available and known; infection prior to March 2021; and any comorbidities. This synthetic control arm data selection was carried out after the authors' data were obtained, to more closely match their subjects, all of whom had some comorbidity and the majority were over 50 years of age. The CDC database was analyzed using CSViewer version 1.3 (EasyMorph, Inc., ON, Canada, http://easymorph.com).

Covidex calculations & statistics

Covidex and Covidex-F are ambulatory SARS-CoV-2 infection disease severity measures that the authors developed and validated in this study. They are weighted particularly to emphasize SpO_2, and Covidex-F includes a variable for body temperature.

Covidex score = 1 point (pt) (if history of sleep apnea) + 1 pt (if history of chronic obstructive pulmonary disease [COPD]) + 1 pt (if history of cardiovascular disease) + 1 pt (if history of asthma) + 1 pt (if history of prior clots, ischemia or stroke) + 1 pt (if obese, that is, BMI between $\geq$30 kg/m^2 and <40 kg/m^2) + 2 pts (if severely obese, that is, BMI $\geq$40) + 1 pt (if age $\geq$60 years old) + (95-[SpO_2 as a percentage]) pts. For instance, a hypothetical patient with a history of asthma and morbid obesity with an SpO_2 prior to treatment of 85% would have a Covidex score of 1 (for asthma) + 2 (for obesity) + 10 (for SpO_2 of 85%) = 13 pts. Covidex-F score = Covidex score + 1 pt (if temperature on presentation between 99.5°F and 100.4°F) + 2 pts (if temperature on presentation between 100.4°F and 103.5°F) + 3 pts (if temperature on presentation $\geq$103.5°F).

Best-fit lines were made to assess the correlation between Covidex scores and time from treatment to symptom resolution. Regression was carried out in Prism version 8 (GraphPad Prism software for Windows, CA, USA, www.graphpad.com) using least square regression without weighting or special handling of outliers. All graphs were prepared by and statistical analysis was done using GraphPad Prism version 8, and the error bars are indicative of the standard error of the mean (SEM).

Results

Table 1 lists all subjects in the study, two of whom did not consent to ICT treatment (subjects #10 and #26, n = 26; n = 24 consenting to treatment), and their associated race, gender, symptoms and fever and other clinical notes. All subjects had COVID-19-related symptoms on presentation, and the symptom range was broad, with several showing shortness of breath (SOB). The vast majority of subjects, 21 of 24 (87.50%), had fever on presentation with a mean temperature for all 24 subjects of 101.2 ± 0.32°F. Specifically, 1/24 (4.17%) had low-grade fever (99.5–100.4°F), 18/24 (75.00%) had medium-grade fever (100.5–103.4°F) and 2/24 (8.33%) had high-grade fever ($\geq$103.4°F).

Given the dates of the study, it is very unlikely any subjects had the Delta or Omicron variant of COVID-19. Six subjects had their strains identified (data not shown) and were found not to have these variants.

Table 2 summarizes the demographics and past medical history (PMH) of subjects who consented to treatment (total n = 24; two additional subjects who declined treatment are excluded). Notably, patients were older (a known

3	2	8.33

COPD: Chronic obstructive pulmonary disease; SEM: Standard error of the mean.

COVID-19 vulnerability), with a mean age of 66 ± 2.75 years old and a range of 43–94 years (Table 2A). The population of the 24 subjects consenting to treatment (not subjects #10 and #26, Table 1) was 63% males. Death of untreated subjects #10 and #26 excluded downstream analysis in the other figures.

Table 2B lists the number of patients who had comorbidities associated with COVID-19 vulnerability, based on CDC guidelines [21]. These comorbidities are chronic kidney disease, COPD, Down syndrome, cardiovascular disease, immunocompromised state (including HIV), obesity (BMI of 30 kg/m^2 or higher but <40 kg/m^2), severe obesity (BMI ≥40 kg/m^2), pregnancy, sickle cell disease, smoking and Type 2 diabetes. Of note, no subjects had cancer, Down syndrome or sickle cell disease and none were pregnant or were smokers.

Many subjects had multiple comorbidities associated with COVID-19 vulnerability, as outlined in Table 2B. In total, 11/24 (45.83%) subjects had COVID-19-vulnerable comorbidities, of which three (12.50%) had two separate comorbidities and two (8.33%) had three comorbidities.

A minority of subjects (n = 7) had other COVID-19 treatment(s) prior to and/or during ICT administration, namely remdesivir (n = 1 subject); involvement in a placebo-controlled trial of hydroxychloroquine, azithromycin, vitamin D, zinc pack (HAZDpaC) (n = 4 subjects, trial clinicaltrial.gov NCT04334512; may have been given treatment or placebo); and hydroxychloroquine (HCQ) (n = 3 subjects).

Figure 1 demonstrates that all subjects recovered from COVID-19, typically within 1 to 2 weeks. Figure 1A shows various durations for each subject and average values (one outlier excluded). Time from onset of symptoms to treatment initiation is shown in column 1 and averaged 9.2 ± 2.1 days. The time from start of treatment to symptom resolution was 11.6 ± 1.4 days. Time from first positive to first negative PCR was 16.9 ± 1.6 days and was less than 3 weeks. The time from start of treatment to first negative PCR was 11.5 ± 1.6 days and was also less than 3 weeks.

Figure 1B shows that 100% of subjects survived COVID-19, without the need for hospitalization or ventilator use. As noted in Table 2, many of these subjects were older and with comorbidities. When compared with the CDC synthetic control arm (see methods and as follows), this was a significant increase in survival rate ($p = 0.044$) and decrease in hospitalization rate ($p = 0.0011$), evaluated via χ^2 test. Of note, the patients in the CDC database likely

10.2217/fmb-2022-0014

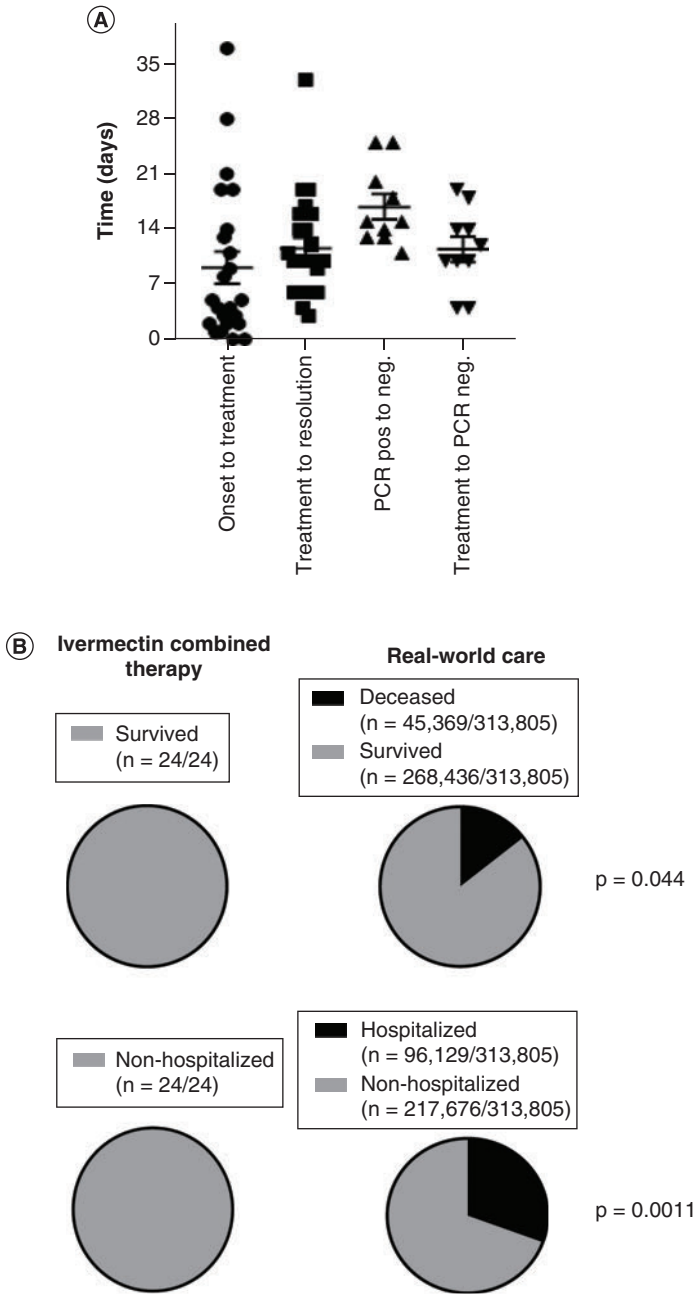

Figure 1. Complete recovery was seen in all patients within 1 to 3 weeks. (A) Time in days to various stages of symptom onset and resolution. Nearly all subjects resolved symptoms and became PCR negative in 3 weeks.
Col 1: Symptom onset to start of treatment (n = 23; mean: 9.17 ± 2.05).
Col 2: Start of treatment to resolution of symptoms (n = 23; mean: 11.61 ± 1.38).
Col 3: First PCR positive to first PCR negative (n = 10; mean: 16.90 ± 1.58).
Col 4: Start of treatment to first PCR negative (n = 10; mean: 11.50 ± 1.60).
(B) Top, 100% survival rate was seen in patients, which is significantly higher (p = 0.044 via Chi-Square, χ^2, test) than synthetic control from CDC database of equivalent or less COVID-vulnerable subjects. Bottom, no (0%) patients required hospitalization, which is significantly less (p = 0.0011 via χ^2 test) than synthetic control from database.

received treatment of an unknown nature. Thus, the survival rate of this synthetic control reflects the "typical" survival rate in the USA, which is significantly less than the 100% survival rate observed on ICT.

