In the guidelines for the treatment of PID from the Centers for Disease Control and Prevention, doxycycline combined with either ceftriaxone (+/– metronidazole), cefoxitin or cefotetan is recommended.[61] Because of concerns about poorer activity against *M. genitalium*, as well as greater ease of use with azithromycin, doxycycline is being used less commonly now in some locations.[62–64] In a comparison of the treatment of PID using ceftriaxone combined with either three doses of azithromycin over two weeks or two weeks of doxycycline, better results were obtained in the azithromycin group.[65]

Three-week courses of doxycycline can be used in the therapy of lymphogranuloma venereum and granuloma inguinale (donovanosis).[66,67] Due to high rates of resistance, doxycycline is no longer recommended for the treatment of gonorrhoea or chancroid (*Haemophilus ducreyi*) without confirming susceptibility first.[67,68]

Cell wall deficient bacteria such as Rickettsia

Worldwide, an increasing number of species of *Rickettsia* are being recognised that cause human disease. These are divided based on their clinical characteristics into the spotted fever group, the typhus group and the scrub typhus group. Doxycycline is the treatment of choice for these rickettsial infections, generally given as 100-mg twice daily for 5–7 days. It is also the treatment of choice in infections caused by *Ehrlichia* spp. and *Anaplasma phagocytophilum*.[69] In most cases, response is rapid, although there have been recent reports about delayed response or reduced susceptibility in cases of scrub typhus and murine typhus.[70]

Q fever infections can be self-limiting but if treatment is used in acute cases, doxycycline for 14 days is preferred. In cases of Q fever endocarditis, prolonged therapy is required, generally for 18 months and combined with another agent such as hydroxychloroquine.[71]

Bartonella

Bartonella spp. can cause a variety of manifestations, including trench fever, endocarditis, pyrexia of unknown origin, cat scratch disease, bacillary angiomatosis, peliosis hepatis and splenitis, Oroya fever, verruga peruana, retinitis and pericarditis. Doxycycline has activity against *Bartonella* spp. and is recommended as first-line therapy for many of these conditions, either alone, or in the more serious illnesses, combined with other agents such as gentamicin or rifampicin. It is generally given for prolonged periods.[72]

Spirochetal infections

In patients with early Lyme disease, treatment with doxycycline for 10–21 days is as effective as other agents such as amoxycillin or cefuroxime.[73,74] One potential benefit of choosing doxycycline is that it will also have activity against *Ehrlichia* or *Anaplasma* infections that may be also be transmitted by ticks. If dissemination has occurred, with either neurologic or cardiac complications, it can still be used and should be given for 21 days, with results equivalent to intravenous penicillin G or ceftriaxone.[75–77] In late cases of Lyme disease that are associated with arthritis, a month of doxycycline is effective in the majority.[78] Other *Borrelia* infections such as relapsing fever can also be treated with doxycycline, although there is greater experience using tetracycline and penicillins.

14–28 days of doxycycline is an alternative for treating primary or secondary syphilis in the penicillin-allergic patient.[79] It is also likely that this will be adequate treatment of endemic treponematoses such as yaws, although clinical studies about this are lacking.

FOI 26-3132 - Document 5

Doxycycline is effective therapy for leptospirosis and is equivalent to both penicillin and cefotaxime.[80] As rickettsial infections may be prevalent in some areas with leptospirosis and the two infections may occur together or be difficult to distinguish, doxycycline is the preferred option in such locations.

Potential agents of bioterrorism

Both naturally occurring anthrax and that due to bioterrorism can be treated with doxycycline. Naturally occurring cutaneous anthrax is treated for 5–7 days while both treatment and post-exposure prophylaxis in the event of bioterrorism require 60 days of therapy. Inhalational anthrax is generally more severe and combination therapy is preferred.[81,82]

Tularaemia is another potential bioterrorism agent. Recommended therapy is generally streptomycin or gentamicin, although doxycycline is a suitable alternative, especially if the patient is not seriously ill.[83] Similar recommendations are made for infections due to *Yersinia pestis*, with 7–10 days therapy suggested and high response rates seen.[84]

Malaria

For chemoprophylaxis against malaria in areas with chloroquine resistance, one of the most commonly used agents is doxycycline 100-mg daily taken from two days before entering until four weeks after leaving the malarial area. This offers protection of over 93% and is equivalent to mefloquine although the tolerability of and compliance with weekly mefloquine may be better.[85–87] At lower doses, or when taken for only two weeks after travel, breakthrough cases of malaria, particularly *Plasmodium vivax*, are not uncommon. In general, for travel to malaria-endemic areas with chloroquine resistance, options for prophylaxis are doxycycline, mefloquine and atovaquone-proguanil. The choice is based on cost, patient preference and ability to adhere, co-morbid illnesses, history of side effects, and presence of widespread resistance to any of these agents in the travel destinations. It is important to seek up to date advice on the rates of drug-resistant malaria in the countries that will be visited.

For treatment of malaria, particularly that caused by *P. falciparum*, doxycycline also has a role as adjunctive therapy. It can be combined with quinine (or quinidine), mefloquine, artesunate or artemether to improve rates of cure.