The 100% survival rate on ICT was compared with survival rates from the CDC database of COVID-19 subjects; 313,805 control subjects were obtained, based on the qualification criteria described in the methods section. These criteria focused on older subjects (50+ years of age), similar to the authors' population, who also had underlying conditions. One should note that the underlying condition criteria information available in this database refers to chronic conditions of any type, whether or not the condition induces COVID-19 vulnerability. With this definition, 100% of control subjects and ICT-treated subjects had underlying conditions of any type.

The critical finding in Figure 2 (see also Table 2) showed that 23/24 patients were hypoxic with SpO_2 < 90%. Some subjects consenting to treatment had SpO_2 as low as 73%, 77%, 84% and 85% on presentation. Figure 2A shows that the SpO_2 of subjects was significantly less than 95%, the defined point of cure (95% CI of mean SpO_2: 85.5% to 89.4%; mean: 87.4% ± 0.93). Subjects' SpO_2 increased within 24 h of treatment. Their mean SpO_2

FOI 26-3132 - Document 5

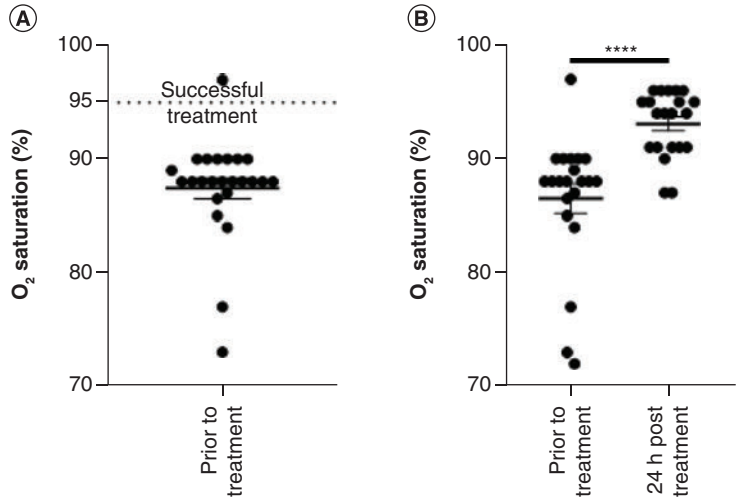

Figure 2. All subjects reached successful treatment (SpO2 above 95%) and experienced significant increase in SpO2 within 24 h. (A) O_2 saturation prior to treatment was significantly ($p < 0.05$) less than 95%, the defined successful treatment reached by all subjects. **(B)** O_2 saturation significantly increased in subjects 24 h after treatment (paired *t*-test, $p < 0.001$, only subjects with data before and after treatment included). O_2 saturation continued to rise until the defined cure of greater than 95% O_2 saturation was reached.

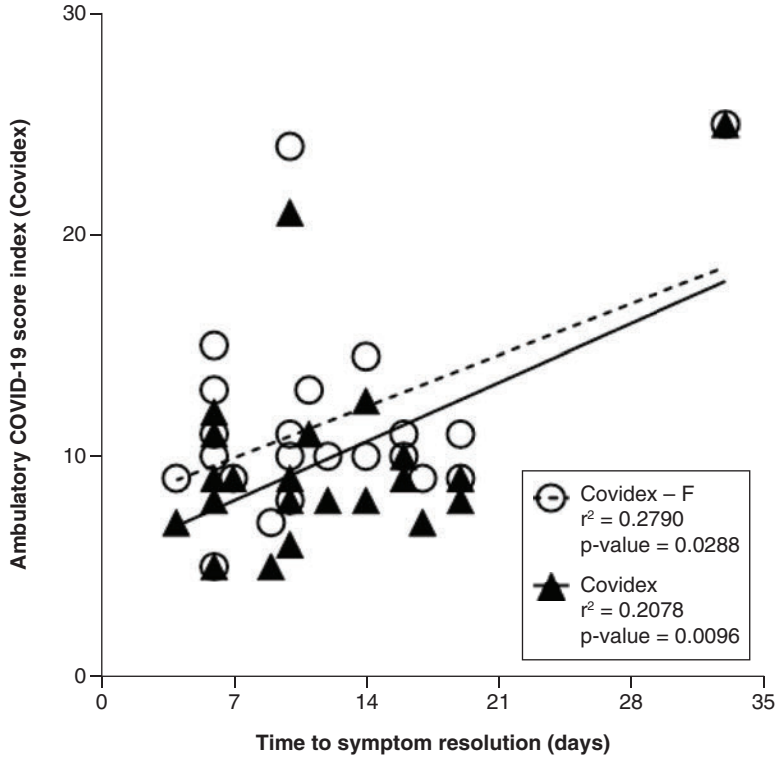

Figure 3. Ambulatory COVID scores, Covidex and Covidex-F (see methods for definition; Covidex-F includes fever measure) versus time from start of treatment to symptom resolution. There was a significant relation between either Covidex score (Covidex: p = 0.0288; Covidex-F: p = 0.0096) and treatment resolution time.

before treatment (for subjects with data before and after 24 h) was 86.5% ± 1.3, and after 24 h of treatment 93.1% ± 0.63, a highly significant and rapid increase ($p < 0.001$). SpO_2 then continued to rise. Treatment continued for 10 days reaching the point of successful treatment or cure, with $SpO_2 > 95\%$. Successful treatment was reached for all subjects. That is, there was a 100% restoration rate in terms of SpO_2. No patient who accepted treatment required hospitalization.

Two subjects (#10 and #26) declined treatment. These subjects did not recover SpO_2 and died from COVID-19 infection. An adverse drug event of dizziness was reported by one treatment subject who nevertheless continued with treatment successfully otherwise.

Figure 3 shows the validation of the Covidex and Covidex-F scores the authors developed, defined in the methods. These scores provide an index of COVID-19 predicted severity, based on PMH, O_2 just before treatment and fever grade on presentation. The mean Covidex score was 10.34 ± 1.08 and the mean Covidex-F score was 11.63 ± 1.13, with 87% and 85% of the score points, respectively, coming from the contribution of the SpO_2

10.2217/fmb-2022-0014

FOI 26-3132 - Document 5

term. In other words, approximately 80–90% of this score is weighted toward SpO_2. It should also be noted that the PMH aspects that contribute to this score emphasize respiratory, cardiovascular and obesity histories and differ from CDC-defined COVID-19 vulnerabilities.

Covidex and Covidex-F are both plotted versus time from treatment to symptom resolution. Both show statistically significant correlations (Covidex: p = 0.0096, r^2 = 0.2078; Covidex-F: p = 0.0288, r^2 = 0.2790), indicating that either Covidex or Covidex-F is associated with and may predict time to symptom resolution.

Discussion

The authors report for the first time a highly effective outpatient ICT, which prevented hospitalization and led to 100% survival and cure in unselected ambulatory 'moderately to severely' ill COVID-19 patients with hypoxia. Given the authors' experience developing combination therapies for *H. pylori*, they clinically explored (without formal comparative studies) several different IVM-based combinations on ambulatory COVID-19 patients, searching for a cure, and found the above combination to be very effective as a therapy for COVID-19. Some patients needed a personalized medicine approach, using HCQ or other components, much the way *H. pylori* resistant to triple therapy sometimes requires quadruple therapy. The authors acknowledge that they did not have the capacity in this study to test every permutation of ingredients with a scientific trial, yet such studies can be useful for future refinement. Applying IVM via weight-based dosing has been suggested [22], but more importantly, appropriate doses may be needed to cover various COVID-19 strains.

Hypoxia is a demonstrated predictor of COVID-19 mortality. For example, several of these patients had profound hypoxia, measured by oximetry at 73%, 77%, 84% and 85% on presentation. Despite a symptom to treatment delay of 9.2 days, this treatment brought rapid improvement – beginning in some within 12 h with a mean SpO_2 rising from 86.5 to 93.1 in the first 24 h. There was a parallel improvement in the symptoms, including loss of cough, fever and tiredness. Also, the time from the start of treatment to the first negative PCR averaged 11.5 $\pm$ 1.6 days. Generally, such ill patients would have been admitted to the hospital, yet all those treated with ICT avoided hospitalization and none died.

Turning to the ECT 'synthetic control arm', it is clear that ICT was statistically superior to the control arm, even though a small patient group was reported. The very low number of adverse effects from reported studies and this treatment group support the use of ICT if clinical symptoms and risk factors for COVID-19 progression are present, even in cases with PCR pending results. ECT arms are now increasingly used, especially where the control arm or 'standard-of-care' arm may have a fatal outcome [23].

The rationale for exploring a combination antiviral therapy approach is based on our growing understanding that intracellular infections – bacterial or viral – generally cannot be cured using a single drug. Multiple drugs address numerous mechanisms of viral replication and can cure multiple strains. Even therapies using two drugs, such as two antibiotics for *H. pylori*, have resulted in resistance. Multiple-drug therapies, especially using three or more, are expected to be more effective at reducing viral load, thereby limiting resistance and variant development [24], as reviewed for HIV [18]. Use of IVM alone, on the other hand, has already led to resistance when treating scabies, nematodes, strongyloidiasis, microfilaridermias and *Onchocerca volvulus* [17,25–28]. All these diseases are based on eukaryotic organism infection, not viral, and are thus far less prone to mutations and consequently resistance. Since IVM resistance has occurred on occasion for these diseases and since COVID-19 has become a pandemic, resistance needs to be proactively prevented for COVID-19 and its future variants. Given the current state of the pandemic, we cannot permit IVM resistance to develop clinically, and be experimentally demonstrated, before it is addressed. Thus, IVM in COVID-19 should not be used as a monotherapy, only in combination therapies, especially so with growing reports of mutant strains resulting in vaccine breakthrough infections. Combination therapy could allow for more rapid cures, resistance prevention and overcoming of mutant strain emergence – 'no replication, no mutation'.

Regarding strategies in the development of combination therapies, intracellular coronavirus replication requires several active drugs to inhibit viral replication. IVM, doxycycline and zinc all individually inhibit coronavirus replication and, although there are other candidates, the authors have proposed the above combination based on its efficacy, component safety profiles, inexpensive nature and lack of drug–drug interaction. The combination of IVM and doxycycline has been shown to be somewhat effective for COVID-19 [7], potentially (statistical trend) more effective than the HCQ and azithromycin combination [29], and mechanistically theorized as synergistic [30], even though doxycycline alone is not considered effective [31]. Further, given that zinc plays a key role in antiviral activity [32,33], it would combine well with the ionophores (IVM and doxycycline) to increase its intracellular

concentration and expedite viral clearance [34]. Also, the combination of zinc with IVM and doxycycline has no reported drug–drug interactions [35]. Additionally, each of these drugs has a low adverse side-effect profile and no QT prolongation as reported with azithromycin [22,36–38].

Overall, based on the current literature, a 10-day combination therapy of IVM, doxycycline and zinc will not only improve symptoms [6,7] but also accelerate recovery from COVID-19. The authors have chosen a safe IVM dosage, approved for parasites, of 36 mg over 10 days, and this dose has been shown to be both effective and safe in COVID-19 treatments [39]. The staggered IVM dosage over 10 days is proposed based on the half-life clearance of the drug in plasma (up to 66 h) [40]. The proposed duration would allow constant availability of adequate plasma level IVM to facilitate zinc entry into the cells. Hence, the above rationale explains why some publications have already shown that IVM alone is not adequate to cure COVID-19, while a multidrug regimen is likely to be more efficacious [41].

This study enrolled consecutive subjects (i.e., as subjects presented, they were enrolled and none were turned down) in the study and did not bias subject selection from different time points. Many of the enrolled subjects were profoundly ill with subjective assessments that may have resulted in hospital admission and/or intubation, yet ICT activity appears to have rapidly restored SpO_2 and reversed other symptoms, which could not be explained simply by the developing immunity. The authors acknowledge that a major limitation of the study is the small sample size (n = 24 consenting to treatment) in this preliminary study, which may limit its generalizability. These subjects consisted of the first set to present to Ventura Clinical Trials, and more data are being collected. Of note, many such severely ill patients may not opt for the unknown of a less established clinical trial for a serious case of COVID-19. The authors' future studies will expand the sample size, test the effect of other IVM dosages and explore the mechanistic contribution of the microbiome to IVM's effectiveness in COVID-19.

While a concomitantly enrolled control arm would be ideal for a true RCT, this is not feasible with severe COVID-19. Given the potentially fatal outcomes, Lawrie *et al.* [42] said, "*Placebo-controlled trials of ivermectin treatment among people with COVID-19 infection are no longer ethical and active placebo-controlled trials should be closed,*" the effects of which observed in the two subjects who declined treatment and did not survive. Hence, this study has made use of the ECT or 'synthetic' control arm [23], which has enabled the authors to make matched age and comorbidity comparisons. Institutional review boards should now include a provision to allow for synthetic arm studies and reject COVID-19 trials that utilize a control arm as published by Lawrie.

Conclusion

This study builds on extensive literature to provide practical, inexpensive, safe, readily available and highly effective IVM triple therapy aiming to prevent resistance and one that can confidently be used as a routine treatment for outpatient COVID-19.

Summary points

- The authors observed the effectiveness of a novel combination of ivermectin, doxycycline, zinc and vitamins D and C in 24 COVID-positive subjects with high-risk features/comorbidities.
- The majority of the subjects were hypoxic (23 out of 24; oxygen saturation [SpO_2] <90%), with 4 below SpO_2 <85% on presentation. Many subjects had related comorbidities (n = 11; 45.8%). The median age of all subjects was 66 years old.
- Intervention consisted of 10 days of doxycycline (100 mg twice a day), ivermectin (12 mg on day 1, day 4 and day 8), zinc (25 mg twice a day), vitamin D3 (1500 IU twice a day) and vitamin C (1500 mg twice a day). All treatment was given orally and ceased at the end of 10 days.
- One hundred percent of patients accepting treatment survived without the need for hospitalization. All subjects recovered from hypoxic symptoms (SpO_2 >95%) within 10 days of treatment.
- The authors report an effective and inexpensive COVID therapy preventing hospitalization and death in all patients and rapid resolution of hypoxia in these ambulatory 'moderately to severely' ill patients.

ABSTRACT

FDA approved for parasitic indications, the small molecule ivermectin has been the focus of growing attention in the last 8 years due to its potential as an antiviral. We first identified ivermectin in a high throughput compound library screen as an agent potently able to inhibit recognition of the nuclear localizing Human Immunodeficiency Virus-1 (HIV-1) integrase protein by the host importin (IMP) α/β1 heterodimer, and recently demonstrated its ability to bind directly to IMPα to cause conformational changes that prevent its function in nuclear import of key viral as well as host proteins. Cell culture experiments have shown robust antiviral action towards a whole range of viruses, including HIV-1, dengue, Zika and West Nile Virus, Venezuelan equine encephalitis virus, Chikungunya, pseudorabies virus, adenovirus, and SARS-CoV-2 (COVID-19). Close to 70 clinical trials are currently in progress worldwide for SARS-CoV-2. Although few of these studies have been completed, the results that are available, as well as those from observational/retrospective studies, indicate clinical benefit. Here we discuss the case for ivermectin as a host-directed broad-spectrum antiviral agent, including for SARS-CoV-2.

1. Introduction

The work identifying ivermectin, a macrocyclic lactone 22,23-dihydroavermectin B produced by the bacterium *Streptomyces avermitilis*, and subsequently demonstrating its activity as a novel therapeutic against "infections caused by roundworm parasites" was recognized, along with the seminal work on the antimalarial artemisin, with the award of the 2015 Nobel Prize for Physiology or Medicine [1,2]. Soon after its discovery in 1975, ivermectin was approved as a treatment for parasitic infection indications in animals (1981), and subsequently for human use to treat onchocerciasis (river blindness) 6 years later. It has since been approved for treatment of a range of human nematode (roundworm) infestations that cause river blindness, filariasis, ascariasis and strongyloidiasis, as well as pediculosis and scabies, caused by ectoparasites, and also for rosacea [1,3]. Because of its importance in treating all of these indications, ivermectin is firmly on the WHO (World Health Organisation)'s List of Essential Medicines [6], with millions of doses prescribed worldwide every year.

Starting in 2012, ivermectin's antiviral properties have been progressively documented towards a number of RNA viruses, including human immunodeficiency virus (HIV)-1, influenza, flaviviruses such as dengue and Zika, and most notably, SARS-CoV-2 (COVID-19) [4,5,7–17], as well as DNA viruses such as pseudorabies, polyoma and adenoviruses [18–20]. Ivermectin's antiviral activity is based on its ability to bind to and inhibit the transport function of the host importin α (IMPα) protein [11,18,20]; IMPα is known to mediate nuclear import of various viral proteins and key host factors, although other actions of ivermectin have been proposed which may also contribute to its activity [eg. [12,21,22]]. In light of the possibility that ivermectin has potential to be a key weapon to help control the SARS-CoV-2 pandemic, this review briefly examines the weight of evidence for ivermectin's broad-spectrum antiviral activity through its action on host factor IMPα, [6,17].

2. FDA-approved anti-parasitic ivermectin

Ivermectin has had an immense impact as a therapeutic to control various parasitic diseases [1–6], its antiparasitic mode of action believed to be through potentiating GABA-mediated neurotransmission, and by binding to invertebrate glutamate-gated Cl^- channels to effect parasite paralysis and death [23]. The selectivity of ivermectin stems from the fact that it does not readily penetrate the central nervous system (CNS) of mammals, where GABA functions as a key neurotransmitter [23]. Doses up to 2000 μg/kg can be well tolerated in patients with parasitic infections [23,24], with analysis of the first 11 years of mass global ivermectin administration indicating a very low incidence of serious adverse side effects [4,25], with no resistance in humans yet confirmed in over 25 years. Ivermectin is in fact usually administered as a single oral yearly dose (eg. 150 or 200 μg/kg, respectively) to treat onchocerciasis and strongyloidiasis, with filariasis similarly treated with a once yearly dose (300–400 μg/kg) in endemic areas, or alternatively bi-yearly (150–200 μg/kg) [26]. Clearly, ivermectin is a safe, efficacious antiparasitic likely to remain an integral part of the WHO List of Essential Medicines [6] long into the future [1,4].