Miscellaneous uses

Doxycycline can be used as a second-line treatment option combined with other agents to treat *Helicobacter pylori*, particularly when clarithromycin resistance is present.[88,89] There is, however, greater experience with tetracycline for this indication. Ocular trachoma infections can also be treated with doxycycline although generally either oral azithromycin or topical tetracycline are preferred.[90] Following induction therapy for Whipple's disease with ceftriaxone or penicillin, doxycycline combined with hydroxychloroquine for one year can be used as maintenance therapy in patients unable to take co-trimoxazole.[91]

In patients with cholera, antibiotics are an adjunct to adequate fluid and electrolyte replacement but may have a role in reducing *Vibrio* excretion as well as volume of diarrhoea. Doxycycline (or tetracycline) has been the treatment of choice although resistance to this class is seen.[92,93] Infections due to non-cholera *Vibrio* spp. and *Aeromonas* spp., which generally involve the skin or gastro-intestinal tract but may cause septicaemic illnesses, can also be treated with doxycycline.[91,92]

In treating adults with brucellosis, doxycycline for 45 days combined with initial streptomycin is frequently given as first-line treatment. Substitution of gentamicin for the streptomycin leads to equivalent outcomes.[94] Alternatively, 45 days of doxycycline plus rifampicin is sometimes used and is superior to doxycycline plus a fluoroquinolone.[95] In patients with osteoarticular brucellosis, aminoglycoside-doxycycline therapy is preferred.[96] Triple antibiotic combination with doxycycline, rifampicin and an aminoglycoside appears to reduce the relapse rate.[95]

Actinomycosis is another infection that can be treated with doxycycline, although penicillins are usually first-line therapy.[97] For infections due to *Nocardia* spp., minocycline is preferred although doxycycline maintenance therapy may be used in patients who are intolerant of this and co-trimoxazole. Melioidosis is treated initially with IV carbapenems or ceftazidime but this is then followed up with at least three months of oral therapy, generally using co-trimoxazole plus doxycycline, for which the MICs are generally low.[98,99]

Rat bite fever due to infection with *Streptobacillus moniliformis* is generally treated with penicillins although doxycycline can be substituted in the allergic patient. Occasional isolates of rapid growing mycobacteria such as *M. fortuitum* are susceptible to doxycycline although this is rarely used clinically.[100] Prolonged courses of doxycycline over three to six months are sometimes used to treat patients with tropical sprue.[101]

An interesting newer use of doxycycline has been for *Wolbachia* endosymbiont infection in filarial infections such as onchocerciasis and Wuchererian filariasis. It is used for 6 weeks and by killing the symbiotic bacteria that assist in the life cycle of the filaria, interrupts embryogenesis in the adult worms for prolonged periods.[102–105]

Non-infectious conditions that can be treated with doxycycline

Doxycycline has also been used in a variety of non-infectious conditions. Most commonly, it can be used for severe acne, although part of its effect may be due to anti-bacterial activity against *Propionibacterium acnes*. Other examples of its use are in periodontitis, rosacea, bullous dermatoses, neutrophilic diseases, pyoderma gangrenosum, sarcoidosis, multiple sclerosis, the medical therapy of aortic aneurysms, autoimmune disorders such as rheumatoid arthritis and scleroderma, and as a sclerosant in pleurodesis procedures and for lymphatic or vascular malformations.[106–115]

An interesting potential use for doxycycline is its use in treating or preventing certain cancer metastases. This particularly relates to bone metastases from breast or prostate primaries, possibly due to the inhibition of certain MMPs that are mediators in the formation of this complication.[116] However, *in vitro* activity against a range of cancers has been demonstrated with members of the tetracycline family, including the recently developed molecule, Col-3.[7,116]

Safety

Doxycycline is generally well tolerated, especially compared with older tetracyclines and minocycline.[34,117]

Gastrointestinal

Common symptoms include nausea, vomiting, diarrhoea and epigastric burning. More severe reactions include oesophagitis, oesophageal ulceration, and mediastinitis. The risk of oesophageal ulceration can be reduced with the use of enteric-coated preparations, and with the monohydrate (rather than hydrochloride) formulation. Patients should take doxycycline with sufficient fluids and remain upright for 30 minutes after administration to reduce symptoms. Doxycycline should be avoided in patients with oesophageal compression or obstruction. Other gastrointestinal effects include *Clostridium difficile*-associated diarrhoea, although this occurs less frequently than with other antibiotics such as clindamycin.[118] Tetracycline-induced hepatotoxicity is increased in the presence of hepatic impairment, however the risk with doxycycline is lower or minimal compared with other tetracyclines.[119]

Dermatological and hypersensitivity

Doxycycline may cause photosensitivity and photo-onycholysis.[120] A wide variety of skin eruptions may occur, including erythematous, maculopapular and pustular rashes, pruritus, urticaria and fixed drug eruptions. Rarely hypersensitivity and serum sickness reactions,[121] Stevens-Johnson syndrome and toxic epidermal necrolysis may occur. The Jarisch-Herxheimer reaction may occur when doxycycline is used for treatment of spirochetal infections. Anaphylaxis has also been reported.

Bones and teeth

The accumulation of doxycycline in teeth and bones leads to discolouration of teeth and is more common in deciduous rather than permanent teeth. However if they are given to children whilst permanent teeth are still in development, this may lead to lifelong discolouration. Discolouration may also occur in permanent teeth, especially with concomitant poor dental hygiene and increased sunlight exposure.[122] It may also cause enamel dysplasia and bone deformities and impairment in bone growth.[123] Premature infants administered doxycycline demonstrated a 40% reduction in fibular bone growth that was reversible upon drug cessation.[124]

Neurological

Doxycycline has also been associated with benign intracranial hypertension. Symptoms usually improve upon cessation of doxycycline and concomitant administration of acetazolamide, however permanent

FOI 26-3132 - Document 5

visual acuity or visual field loss has occurred in a percentage of patients, necessitating optic nerve fenestration or CSF shunting.[125,126]