3. Ivermectin as an IMPα targeting agent

Transport into and out of the nucleus is an integral part of normal eukaryotic cell function, as well as in the case of viral infection, since viruses commonly hijack the system in order to antagonize the cellular antiviral response that is driven to a large extent by nuclear factors such as transcription factors [14,27]. The key signal-dependent mediators of this transport are the members of the IMP superfamily of proteins, of which there are multiple α and β forms [14,27]. Nuclear transport mediated by the IMPα/β1 heterodimer is the best characterized pathway by which host proteins enter the nucleus through nuclear envelope-embedded nuclear pores; host proteins transported into the nucleus include members of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB) and signal transducers and activators of transcription (STATs) inducible transcription factor families that play key roles in the response to infection. Specific viral proteins [see [27,28]] also use this pathway (see Fig. 1). Briefly, IMPα within the IMPα/β1 heterodimer performs the adaptor role of signal-specific recognition of the nuclear import cargo, while IMPβ1 performs the main transport roles of binding to/translocation through the nuclear pores, and subsequent release of the nuclear import cargo within the nucleus upon interaction with another transport factor, the monomeric guanine nucleotide binding protein Ran (not shown in Fig. 1) [see 27]. Specific high affinity recognition by IMPα is critical to nuclear localization of various viral proteins such as dengue non-structural protein (NS) 5, as shown in mutagenic studies [32]; significantly, dengue virus with impaired NS5 interaction with IMPα is severely attenuated, underlining the critical importance of the NS5-IMPα interaction for dengue infection. The importance of this interaction to dengue infection is the basis for the fact that multiple distinct small molecules that disrupt IMPα recognition of dengue NS5 are able to limit dengue infection [eg. [7,8,11,31,33]]. Significantly in the case of ivermectin, this activity extends to a large number of different viruses (see below) [7–17], including SARS-CoV-2 [18].

We identified ivermectin in 2011 in a high throughput screen using bacterially expressed proteins and a 1200-compound library of small molecules for inhibitors of HIV-1 Integrase (IN) recognition by IMPα/β1 [34]; specific inhibitors targeting IMPα/β1 directly (such as ivermectin) and not IN (such as budesonide) were identified using a nested counterscreening strategy [34,35]. Of several compounds now confirmed to be active against IMPα/β1 and possessing antiviral activity as a consequence [7,14,31,36], ivermectin is the best characterized, shown to have broad-spectrum activities (summarized in Tables 1–3). It was initially shown to inhibit nuclear import not only of IN, but also of simian virus SV40 large tumour antigen (T-ag) and other IMPα/β1- (but not IMPβ1-) dependent cargoes, consistent with the idea that IMPα (not IN) is the direct target of ivermectin [34,35]. Subsequent work has confirmed this, with ivermectin's ability to inhibit the nuclear accumulation of various different host, including NF-kB p65 [37,38] and viral proteins demonstrated in transfected and infected cell systems (see Table 1) [14,34]. Ivermectin's ability to inhibit binding of IMPα to the viral proteins NS5 and T-ag has also been confirmed in a cellular context using the biomolecular fluorescence complementation technique [11] (Table 1).

Although targeting of IMPα by ivermectin was implicated by many years of research (see also below), direct binding was only recently formally demonstrated using a set of biophysical techniques, including thermostability, analytical ultracentrifugation, and circular dichroism (CD) [11]. Importantly, the CD/thermostability studies indicate that binding of ivermectin to IMPα induces structural changes which are likely the basis of ivermectin inhibition of IMPα binding to viral nuclear import cargoes. Strikingly, the structural change also appears to impair heterodimerisation of IMPα with IMPβ1 [11 - see however 20]; thus, ivermectin inhibits nuclear import not only by preventing signal recognition by IMPα, but also by ensuring that the IMPα/β1 complex essential to mediate subsequent transport through the nuclear pore is prevented from forming (see Fig. 1).

4. Ivermectin's broadspectrum antiviral activity

Consistent with the fact that many viruses are known to rely on IMPα/β1-dependent nuclear import of specific viral proteins for robust infection, including many viruses for which the lifecycle is entirely carried out in the cytoplasm [14,27,28], a body of *in vitro* studies have confirmed ivermectin to be active in limiting infection by a range of different RNA viruses [10,14], including HIV-1 [7], DENV (all 4 serotypes) and related flaviviruses [8,11,12], influenza, and alphaviruses such as Venezuelan equine encephalitis virus (VEEV) and Chikungunya [9,15,16] (see Table 2); it is also active against DNA viruses [18–20]. Exciting recent studies indicate it is a potent inhibitor of SARS-CoV-2 [17].

A striking aspect of this antiviral activity is that, where determined, the EC50 for viral inhibition as assessed by a range of different techniques is in the low uM range (see right column, Table 2), interestingly aligning perfectly with its activity in inhibiting recognition of viral nuclear import cargoes by IMPα (see Table 1). The clear implication is that the mechanism of inhibition of infectious virus production in the case of all of the viruses listed in Table 2 is largely through targeting IMPα to prevent its role in nuclear import, and of viral proteins in particular (see Fig. 1). Significantly, two other small molecules (GW5074 and gossypol) that appear to target IMPα in a very similar way to prevent its nuclear import function [31 and unpublished] have comparable antiviral properties [13,31,36], consistent with the idea that the host protein IMPα is a key contributor to infection by a number of medically important viruses.

5. Ivermectin in the clinic as an antiviral ?

As in many other disciplines, one of the biggest challenges in antiviral research is to transition from laboratory experiments to preclinical/clinical studies, with the question of dosing in the case of ivermectin for viral infectious indications contentious [see 6,39,40]. It is important, firstly, to stress the obvious in this context:

FOI 26-3132 - Document 5

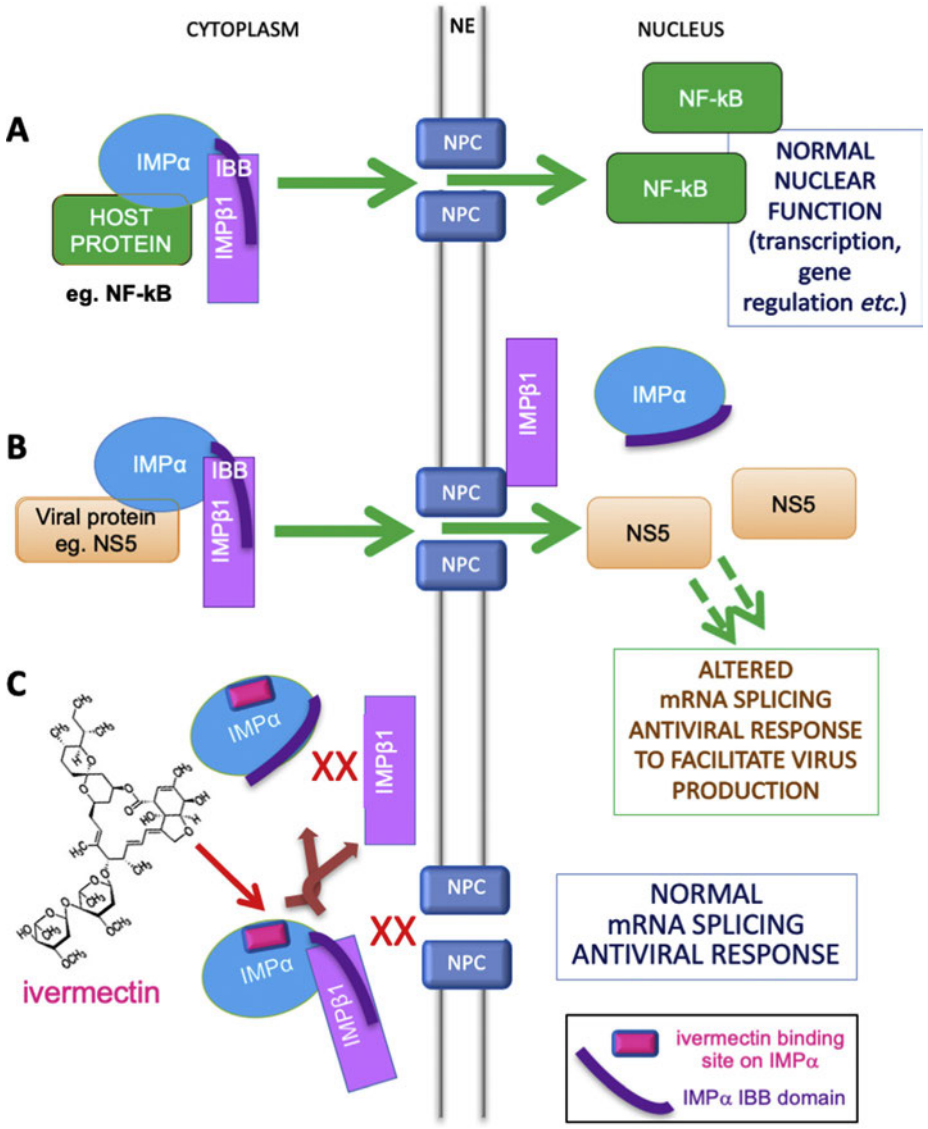

Fig. 1. Model of IMPα′s role in nuclear transport of host and viral proteins, and mechanism of inhibition by ivermectin. **A.** Host proteins such as members of the NF-κB transcription factor family localize in the nucleus through IMPα/β1, where the "IBB" (IMPβ-binding) region of IMPα (purple curved line) is bound by IMPβ1 to enable cargo recognition by IMPα within the heterodimer. Subsequently, IMPβ1 mediates transport of the trimeric complex into the nucleus through the nuclear envelope (NE)-embedded nuclear pore (NPC, nuclear pore complex). Release within the nucleus enables the transcription factor to carry out normal function in transcriptional regulation, including in the antiviral response. IMPα cannot mediate nuclear import, unless heterodimerised with IMPβ1. **B.** In viral infection, specific viral proteins (eg. NS5 in the case of DENV, ZIKV) able to interact with IMPα utilize the IMPα/β1 heterodimer to access the nucleus and antagonize the antiviral response [14,27,28]. This is critical for optimal virus production as shown by mutagenic and inhibitor studies. The SARS-CoV-2 proteins that may access the nucleus via IMPα/β1 in infected cells has not been examined, but in ORF6 (Open Reading Frame 6) protein from SARS-CoV1 has been shown to bind IMPα [29], and ORF4b from MERS-CoV (Middle Eastern Respiratory Syndrome Coronavirus) are both known to access the nucleus in NLS-dependent fashion [30]. **C.** The small molecule ivermectin (structure shown) binds to IMPα (binding site shown as red lozenge) both within the IMPα/β heterodimer to dissociate it, and to free IMPα to prevent it binding to IMPβ1, thereby preventing NS5 nuclear import [11], contributing to reduced virus production. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