Other

Oropharyngeal and vaginal candidiasis from fungal overgrowth is common. Rare side effects include taste perversion, rhinitis, hiccups, and blood dyscrasias.[34,117,127] Drug-induced lupus is associated with minocycline but not doxycycline, however doxycycline may exacerbate systemic lupus erythematosus.[121] There are fewer side effects when doxycycline is used in lower doses without an increase in resistance of microorganisms.[34]

Pregnancy, lactation and children

Doxycycline can be given during the first 18 weeks of pregnancy but is contraindicated after this time due to potential discolouration and malformation of fetal teeth. It is potentially teratogenic in animal studies. There was a minor increase in fetal abnormalities (odds ratio 1.6, 95% confidence interval 1.1–2.3) in a large survey of over 18,000 pregnancies, however another study of 1795 doxycycline-exposed pregnancies demonstrated no increased risk of fetal abnormalities.[128,129] High doses of doxycycline have been associated with fatty necrosis of the liver in pregnant women, especially those with pyelonephritis. A short course of doxycycline for 7 to 10 days is considered safe during breast-feeding if there are no other alternatives available. Otherwise they should be used with caution as doxycycline is present in breast milk and may also lead to abnormalities in tooth development in the baby. Doxycycline is contraindicated in children younger than 8 years of age due to discolouration of teeth, enamel dysplasia and possible bone deformities. In rare situations doxycycline may be administered to children with a dose of 2.2 mg/kg twice daily where benefits of doxycycline outweigh the risks, such as infections with rickettsiae, *Yersinia pestis*, and *Burkholderia pseudomallei*.[130]

Efficacy

Resistance to doxycycline occurs due to acquisition of genes such as the *tet* and *otr* genes.[131] Generally they are acquired through conjugation from transposons, plasmids and integrons. The majority of these genes encode for efflux proteins that export tetracycline from the cell via an energy-dependent process. Some genes encode ribosomal protection proteins that result in ribosomal conformational changes, preventing doxycycline from binding to the ribosome. *Shigella dysenteriae* was the first tetracycline-resistant organism isolated. Since 1953 there has been a significant increase in doxycycline resistance in Gram-negative organisms including Enterobacteriaceae, Pseudomonodaceae, *Neisseria*, *Haemophilus, Mannheimia, Treponema, Vibrio* spp., and fastidious nonfermentative organisms such as *Kingella*, *Eikenella* and *Actinobacillus* spp.[1] Multi-drug resistance now occurs as *tet* genes are carried on integrons and plasmids with other genes encoding resistance to other antibiotics. Gram-positive organisms such as *Staphyloccocus aureus*, *Streptococcus agalactiae*, *Enteroccocus faecalis*, and *Streptococcus pneumoniae* have also developed doxycycline resistance and multi-drug resistance. Other organisms that may acquire *tet* and *otr* genes include *Mycoplasma*, *Ureaplasma*, *Actinomyces*, *Nocardia* and rapidly growing *Mycobacterium* species.

There are 2 newly discovered genes that encode tetracycline-inactivating enzymes in *Bacteroides* species.[132,133] Doxycycline resistance rarely occurs through chromosomal mutation where permeability of outer membrane pores affects diffusion of tetracycline into the cell. Clinically important chromosomal mutations occur in *H. pylori*, *M. avium* complex and *N. gonorrhoeae*. As yet there is no tetracycline resistance amongst obligate intracellular pathogens and protozoa.[134] Tetracycline-resistant *Chlamydophila suis* has been detected in pigs, so there is potential for doxycycline resistance in chlamydophilae.[135]

The increasing prevalence of doxycycline resistance in various geographic locations has limited its use as treatment for many organisms including Enterobacteriaceae, *S. aureus*, *S. pneumoniae* (including penicillin-resistant pneumococci) and *Bacteroides*.[136] Fortunately doxycycline remains active against a wide range of other infections where its use is now first line, for example, *Coxiella burnetii*, *Brucella melitensis*, *Borrelia burgdorferi*, and in penicillin-allergic patients with early syphilis.

Patient Preference

Doxycycline is inexpensive and available worldwide, and can be conveniently administered via oral or

FOI 26-3132 - Document 5

parenteral routes. This makes it practical for use in community and hospital settings. Excellent absorption and tissue distribution make it particularly useful for the severely ill patient compared with other antibiotics. Common adverse reactions such as gastrointestinal upset or oesophagitis can be prevented with careful attention to correct administration. Enteric-coated pellets have fewer gastrointestinal side effects.[34] Photosensitivity can be prevented or ameliorated with adequate attention to sun protection. It is important to remind women that the efficacy of the contraceptive pill is reduced and that barrier methods of contraception are required during and after doxycycline therapy.

Conclusions

Given its broad spectrum of activity and the wide array of clinical uses, including against some more obscure and difficult to diagnose conditions, doxycycline is sometimes referred to as the "secret weapon of the infectious diseases physician." Although the long acting macrolide azithromycin has taken on many of its uses, it retains a very important place in the antibiotic armamentarium. It is generally well tolerated and has excellent clinical activity in many sexually transmitted infections, rickettsial and related infections, Lyme disease, brucellosis, anthrax, Q fever and atypical respiratory pathogens as well as the prevention of malaria.

Accepted 12 December 2021; Available online 18 December 2021

Abstract

Objective: The objective of this systematic review is to summarize the effects of ivermectin for the prevention and treatment of patients with COVID-19 and to assess inconsistencies in results from individual studies with focus on risk of bias due to methodological limitations.

Methods: We searched the L.OVE platform through July 6, 2021 and included randomized trials (RCTs) comparing ivermectin to standard or other active treatments. We conducted random-effects pairwise meta-analysis, assessed the certainty of evidence using the GRADE approach and performed sensitivity analysis excluding trials with risk of bias.