that the antiviral activities of ivermectin documented in Table 2 have been derived from laboratory experiments that largely involve high, generally non-physiological, multiplicities of infection, and cell monolayer cultures, often of cell lines such as Vero cells (African green monkey kidney cells impaired in interferon α/β production) that are not clinically relevant. Clearly, the results in Table 2 for low uM EC50 values reveal robust, dose-dependent antiviral activity in the particular model system used, but it would be naïve to believe that it is necessary to achieve uM concentrations of ivermectin in a patient for maximum clinical benefit.

In fact, a key consideration in clinical intervention using ivermectin is its host-directed (IMPα-directed) mechanism of action. Host-directed agents that impact cellular activities that are essential to healthy function must be tested with caution; although ivermectin has an established safety profile in humans [24,26], and is FDA-approved for a number of parasitic infections [1,3,5], it targets a host function that is unquestionably important in the antiviral response, and titration of a large proportion of the IMPα repertoire of a cell/tissue/organ is likely to lead to toxicity. With this in mind, where a host-directed agent can be a "game-changer" in treating viral infection may well be in the initial stages of infection or potentially even prophylactically by keeping the viral load low so that the body's immune system has an opportunity to mount a full antiviral response [11,17].

FOI 26-3132 - Document 5

Table 1
In vitro effects of ivermectin on IMPα.[a]

Effect on IMPα	Cargo Protein	
	Virus	Host
In vitro		
Inhibits direct binding of IMPα (ALPHASCREEN/AUC)	HIV IN (IC50 5 μM) {34] DENV1 NS5 (IC50 2 μM)) [8] DENV2 NS5 (IC50 1 μM) [7,8,11] Hendra V (IC50 15 μM) [13] SV40 T-ag [34]	IMPβ1 (IC50 7 μM) [11]
Cellular Context		
1) Inhibits binding of IMPα in transfected cell context (BiFC/CoIP)	SV40 T-ag [11,20] DENV2 NS5 ([7,11] Adenovirus EIA [20]	
2) Inhibits nuclear accumulation in a transfected cell context of IMPα/β1- (but not β1-) recognised proteins (CLSM) [7]	HIV-IN [7] SV40 T-ag [7,16,34] DENV2 NS5 [7] VEEV Capsid [16] adenovirus E1A [20] PSV UL42 [18] hCMV ppUL44, pUL5 [7]	TRF1 [7,34] p53 [7] NF-kB (LPS-induced) [37,38]
3) Reduces nuclear localisation in infected cells	VEEV Capsid [9] adenovirus E1A [20]	

[a]Abbreviations: HIV-1, human immunodeficiency virus; DENV, dengue virus; VEEV, Venezuelan equine encephalitis virus; PSV, Pseudorabies virus; hCMV, human cytomegalovirus; T-ag, SV40 large T-antigen; DENV, dengue virus; TRF1, telomere repeat factor 1; LPS, lipopolysaccharide.
[b]Inhibits helicase activity (FRET based assay) of DENV2, YFV and WNV NS3 (IC50 0.2–0.5 μM) [12].

Ivermectin's potential as an antiviral to treat infection can of course only be demonstrated in clinical studies. Preclinical studies in a lethal Pseudorabies (PRV) mouse challenge model showed that dosing (0.2 mg/kg) 12 h post-infection protected 50% of mice, which could be increased to 60% through administration of ivermectin at the time of infection [18]. Clinical data for a phase III trial against DENV infection similarly indicate antiviral activity, with daily dosing (0.4 mg/kg) found to be safe, and virological efficacy demonstrated, although it was concluded that dosing regimen modification was required to achieve clinical benefit [41]. These studies underline ivermectin's real potential as an antiviral able to reduce viral load in a clinical context.

Table 2
Documented antiviral action of ivermectin.[a]

Virus	Inhibitory Concentration/Fold reduction (Assay)
Coronavirus	
SARS-CoV-2	EC50 = 2.2/2.8 μM/5000-fold reduction (qPCR/released/cell-associated virus) [17]
Lentivirus	
HIV-1 (VSV-G-pseudotyped NL4-3.Luc.R-E-HIV)	50 μM > 2-fold reduction (luciferase) [7]
Orthomyxovirus	
Influenza VLPs (avian influenza A/MxA escape mutants)	10 μM total inhibition (luciferase) [10]
Flavivirus:	
YFV (17D)	EC50 = 5/0.5 nM (CPE/qPCR) [12]/3 μM > 50,000-fold reduction (pfu) [15]
DENV1 (EDEN-1)	EC50 = 2.3/3 μM (CFI, 2 hosts) [8]/EC50 = 0.7 μM (qPCR) [12]
DENV2 (NGC)	EC50 = 0.4/0.6 μM (pfu/qPCR) [11]/50 μM total inhibition (pfu) [7]
DENV2 (EDEN-2)	EC50 = 2.1/1.7 μM (CFI, 2 hosts) [8]
DENV3 (EDEN-3)	EC50 = 1.7 μM (CFI) [8]
DENV4 (EDEN-4)	EC50 = 1.9 μM (CFI) [8]
WNV (NY99)	EC50 = 4 μM (qPCR) [12]
WNV (MRM61C)	EC50 = 1/0.5 μM (pfu/qPCR) [11]
ZIKV (Asian/Cook Islands/2014)	EC50 = 1.3/1.6 μM (pfu/qPCR) [11]
Alphavirus:	
Chikungunya virus (CHIKV-Rluc)	EC50 = 1.9/0.6 μM (luciferase, 2 hosts)/3 μM > 5000-fold reduction (pfu) [15]
Sindbis (HR)	3 μM > 1000-fold (pfu) [15]
Semlicki Forest Virus	3 μM > 200-fold (pfu) [15]
VEEV (TC83)	1 μM c. 20-fold (pfu) [9]
Henipavirus:	
Hendra (Hendra virus/Australia/Horse/1994)	est. EC50 = 2 μM (TCID/luciferase) [13]
DNA viruses	
Adenovirus (HAdV-C5)	EC50 = c. 2.5 μM; 10 μM 20-fold reduction (qPCR) [20]
Adenovirus (HAdV-B3)	10 μM c. 8-fold reduction (qPCR) [20]
BK polyomavirus (BKPyV)	Est. EC50 1.5 μM (pfu/CPE/qPCR) [19]
Pseudorabies	Est. EC50 c. 0.8 μM 1000-fold [18]

[a]*In vitro*
[b]Inhibits helicase activity (FRET based assay) of DENV2, YFV and WNV NS3 (IC50 0.2–0.5 μM) [12].
Abbreviations: HIV-1, human immunodeficiency virus; VLP, virus like particle; PSV, Pseudorabies virus; YFV (yellow fever virus); DENV, dengue virus; ZIKV, zika virus; WNV, West Nile virus; TCID; pfu, plaque forming unit (infectious virus assay); CPE, cytopathic effects; qPCR, quantitative polymerase chain reaction; CFI, cell fluorescence-based immunofluorescence assay.

Table 3
Summary of Current Clinical Trials using Ivermectin for SARS-CoV-2.