Results: We included 29 RCTs which enrolled 5592 cases. Overall, the certainty of the evidence was very low to low suggesting that ivermectin may result in important benefits. However, after excluding trials classified as "high risk" or "some concerns" in the risk of bias assessment, most estimates of effect changed substantially: Compared to standard of care, low certainty evidence suggests that ivermectin may not reduce mortality (RD 7 fewer per 1000) nor mechanical ventilation (RD 6 more per 1000), and moderate certainty evidence shows that it probably does not increase symptom resolution or improvement (RD 14 more per 1000) nor viral clearance (RD 12 fewer per 1000).

Conclusion: Ivermectin may not improve clinically important outcomes in patients with COVID-19 and its effects as a prophylactic intervention in exposed individuals are uncertain. Previous reports concluding important benefits associated with ivermectin are based on potentially biased results reported by studies with substantial methodological limitations. Further research is needed. © 2022 The Authors. Published by Elsevier Inc. This is an open access article under the CC BY-NC-ND license (http://creativecommons.org/licenses/by-nc-nd/4.0/)

What is new?

- We found substantial differences in the results of studies with or without important methodological limitations.
- Ivermectin's suggested benefits are mainly based on potentially biased results.
- There is substantial uncertainty on ivermectin's effects for patients with COVID-19 or exposed to SARS-COV-2 and further research is needed.

1. Introduction

There is an urgent need to expand the evidence base on interventions for the prevention and treatment of COVID-19, an infection caused by SARS-CoV-2 that has the potential of progression into pneumonia, multi-organ failure and death [1]. The COVID-19 pandemic has seen a rapid increase in the number of studies testing potential therapeutic options, raising concerns about the quality and lack of scientific integrity, and also about the spread of this information, leading to the so-called "infodemic" [2,3]. According to the World Health Organization (WHO) international registry of clinical trials platform (ICTRP) [4], hundreds of potential interventions are being assessed in more than 10,000 clinical trials and observational studies.

Many drugs including ivermectin, were repurposed for the treatment of COVID-19, most often based on biological plausibility, *in vitro* research, or pathophysiological considerations. Ivermectin is a successful broad-spectrum antiparasitic, included in WHO essential medicines list used to treat several neglected tropical diseases [5]. It emerged as a potential treatment for COVID-19 in mid-2020, following an *in vitro* study demonstrating its anti-viral properties [6].

Multiple systematic reviews have assessed the benefits and harm of ivermectin for COVID-19 patients with inconsistent findings and conclusions [7]. Although some organizations and groups have argued strongly in favor of implementing ivermectin for treatment and/or prevention of COVID-19 [8], current key clinical practice guidelines recommend against its use outside the context of clinical trials [9–12].

Reasons for these major discrepancies are probably related to different evidence analytical and/or interpretation approaches. Assessing the risk of bias is one of the pillars of any systematic review and has proven to be essential for evidence interpretation in the present pandemic context where results of studies with major methodological limitations have led to erroneous conclusions, waste of resources and patients' exposure to potentially harmful interventions [3,13,14]. Nevertheless, most available systematic reviews on ivermectin for COVID-19 have not appropriately assessed risk of bias as a potential explanation for inconsistency between trial results. Therefore, this systematic review aims to summarize the best available evidence on ivermectin for prevention and treatment of COVID-19 patients and explore potential explanations for heterogeneity in RCTs results with focus on studies methodological limitations.

2. Methods

This systematic review report is consistent with Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement [15].

2.1. Protocol registration

This systematic review is part of a larger project that aims to conduct multiple systematic reviews for different questions relevant to COVID-19. The protocol stating the shared objectives and methodology of these reviews was published elsewhere [16].

2.2. Search strategy

We systematically searched in the Living OVerview of Evidence (L.OVE; https://app.iloveevidence.com/covid19) platform, for studies on Ivermectin for COVID-19. L.OVE platform is a system that maps PICO (Patient–Intervention–Comparison–Outcome) questions to a repository developed by Epistemonikos Foundation and is the search platform for the Pan American Health Organization (PAHO) living systematic review of potential therapeutics for COVID-19.[7] The search terms and databases covered are described on the L.OVE platform methods section available at: https://app.iloveevidence.com/covid19/methods. The repository that feeds the L.OVE platform was developed and is maintained through the automated and manual screening of multiple databases, trial registries, preprint servers and other sources. The last version of the methods, the total number of sources screened, and a living flow diagram and report of the project is updated regularly on the website. The searches cover the period from inception date of each database. We last searched the platform on July 6, 2021. There were no restrictions applied to the language or publication status.

2.3. Study selection

Two reviewers (A.I and G.R) working independently and in duplicate, performed study selection, including screening of titles and abstracts and of potentially eligible full-text articles. Reviewers resolved disagreements by discussion.

We included randomized controlled trials (RCTs) that recruited adults with suspected, probable, or confirmed

FOI 26-3132 - Document 5

COVID-19, or that were exposed to SARS-COV-2, comparing systemic ivermectin alone or in combination with other drugs, against placebo, standard care or other interventions, and reported on clinical important outcomes (see "Outcomes of interest" below). We included trials regardless of publication status (peer reviewed, in press, or preprint) or language. No restrictions were applied based on severity of COVID-19 illness, setting in which the trial was conducted (e.g., outpatient, inpatient, critical), dose administered or duration of treatment. We excluded studies in which inhaled ivermectin was used as intervention.

2.4. Data extraction

For each eligible trial one reviewer (A.I) extracted data using a standardized, pilot-tested data extraction form. The reviewer collected information on trial characteristics (trial registration, publication status, study status, design), participant characteristics (country, age, sex, comorbidities, and severity), and outcomes of interest. Extracted data was confirmed by a second reviewer (F.T). Discrepancies were resolved through discussion

2.5. Outcomes of interest

We selected clinically important outcomes considering published prioritization exercises performed in the context of different clinical practice guidelines [9,11]. We included all-cause mortality and invasive mechanical ventilation as critical outcomes, and symptom resolution or improvement, hospitalizations, viral clearance, symptomatic infection, and severe adverse events as important outcomes. For symptom resolution or improvement, we considered the proportion of patients with complete resolution of symptoms, or the proportion of patients discharged from hospital or the proportion of patients with important symptom improvement as reported by investigators. For viral clearance we considered the proportion of patients with negative PCR test. For severe adverse events we used the definition implemented by the investigators.

2.6. Risk of Bias

Two reviewers (A.I and M.R) independently assessed the risk of bias of all included trials using the revised Cochrane Risk of Bias 2.0 tool for randomized trials (RoB 2) [17], focusing on randomization, allocation concealment, blinding, attrition, or other biases relevant to the estimates of effect. In assessing the domain "risk of bias arising from randomization process", in addition to exploring the balance of baseline prognostic in individual trials, we assessed overall balance by constructing Forest plots. We assumed that lack of blinding was less likely to introduce bias to "mortality" and "mechanical ventilation" outcomes hence we assessed risk of bias separately for those two outcomes as follows. For "mortality" and "mechanical ventilation" outcomes we rated trials at high risk of bias overall if one or more domains were rated as "high risk of bias", and as "some concerns" if no domains were rated as "high risk of bias" and "Risk of bias arising from randomization process" and/or "Risk of bias due to missing outcome data" and/or "Risk of bias in selection of reported results" domains were classified as "some concerns". The remaining trials were rated as "low risk of bias". For other outcomes, we rated trials at high risk of bias overall if one or more domains were rated as "high risk of bias", as "some concerns" if no domains were rated as "high risk of bias" and one or more domains were rated as "some concerns", and low risk of bias overall if all domains were rated as "low risk of bias". Reviewers resolved discrepancies by discussion.

2.7. Data synthesis

We summarized the effect of interventions on selected outcomes using relative risks (RRs) and corresponding 95% confidence intervals (95%CIs). We conducted frequentist random-effects pairwise meta-analyses using the R package "meta" in RStudio Version 1.4.1103 [18]. For the primary analysis, we assumed that interventions used in some trials as active comparators (hydroxychloroquine and lopinavir-ritonavir), are not related to important effects in patients with COVID-19 [9]. We considered those interventions as standard of care and performed sensitivity analysis to assess the robustness of results (see subgroup and sensitivity analyses).

2.8. Certainty of the evidence

We assessed the certainty of evidence using the grading of recommendations assessment, development, and evaluation (GRADE) approach [19]. Two methodologists with experience in using GRADE rated each domain for each comparison separately and resolved discrepancies by consensus. We rated the certainty for each comparison and outcome as high, moderate, low, or very low, based on considerations of risk of bias, inconsistency, indirectness, publication bias, and imprecision. We made judgments of imprecision using a minimally contextualised approach with the null effect as a threshold. This minimally contextualised approach considers whether the 95%CI includes the null effect, or, when the point estimate is close to the null effect, whether the 95%CI lies within the boundaries of small but important benefit and harm that corresponds to every outcome assessed [20,21]. To define severe or very severe imprecision we considered if the 95%CI included not only the null effect, but important benefits and harms. We used MAGIC authoring and publication platform (https://app.magicapp.org/) to generate the tables summarizing our findings. We calculated the absolute risks and risk differences from the RRs (and their 95%CIs) and

FOI 26-3132 - Document 5

the median risk in the control groups of studies reporting on severe patients for "mortality" and "mechanical ventilation" outcomes. For the remaining outcomes we used RRs (and their 95%CIs) and the median risk in the control groups of all analysed trials.

To communicate our findings and conclusions using statements we followed published guidance [22].

2.9. Subgroup and sensitivity analyses

To assess if overall estimates of effects could be influenced by trials reporting potentially biased results, we performed sensitivity analysis excluding trials categorized as "high risk of bias" and "some concerns". We expected smaller effects after excluding those trials. In addition, as there is high certainty evidence on the lack of efficacy of some interventions for the treatment of patients with COVID-19 such as hydroxychloroquine and Lopinavir-Ritonavir [9], for the primary analysis, we considered those interventions as a part of the standard of care. However, we performed sensitivity analyses excluding trials in which hydroxychloroquine or Lopinavir-Ritonavir were used as comparators. We performed subgroup analysis based on intervention implemented and baseline disease severity, we expected larger effects in trials in which ivermectin was implemented in combination with other interventions and in patients with less severe disease.

2.10. Update of this systematic review

An artificial intelligence algorithm deployed in the COVID-19 topic of the L.OVE platform (https://app.iloveevidence.com/covid19) will provide instant notification of articles with a high likelihood of eligibility. These will be screened by paired reviewers iteratively who will also conduct data extraction and updates of the estimates of effects and certainty of the evidence. We will consider resubmission to a journal if there is a substantial modification of the effect estimate or certainty of the evidence for ivermectin, at the discretion of the reviewer team.