	Title, URL	Status[a]	N[b]	Interventions[c]	Start	Locations
1	Ivermectin Effect on SARS-CoV-2 Replication in Patients With COVID-19; https://ClinicalTrials.gov/show/NCT04381884	R	45	**Ivermectin** 0.6 mg/kg QD plus SC vs. SC	18.5.20	CEMIC, Buenos Aires, Ciudad De Buenos Aires, Argentina
2	Ivermectin and Nitazoxanide Combination Therapy for COVID-19; https://ClinicalTrials.gov/show/NCT04360356	NY	100	**Ivermectin** 0.2 mg/kg once plus NZX 500 mg BID for 6 days vs. SC	20.5.20	Tanta University, Egypt
3	Ivermectin vs. Placebo for the Treatment of Patients With Mild to Moderate COVID-19; https://ClinicalTrials.gov/show/NCT04429711	R	100	**Ivermectin** 12–15 mg/day for 3 days vs. Placebo	12.5.20	Sheba Medical Center, Ramat-Gan, Israel
4	Hydroxychloroquine and Ivermectin for the Treatment of COVID-19 Infection; https://ClinicalTrials.gov/show/NCT04391127	A	200	**Ivermectin** 12 mg (<80 kg) or 18 mg (>80 kg) once vs. HCQ 400 mg BID for 1 day then 200 mg BID for 4 days vs. Placebo	4.5.20	Jose Manuel Arreola Guerra, Aguascalientes, Mexico
5	Efficacy of Ivermectin in Adult Patients With Early Stages of COVID-19; https://ClinicalTrials.gov/show/NCT04405843	R	400	**Ivermectin** 0.3 mg/kg daily for 5 days vs. Placebo	20.6.20	Colombia
6	Ivermectin In Treatment of COVID 19 Patients; https://ClinicalTrials.gov/show/NCT04425707	R	100	**Ivermectin** (dose unlisted) vs. SC vs. **Ivermectin** (dose unlisted) plus SC	9.6.20	Isolation and referral hospitals for COVID 19 patients, Cairo, Egypt
7	Efficacy and Safety of Ivermectin and Doxycycline in Combination or IVE Alone in Patients With COVID-19 Infection; https://ClinicalTrials.gov/show/NCT04407130	E	72	**Ivermectin** 0.2 mg/kg once plus 200 mg DOC day 1 followed by 100 mg DOC BID for 4 days vs. **Ivermectin** 0.2 mg/kg QD for 5 days vs. Placebo	16.6.20	ICDDR, Dhaka, Bangladesh
8	Efficacy of Ivermectin as Add on Therapy in COVID19 Patients; https://ClinicalTrials.gov/show/NCT04343092	C	100	**Ivermectin** 0.2 mg/kg once weekly plus HCQ 400 mg QD plus ATM 500 mg QD vs. HCQ 400 mg QD plus ATM 500 mg QD	18.4.20	General Directorate of Medical City, Bagdad, Baghdad, Iraq
9	COVidIVERmectin: Ivermectin for Treatment of Covid-19 (COVER); https://ClinicalTrials.gov/show/NCT04438850	R	102	**Ivermectin** 0.6 mg/kg QD for 5 days vs. **Ivermectin** 1.2 mg/kg QD for 5 days vs. Placebo	20.6.20	Negrar, Verona, Italy; Bologna, Italy; Milan, Italy; Rovereto, Italy; Turin, Italy; Barcelona, Spain; Madrid, Spain
10	Efficacy, Safety and Tolerability of Ivermectin in Subjects Infected With SARS-CoV-2 With or Without Symptoms (SILVERBULLET); https://ClinicalTrials.gov/show/NCT04407507	NY	66	**Ivermectin** 12 mg/day for 3 days plus paracetamol 500 mg QID for 14 days vs. Placebo plus paracetamol 500 mg QID for 14 days	20.6.20	Investigacion Biomedica para el Desarrollo de Farmacos S.A. de C.V., Mexico
11	Sars-CoV-2/COVID-19 Ivermectin Navarra-ISGlobal Trial (SAINT); https://ClinicalTrials.gov/show/NCT04390022	A	24	**Ivermectin** 0.4 mg/kg once vs. Placebo	14.5.20	Clinica Universidad de Navarra, Pamplona, Navarra, Spain
12	A Comparative Study on Ivermectin and Hydroxychloroquine on the COVID19 Patients in Bangladesh; https://ClinicalTrials.gov/show/NCT04434144	C	116	**Ivermectin** 0.2 mg/kg once plus DOC 100 mg BID for 10 days vs. HCQ 400 mg day 1 then 200 mg BID for 9 days plus ATM 500 mg/day for 5 days	2.5.20	Chakoria Upazilla Health Complex, Cox's Bazar, Bangladesh
13	Ivermectin vs Combined Hydroxychloroquine and Antiretroviral Drugs (ART) Among Asymptomatic COVID-19 Infection (IDRA-COVID19); https://ClinicalTrials.gov/show/NCT04435587	NY	80	**Ivermectin** 0,6 mg/kg daily for 3 days vs. HCQ 400 mg BID Day 1 then 200 mg BID for 4 days plus Darunavir/ritonavir (400 mg/100 mg) BID for 5 days	20.7.20	Siriraj Hospital, Bangkok Noi, Bangkok, Thailand
14	IVERMECTIN Aspirin Dexametasone and Enoxaparin as Treatment of Covid 19; https://ClinicalTrials.gov/show/NCT04425863	A	100	**Ivermectin** 5 mg/ml oral to be repeated 1 week later (dose unlisted)	1.5.20	Hospital Eurnekian, Buenos Aires, Argentina
15	A Preventive Treatment for Migrant Workers at High-risk of Covid-19; https://ClinicalTrials.gov/show/NCT04446104	C	5000	**Ivermectin** 12 mg once vs. HCQ 400 mg day 1 then 200 mg/day for 42 days vs. Zinc 80 mg/day plus vitamin C 500 mg/day for 42 days vs. Povidone-iodine throat spray TID for 42 days vs. Vitamin C 500 mg/day for 42 days	13.5.20	Tuas South Dormitory, Singapore, Singapore
16	New Antiviral Drugs for Treatment of COVID-19; https://ClinicalTrials.gov/show/NCT04392427	NY	100	**Ivermectin** (dose unlisted) plus NZX (dose unlisted) plus ribavirin 200 mg or 400 mg vs. Control (untreated)	20.5.20	Mansoura University, Mansoura, Select A State Or Province, Egypt
17	Early Treatment With Ivermectin and LosarTAN for Cancer Patients With COVID-19 Infection (TITAN); https://ClinicalTrials.gov/show/NCT04447235	R	176	**Ivermectin** 12 mg once plus losartan 50 mg/day for 15 days vs. Placebo	20.7.20	Instituto do Cancer do Estado de São Paulo, Brazil
18	Ivermectin in Treatment of COVID-19; https://ClinicalTrials.gov/show/NCT04445311	R	100	**Ivermectin** daily (dose unlisted) for 3 days plus SC vs. SC	31.5.20	Waheed Shouman, Zagazig, Sharkia, Egypt
19	Efficacy of Ivermectin in COVID-19; https://ClinicalTrials.gov/show/NCT04392713	R	100	**Ivermectin** 12 mg once plus SC vs. SC	15.4.20	Combined Military Hospital Lahore, Lahore, Punjab, Pakistan
20	Ivermectin and Doxycycine in COVID-19 Treatment; https://ClinicalTrials.gov/show/NCT04403555	R	40	**Ivermectin** (dose unlisted) plus DOC (dose unlisted) vs. CQ (dose unlisted)	1.6.20	Sherief Abd-Elsalam, Tanta, Egypt
21	The Efficacy of Ivermectin and Nitazoxanide in COVID-19 Treatment; https://ClinicalTrials.gov/show/NCT04351347	R	300	**Ivermectin** (dose unlisted) vs. **Ivermectin** (dose unlisted) plus NZX (dose unlisted) vs. **Ivermectin** (dose unlisted) plus CQ (dose unlisted)	16.6.20	Tanta University, Tanta, Egypt
22	Prophylactic Ivermectin in COVID-19 Contacts; https://ClinicalTrials.gov/show/NCT04422561	C[d]	304	**Ivermectin** (dose unlisted) 2 doses 72 h apart vs. Control (untreated)	31.5.20	Zagazig University, Zagazig, Sharkia, Egypt
23	Max Ivermectin- COVID 19 Study Versus Standard of Care Treatment for COVID 19 Cases. A Pilot Study; https://ClinicalTrials.gov/show/NCT04373824	R	50	**Ivermectin** 0.2–0.4 mg/kg daily for 2 days plus SC vs. SC	25.4.20	Max Super Speciality Hospital, Saket (A unit of Devki Devi Foundation), New Delhi, Delhi, India

64	Ivermectin effect in the treatment of patients with covid-19; http://en.irct.ir/trial/49180	R	40	**Ivermectin** 0.2 mg/kg QD for 2 days vs. antiviral drugs (eg. HCQ) as per SC	20.07.20	Mashhad University of Medical Sciences, Mashhad, Iran
65	Randomized phase IIA clinical trial to compare the efficacy of ivermectin versus placebo to obtain negative PCR results in patients with early phase Covid-19; PER-034-20	R	68	**Ivermectin** 0.3 mg/kg QD for 3 days vs. Placebo	17.07.20	Universidad Peruana Cayetano Heredia, Lima, Peru
66	Evaluation of ivermectin effects on Covid-19; http://en.irct.ir/trial/49280	R	50	**Ivermectin** 0.15 mg/kg/day plus SC vs. SC	22.08.20	Kermanshah University of Medial Sciences, Kermanshah, Iran
67	A placebo-controlled, randomized, double-blind study in COvid-19 patients with iveRmectin; An inVEstigator iniTiaTEd trial (CORVETTE-01); jRCT2031200120	R	240	**Ivermectin** 0.2 mg/kg once vs. Placebo	16.09.20	Kitasato University Hospital, Kanagawa, Japan
68	A single-centre, open-label, randomized controlled study of ivermectin treated mild to moderate COVID-19 cases; Debidwar Upazila Health Complex	C[h]	62	**Ivermectin** 0.2 mg/kg once plus SC vs. SC	01.05.20	Debidwar Upazila Health Complex, Comilla, Bangladesh