3. Results

The search strategy identified 680 potentially eligible records, of which 29 RCTs (reported in 78 references) were included. We identified two additional studies which we decided not to include. One was reported as a cluster randomized trial but methods and results were poorly reported and not consistent with a RCT [23]. The other was mentioned in a published review[24] but we were unable to obtain the full text [25]. We intended to contact the authors of these and other three included studies[26, 27, 28] for further methodological details by email, but only one responded [28]. On July 14, 2021, one of the included studies was retracted from the preprint server due to research misconduct concerns that are being investigated [29]. As the primary aim of our review was to assess the influence of potentially biased results on ivermectin's effects interpretation, we decided not to exclude it. The selection process is described by the PRISMA flow diagram in S1 Figure. The list of excluded studies is available upon request.

3.1. Trial characteristics

There was a total of 5592 patients from 29 RCTs, [26–54] in which ivermectin was compared against standard of care or other treatments (S1 Table). Twenty trials were published in peer reviewed journals and nine were only published as preprints. One trial reported the results of three different cohorts, one of severe patients, one of mild patients and one of exposed persons, we therefore analyzed each cohort as a different trial [29]. The sample size ranged from 24 to 1342, with 2830 assigned to Ivermectin and 2483 assigned to control. Eighteen trials included patients with mild to moderate COVID-19 [26,28-30,32-45], three studies included patients with severe to critical COVID-19 [29,46,47], six studies included patients with mild to critical disease [27,48,49,50,51,52], and four studies included non-infected patients exposed to SARS-COV-2 [29,31,53,54].

Ivermectin administered dose varied from 12 mg once to 400 μgm/kg once a day for 4 days. Ivermectin alone was used in most trials but five in which the intervention implemented was a combination of ivermectin with doxycycline [26,32,34,48], or iota-Carrageenan [54]. Comparator was standard of care with or without placebo in most trials. Active comparators included hydroxychloroquine or cloroquine [29,47], hydroxychloroquine plus azythomicin [32], lopinavir-ritnonavir[50] and vitamin C [31].

3.2. Risk of bias

The risk of bias assessment of the 29 included trials is summarized in (Table 1). For mortality and mechanical ventilation, our assessment resulted in high risk of bias for four RCT (including the study retracted due to misconduct concerns) [29], some concerns for two and low risk of bias for seven RCTs. For all remaining outcomes, our assessment resulted in high risk of bias for thirteen RCTs, some concerns for nine and low risk of bias for seven RCTs. Most trials did not provide enough information to assess baseline differences between arms. Overall assessment of baseline prognostic factors suggested that ischemic heart disease was less frequent in patients assigned to ivermectin (S2 Figure). A detailed description of the trials' methodological limitations is provided in a supplementary table (S2 Table).

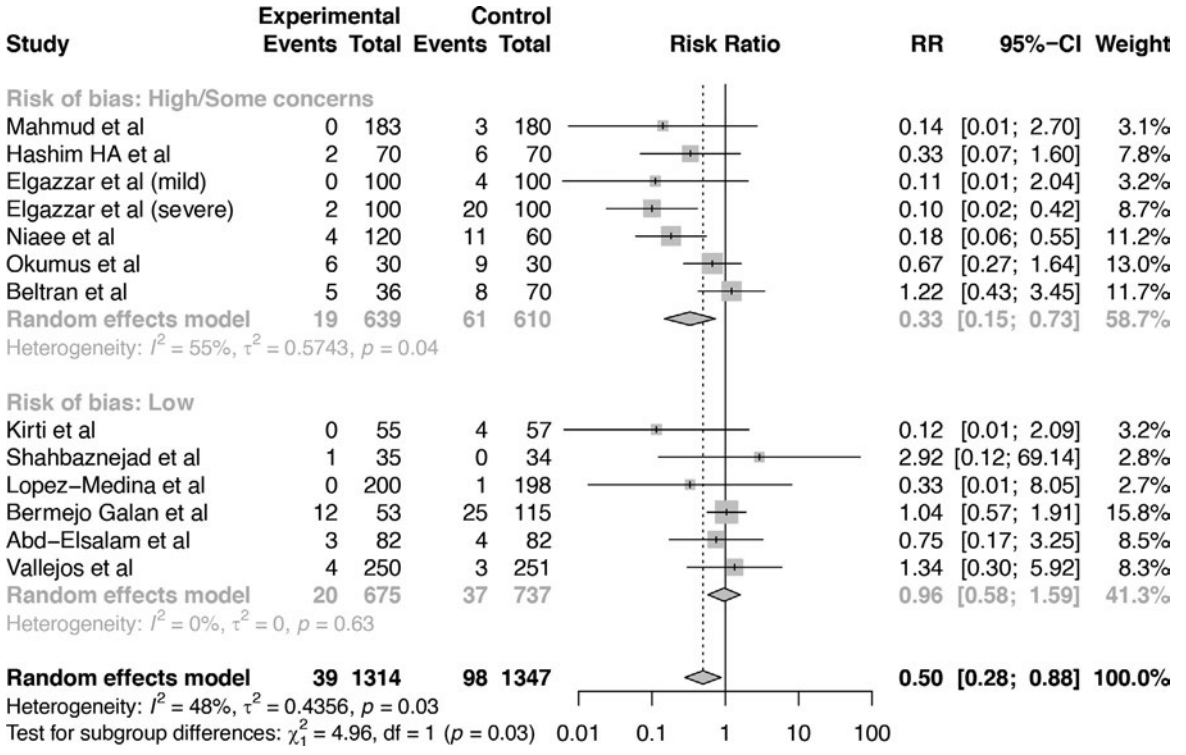

Fig. 1. Results of primary analysis and sensitivity analysis excluding trials with significant methodological limitations.

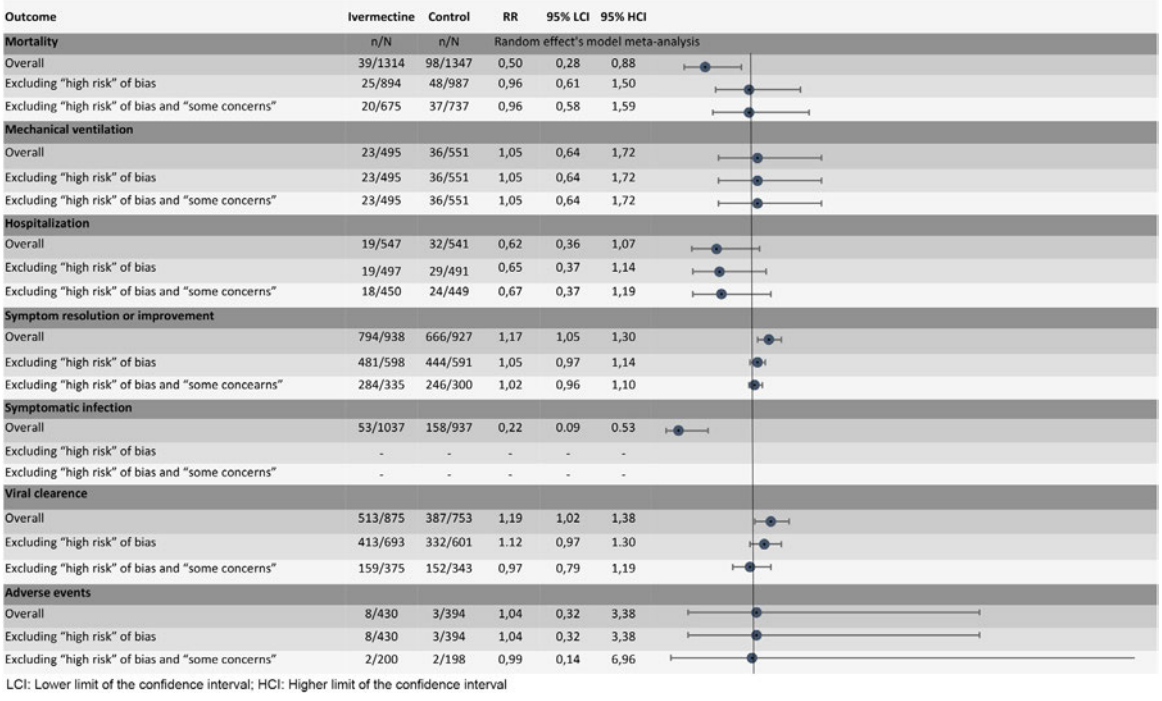

Fig. 2. Comparison: ivermectin vs. Standard of care; Outcome: mortality; Analysis: subgroups by risk of bias classification.

3.3. Effects on assessed outcomes

Table 2. and Fig. 1. provide a summary of finding for all assessed outcomes.

3.4. Mortality

Twelve trials with 2661 patients reported on mortality [27,28,29,34,37,41,43,46-49,51]. Ivermectin may reduce mortality (RR 0.50, 95% CI:0.28 to 0.88; RD 91

FOI 26-3132 - Document 5

Table 2. Summary of findings table

Outcome Timeframe	Study results and measurements	Absolute effect estimates		Certainty of the Evidence (Quality of evidence)	Plain text summary
		SOC	Ivermectin		
Mortality (Overall)	Relative risk: 0.50 (CI 95% 0.28 – 0.88) Based on data from 2661 patients in 12 studies Follow up: median 30 days	183 per 1000 Difference: 91 fewer per 1000 (CI 95% 132 fewer – 22 fewer)	92 per 1000	Low Due to serious risk of bias and serious inconsistency[a,b]	Ivermectin may reduce mortality
Mortality (excluding "some concerns" and "high risk of bias" trials)	Relative risk: 0.96 (CI 95% 0.58 – 1.59) Based on data from 1412 patients in 6 studies Follow up: median 25.5 days	183 per 1000 Difference: 7 fewer per 1000 (CI 95% 71 fewer – 92 more)	176 per 1000	Low Due to very serious imprecision[c]	Ivermectin may have little or no difference on mortality
Mechanical ventilation (overall - all studies classified as low risk of bias)	Relative risk: 1.05 (CI 95% 0.64 – 1.72) Based on data from 1046 patients in 6 studies Follow up: median 30 days	119 per 1000 Difference: 6 more per 1000 (CI 95% 43 fewer – 86 more)	125 per 1000	Low Due to very serious imprecision[c]	Ivermectin may have little or no difference on mechanical ventilation
Symptom resolution or improvement (overall)	Relative risk: 1.17 (CI 95% 1.05 – 1.3) Based on data from 1865 patients in 11 studies Follow up: median 10 days	714 per 1000 Difference: 121 more per 1000 (CI 95% 36 more – 214 more)	835 per 1000	Low Due to serious risk of bias and serious inconsistency[a,b]	Ivermectin may increase symptom resolution or improvement
Symptom resolution or improvement (excluding "some concerns" and "high risk of bias" trials)	Relative risk: 1.02 (CI 95% 0.96 – 1.1) Based on data from 635 patients in 3 studies Follow up: median 14 days	714 per 1000 Difference: 14 more per 1000 (CI 95% 29 fewer – 71 more)	728 per 1000	Moderate Due to serious imprecision[d]	Ivermectin probably has little or no difference on symptom resolution or improvement
Hospitalization (overall)	Relative risk: 0.62 (CI 95% 0.36 – 1.07) Based on data from 1088 patients in 4 studies Follow up: median 17.5 days	54 per 1000 Difference: 21 fewer per 1000 (CI 95% 35 fewer – 4 more)	35 per 1000	Low Due to very serious imprecision[e]	Ivermectin may reduce hospitalizations