[a] R, Recruiting, NY, Not yet recruiting, A, Active not recruiting, C, Completed, E, Enrolling by invitation, O, ongoing.
[b] Number of patients.
[c] SC, standard care, QD, once per day, BID, twice daily, QID, 4 times daily, TID, 3 times daily, PPE, personal protective equipment, vs. versus, HCQ, hydroxychloroquine; DOC, doxycycline; CQ, chloroquine, ATM, Azithromycin, NZX, Nanozoxide
[d] Raw data for asymptomatic family close contacts of confirmed COVID patients show that 2 doses of ivermectin 72 h apart resulted in only 7.4% of 203 subjects reporting symptoms of SARS-CoV-2 infection, in contrast to 101 control untreated subjects, of whom 58.4% reported symptoms; evidence of prophylaxis by ivermectin.
[e] Recovery rate of the 28 patients that received ivermectin/AZM/cholecalciferol was 100%, with mean symptomatic recovery 3.6 days (negative PCR confirmed day 10). Imaging on day 10 showed improvement in all patients with pneumonia. Authors conclude the combination therapy might mitigate disease progression without significant adverse effects but further studies required (preferably controlled) [46].
[f] Preliminary results for 1195 subjects consistent with prophylaxis effected by ivermectin/carrageenan topical combination [47].
[g] Raw data shows a significant reduction in the number of 183 patients with late clinical recovery (requiring >12 days to show clinical improvement) in the ivermectin/DOC group compared to placebo (23 versus 37.2%), as well as a significant reduction (8.7 versus 17.8%) in patients showing clinical deterioration (from mild/moderate to moderate or severe), and a significant reduction (7.7 versus 20%) in persistent Covid-19 positive patients at 14 days compared to 180 control patients; evidence of efficacy for ivermectin/DOC.
[h] No statistically significant clinical benefit in 32 treated subjects compared to 30 subjects given placebo, but authors concluded study requires confirmation with larger numbers of subjects [48].

6. Ivermectin as a therapeutic for SARS-CoV-2 infection ?

The current SARS-CoV-2 pandemic has eclipsed the porcine flu epidemic in terms of numbers of infections (currently >70 million) and deaths (>1.6 million, with >310,000 of these in the US alone) worldwide. The search for antivirals through repurposing existing drugs has proved challenging (eg. see Ref. [42,43]), one important aspect of repurposing being the perceived need to achieve therapeutic levels in the lung. Published pharmacokinetic modelling based on both the levels of ivermectin achievable in human serum from standard parasitic treatment dosing and robust large animal experiments where lung levels of ivermectin can be measured, indicates that concentrations of ivermectin 10 times higher than the c. 2.5 μM EC_{50} indicated by *in vitro* experiments (Table 2) are likely achievable in the lung in the case of SARS-CoV-2 [39]; modelling based on different assumptions predicts lower values, but highlights the long-term stability of ivermectin in the lung (for over 30 days) based on data from animals [40]. It should also be noted that liquid formulations for intravenous administration of long-acting ivermectin have been described, with aerosol administration also in development, to enable ivermectin administration to achieve even higher concentrations to tackle SARS-CoV-2, whilst the use of ivermectin in combination with other agents may enhance efficacy at lower doses.

Ivermectin as a treatment for SARS-CoV-2 in humans has already been approved in a number of states and countries, including the Republic of Peru [44] and Northeastern Beni region of Bolivia [45]. Importantly, close to 70 trials worldwide are currently testing the clinical benefit of ivermectin to treat or prevent SARS-CoV-2 (see Table 3); these include variations on dosing regimens, combination therapies (preliminary results for NCT04523831 in Table 3, #45) [46,47], and prophylactic protocols. With respect to the latter, preliminary results from recently completed study NCT04422561 (Table 3, #22, and footnote) examining asymptomatic family close contacts of confirmed COVID patients, reveal that two doses of ivermectin 72 h apart result in only 7.4% of 203 subjects reporting symptoms of SARS-CoV-2 infection, in stark contrast to control untreated subjects, of whom 58.4% reported symptoms, underlining ivermectin's potential as a prophylactic. Results from retrospective/observational trials [48–52] are also consistent with clinical benefit. Mymensingh Medical College Hospital (Bangladesh) reported that none of 115 subjects receiving a single 12 mg dose of ivermectin developed pneumonia/cardiovascular complications, compared to 9.8% (pneumonia) and 1.5% (ischemic stroke) in 133 control subjects [49]. Further, significantly fewer ivermectin group patients developed respiratory distress (2.6 versus 15.8%), or required oxygen (9.6 versus 45.9%), antibiotics (15.7 versus 60.2%) or intensive care management (0.09 versus 8.3%). Ivermectin-treated patients became SARS-CoV-2 negative significantly faster (median 4 compared to 15 days), had significantly shorter hospital stays (median 9 versus 15 days), and significantly lower mortality (0.9 vs 6.8%). Although combinations of therapies were used, the results for a 196 patient propensity-matched cohort study (ICON - Ivermectin in COvid Nineteen – study) at Broward Health Medical Centre (Florida, USA) [50] indicate significantly reduced mortality (13.3%) in subjects receiving 0.2 mg/kg ivermectin (optional second dose 8 days later), compared to 24.5% mortality in those not receiving ivermectin, with more

FOI 26-3132 - Document 5

significant differences for patients with severe pulmonary involvement (mortality rates of 38.8 versus 80.7%). Although these early results are consistent with efficacy, it is clear that only the results from large rigorous randomized clinical trials (Table 3) will definitively establish ivermectin's utility to treat or prevent SARS-CoV-2 infection. It is to be hoped that the results from these trials will emerge in the next few months to document ivermectin's credentials or otherwise as a viable therapeutic for COVID-19 infection, and potentially infection by many other viruses.

Author contributions

Conceptualization, D.A.J.; writing—original draft preparation, D.A.J., K.M.W.; review and editing, D.A.J., K.M.W. Both authors have read and agreed to the published version of the manuscript.

REVIEW

Safety and Efficacy Review of Doxycycline

Natasha E. Holmes and Patrick G.P. Charles

Department of Infectious Diseases, Austin Health, PO Box 5555, Heidelberg VIC 3084, Australia.
Email: patrick.charles@austin.org.au

Abstract: Doxycycline is a member of the tetracycline class of antibiotics and has been used clinically for more than 40 years. It is a well-tolerated drug that is bacteriostatic and acts via the inhibition of bacterial ribosomes. It is generally given at a dose of 100-mg daily or twice daily. It is well absorbed and has generally good tissue penetration. The serum half-life is 18–22 hours and dosage does not need to be adjusted in the presence of renal or hepatic impairment. Major side effects are gastro-intestinal and dermatological and it is generally contra-indicated in pregnancy or childhood because of concerns about discolouration of developing teeth and potential effects on growing bones. Drug interactions are not common although can occur with the concomitant use of methotrexate and the oral contraceptive pill, and its absorption can be reduced by the co-administration with some antacids and iron preparations. It has activity against many organisms, including Gram-positives, Gram-negatives and atypical bacteria. In addition, it appears to have some potentially clinically useful anti-inflammatory properties.

Keywords: doxycycline, tetracyclines, antibiotics, infections

Introduction

Tetracycline antibiotics were one of the first classes developed following the introduction of penicillin G and the sulphonamides. Doxycycline (alpha-6-deoxytetracycline; see Fig. 1) was developed by Pfizer and is a semi-synthetic derivative of oxytetracycline that first became available in 1967. It has the advantage over other members of the tetracycline family of improved oral absorption and a prolonged serum half-life. Doxycycline has activity against a very broad range of Gram-positive, Gram-negative and 'atypical' bacteria as well as some protozoa such as malaria. It is also a useful antibiotic for prophylaxis against and treatment of several important potential biological warfare agents. As such it is widely used in many parts of the world, in particular for sexually transmitted infections, respiratory tract infections, malaria prophylaxis and for the therapy of some arthropod-borne rickettsial infections.

Mechanism of Action

Doxycycline inhibits bacterial protein synthesis by reversibly binding to the 30S ribosomal subunit and preventing the association of aminoacyl-tRNA with the bacterial ribosome. Further inhibition of protein synthesis occurs in mitochondria through binding to the 70S ribosomes. It is therefore a bacteriostatic drug. Doxycycline enters the cell via hydrophilic pores in the outer cell membrane and a pH-dependent active transport system in the inner cytoplasmic membrane.[1] It also inhibits apicoplast ribosomal subunits in *Plasmodium falciparum*, leading to impaired fatty acid synthesis and impaired heme biosynthesis late in the malarial cell cycle.[2,3]

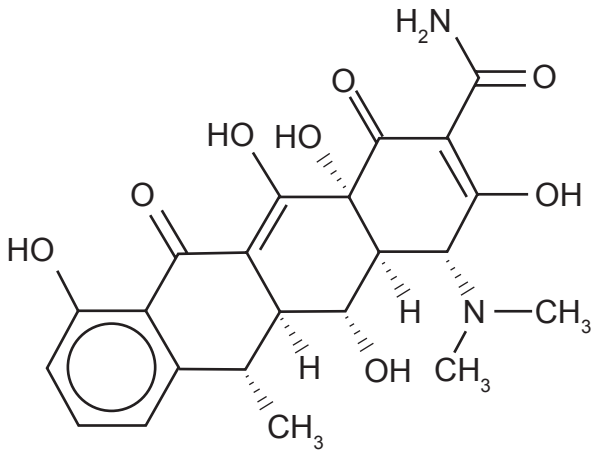

Figure 1. Chemical structure of doxycycline.

In addition, it has multiple other actions including the prevention of angiogenesis and apoptosis, enhancement of gingival fibroblast attachment, and wound healing.[4–6] It is known to inhibit certain matrix metalloproteases (MMPs), which are proteolytic enzymes produced by inflammatory cells. This has led to potential use in various anti-inflammatory and anti-neoplastic roles.[7,8] Subantimicrobial doses of doxycycline in periodontitis inhibit collagen degradation and the action of destructive MMPs in the gingivae.[9,10]

Pharmacokinetics and Pharmacodynamics

Doxycycline is almost completely absorbed following oral administration in the stomach and proximal small bowel. Food or dairy products do not significantly alter absorption, unlike for tetracycline and minocycline, with serum levels only falling by 20%.[11,12] It forms complexes with metal ions in food which are unstable in the acidic conditions in the stomach, and doxycycline enters the small bowel as free drug. However metal complexes formed in the duodenum are stable so a small amount of doxycycline is not absorbed. The presence of multivalent cations will impair doxycycline absorption.

There is a prolonged serum half-life of 18–22 hours, and this is not altered by impaired renal function. Peak serum levels occur 2–3 hours after oral administration and within 30 minutes after intravenous administration.[12,13] A single dose of oral doxycycline 200 mg achieves peak serum concentrations of approximately 3.0–5.0 µg/mL, and a single dose of intravenous doxycycline at the same dose achieves peak serum concentrations of 4–10 µg/mL.[12–14]

Penetration occurs in body fluids and tissues. Doxycycline is more lipid soluble than tetracycline, so high levels are detected in a range of tissues including lymphatic fluid, peritoneal fluid, colonic tissue, prostate tissue, and breast milk. Doxycycline penetrates more readily into bacterial cells compared with other tetracyclines.[15] Doxycycline also penetrates into cerebrospinal fluid with mean levels of 0.37–1.3 µg/mL or 14%–26% of serum concentration.[16–18] Concentrations are highest in excretory organs including the biliary system.[19] There is poor concentration in saliva and sputum.[20,21] Accumulation

occurs in teeth and bones via the formation of a stable calcium complex and leads to discolouration of teeth. Doxycycline also crosses the placenta, achieving umbilical cord plasma concentrations of 54% of maternal serum concentration.[22] The topical application of doxycycline to gingivae leads to detectable levels in gingival crevicular fluid but not serum.[23] Although oral doxycycline may reduce symptoms of ocular surface diseases (for example, meibomian gland dysfunction), it is not detectable in tear fluid samples.[24]

There is variable protein binding, reported up to 82%–90%.[25,26] The metabolism of doxycycline and other tetracyclines has not been investigated. More than one-third of doxycycline is excreted by the kidneys via glomerular filtration,[14,26,27] and a small percentage is excreted in the bile.[26,27] The remainder of doxycycline is excreted in faeces. In the presence of renal impairment, more doxycycline is excreted in faeces so that the same dose of doxycycline can be given without drug accumulation.[26–28] More than 90% of an oral dose of doxycycline is eliminated from the body within 72 hours of drug administration.

There are no data on the impact of sex, pregnancy, breast-feeding or hepatic impairment on pharmacokinetics and there are limited data available on doxycycline pharmacodynamics.[19] Concentration-dependent killing or area under the curve (AUC) is considered the significant parameter for doxycycline activity however there are no AUC/MIC targets. Doxycycline exerts a post-antibiotic effect (PAE) that is concentration dependent against a variety of organisms.[29] The significance of this is uncertain because adequate serum concentrations are maintained during the dosing interval if given on a daily or twice-daily regimen.[29]

Drug Interactions

Absorption is impaired by ferrous sulfate, bismuth and other antacids containing aluminium, calcium and magnesium salts.[13,30–34] Doxycycline should be given 2 hours prior to or 3 hours after iron supplementation.[13] It is not reduced by concomitant ranitidine.[35] Cytochrome P450 3A4 inducers such as rifampicin will reduce serum levels due to increased hepatic metabolism.[36] Barbiturates, anticonvulsants (phenytoin, carbamazepine), sodium bicarbonate, and acetazolamide will also lower plasma doxycycline levels.[37,38] Tetracyclines may lower plasma prothrombin activity, so patients on anticoagulant therapy may require reduction of their anticoagulant dosage.[39] The concurrent use of tetracycline and methoxyflurane has been reported to result in fatal renal toxicity.[40] The efficacy of oral contraceptives is impaired by concurrent doxycycline, so barrier contraception must be used during doxycycline therapy and for seven days after completion of therapy.[41–43] It may also lead to breakthrough inter-menstrual bleeding. Doxycycline should be used with caution in patients with chronic alcoholism as the half-life of doxycycline is reduced.[44] Doxycycline also may displace methotrexate from its binding site, leading to elevated methotrexate levels and toxicity.[34,45] Synergistic or additive effects with beta-lactams have been demonstrated experimentally with *Stenotrophomonas maltophilia* and *Chlamydophila trachomatis* with uncertain clinical significance.[46,47]

Dosage and Administration

Doxycycline is usually commenced with a starting dose of 200-mg daily, followed by a maintenance dose of 100-mg daily (or twice-daily for severe infections). It can be administered orally or intravenously. The oral dose should be taken with sufficient fluids and the patient should remain upright for 30 minutes following administration. The maximum recommended dose is 300-mg daily.[34] In children, when doxycycline benefits outweigh the risks, a weight-adjusted dose of 2.2 mg/kg daily or twice daily is used. A higher loading dose of doxycycline, for example 200-mg twice daily for 72 hours, is recommended for optimal dose-dependent killing in serious infections.[48] Variations exist with dosing and duration for specific indications, for example, malaria prophylaxis, syphilis, and scrub typhus. Lower doses, for example 20-mg twice daily, are used for acne vulgaris and rosacea. Topical preparations are also available for periodontitis.

Clinical Uses

Doxycycline has a broad-spectrum of activity against many Gram-positive, Gram-negative and 'atypical' bacteria, as seen in Table 1. As a result, it has many potential uses.

Respiratory infections

Doxycycline is frequently used in some parts of the world to treat respiratory tract infections such as community-acquired pneumonia (CAP) and acute

Table 1. Doxycycline activity against selected pathogens.

Organism	Typical MIC_{90} µg per ml	Range
Gram-negative bacteria		
Escherichia coli	32	0.5–>64
Klebsiella pneumoniae	64	1–>64
Yersinia pestis	1	0.125–2
Haemophilus influenzae	1	0.5–8
Moraxella catarrhalis		0.1–4
Burkholderia pseudomallei	1.5	0.125–4
Stenotrophomonas maltophilia	2	0.5–4
Brucella melitensis	0.064	0.0156–0.094
Bartonella spp.	0.12	<0.016–0.25
Neisseria meningitides	1	0.12–2
Gram-positive bacteria		
Staphylococcus aureus	4	0.03–>16
Streptococcus pyogenes	8	0.1–>16
Streptococcus pneumoniae	8	0.04–16
Enterococcus faecalis	32	0.12–>64
Listeria monocytogenes	0.25	0.125–1
Bacillus anthracis	0.063	0.031–0.125
Nocardia spp.	16–32	0.125–32
Tropheryma whipplei		0.25–2
Other bacteria		
Legionella pneumophila	2	0.5–2
Mycoplasma pneumoniae	0.25	0.06–0.25
Chlamydophila pneumoniae	0.25	0.06–0.5
Chlamydophila trachomatis	0.25	0.125–0.25
Rickettsia spp.		0.06–0.125
Coxiella bunetii		2–4

exacerbations of chronic bronchitis (AECB). Its activity against 'atypical' bacteria such as *Mycoplasma pneumoniae*, *Chlamydophila* spp., *Legionella* spp. and *Coxiella burnetii* is reliable although resistance rates for 'typical' bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* are variable. Pneumococcal resistance rates for doxycycline range from 5%–25%.[49–51] Thus, in areas where resistance rates are either high or unknown, doxycycline should be combined with another agent that has more reliable anti-pneumococcal activity, such as a beta-lactam. In Australian patients with CAP treated with doxycycline combined with either benzylpenicillin, amoxycillin or ceftriaxone, very good outcomes were obtained,[52] and outcomes have been good even for confirmed cases of legionellosis.[53] Recent randomized studies comparing doxycycline with other agents are not available. In the CAP guidelines from the Infectious Diseases Society of America/American Thoracic Society, doxycycline is listed as one of the options for treating ambulatory patients with CAP who have no risk factors for drug-resistant pneumococcal infections.[54]

Doxycycline is generally listed as one of the first-line treatment options for AECB. Recent data for this is limited but in one study, it was superior to cefaclor and equivalent to amoxicillin, cephalexin and enoxacin.[55] Another small study compared it to roxithromycin and

found slightly lower rates of mortality and adverse events in the roxithromycin group.[56]

Genitourinary infections

For many years, seven-day courses of doxycycline were the treatment of choice for non-gonococcal urethritis (NGU) because of its reliable activity against *Chlamydophila* spp. With the availability of azithromycin, which can be given as a single oral dose to improve adherence, doxycycline use has decreased for this indication. Both drugs achieve similar high rates of successful outcomes of at least 97% for NGU due to *Chlamydophila trachomatis*.[57] Activity of doxycycline against *Ureaplasma urealyticum* is also good although occasional resistant strains are seen.[58] These same organisms can cause chronic prostatitis or epididymo-orchitis and four-week courses of doxycycline achieve equivalent responses to weekly doses of azithromycin for four weeks.[59,60]