(*continued on next page*)

Table 2 (*continued*)

Outcome Timeframe	Study results and measurements	Absolute effect estimates		Certainty of the Evidence (Quality of evidence)	Plain text summary
		SOC	Ivermectin		
Hospitalization (excluding some concerns and high risk of bias studies)	Relative risk: 0.67 (CI 95% 0.37 – 1.19) Based on data from 899 patients in 2 study Follow up: median 25.5 days	54 per 1000 Difference: 18 fewer per 1000 (CI 95% 34 fewer – 8 more)	36 per 1000	Low Due to very serious imprecision[e]	Ivermectin may reduce hospitalizations
Symptomatic infection (overall - all studies classified as high risk of bias)[14]	Relative risk: 0.22 (CI 95% 0.09 – 0.53) Based on data from 1974 patients in 4 studies Follow up: median 21 days	159 per 1000 Difference: 124 fewer per 1000 (CI 95% 145 fewer – 75 fewer)	35 per 1000	Low Due to very serious risk of bias[a]	Ivermectin may decrease symptomatic infection
Viral clearance (overall)	Relative risk: 1.19 (CI 95% 1.02 – 1.38) Based on data from 1628 patients in 13 studies Follow up: median 6 days	400 per 1000 Difference: 76 more per 1000 (CI 95% 8 more – 152 more)	476 per 1000	Low Due to serious risk of bias and serious inconsistency[a,b]	Ivermectin may increase viral clearance
Viral clearance (excluding "some concerns" and "high risk of bias" trials)	Relative risk: 0.97 (CI 95% 0.79 v 1.19) Based on data from 718 patients in 3 studies Follow up: median 5 days	400 per 1000 Difference: 12 fewer per 1000 (CI 95% 84 fewer – 76 more)	388 per 1000	Moderate Due to very serious imprecision[d]	Ivermectin probably has little or no difference on viral clearance
Severe adverse events (overall)	Relative risk: 1.04 (CI 95% 0.32 – 3.38) Based on data from 824 patients in 4 studies Follow up: median 29 days	5 per 1000 Difference: 0 fewer per 1000 (CI 95% 3 fewer – 12 more)	5 per 1000	Very low Due to serious risk of bias and very serious imprecision[a,c]	We are uncertain whether ivermectin increases or decreases severe adverse events
Severe adverse events (excluding "some concerns" and "high risk of bias" trials)	Relative risk: 0.99 (CI 95% 0.14 – 6.96) Based on data from 398 patients in 1 study Follow up: median 21 days	5 per 1000 Difference: 0 fewer per 1000 (CI 95% 4 fewer – 30 more)	5 per 1000	Very low Due to extremely serious imprecision[f]	We are uncertain whether ivermectin increases or decreases severe adverse events

[a] Risk of Bias: Serious or very serious. See Table 1 and Appendix Table 2.
[b] Inconsistency: Serious. The confidence interval of some of the studies do not overlap with those of most included studies.
[c] Imprecision: Very serious. 95%CI includes important benefits and harms.
[d] Imprecision: Serious. 95%CI includes important benefits.
[e] Imprecision: Very serious. 95%CI includes absence of benefits and low number of events.
[f] Imprecision: Extremely serious. 95%CI includes important benefits and harms and very low number of events.

FOI 26-3132 - Document 5

fewer per 1,000 participants, 95% CI: 132 fewer to 22 fewer). The certainty of the evidence was low because of serious risk of bias and serious inconsistency (I^2 48%). Sensitivity analysis excluding six trials classified as "some concerns" or "high risk of bias" showed that ivermectin may not reduce mortality (RR 0.96, 95% CI: 0.58 to 1.59; RD 7 fewer per 1,000 participants, 95% CI: 71 fewer to 92 more) (Fig. 2).

3.5. Mechanical ventilation

Six trials with 1046 patients, classified as "low risk of bias", reported on mechanical ventilation [28,35,37,43,47,51]. Ivermectin may not reduce the requirement of mechanical ventilation (RR 1.05, 95% CI:0.64 to 1.72; RD 6 more per 1,000 participants, 95% CI: 43 fewer to 86 more) (S3 Figure in S1 Appendix). The certainty of the evidence was low because of very serious imprecision.

3.6. Symptom resolution or improvement

Eleven trials with 1865 patients reported on symptom resolution or improvement [27,29,32,34,36-38,41,42,45,46]. Ivermectin may increase symptom resolution or improvement (RR 1.17, 95% CI:1.05 to 1.30); RD 121 more per 1,000 participants, 95% CI: 36 more to 214 more). The certainty of the evidence was low because of serious risk of bias and serious inconsistency (I^2 79%). Sensitivity analysis excluding eight trials classified as "some concerns" or "high risk of bias" showed that ivermectin probably does not increase symptom resolution or improvement (RR 1.02, 95% CI:0.96 to 1.10; RD 14 more per 1,000 participants, 95% CI: 29 fewer to 71 more) (S4 Figure in S1 Appendix).

3.7. Hospitalization

Four trials with 1088 patients reported on hospitalization[28,39,41,44]. Ivermectin may decrease hospitalizations (RR 0.62, 95% CI:0.36 to 1.07); RD 21 fewer per 1,000 participants, 95% CI: 35 fewer to 4 more). The certainty of the evidence was low because of very serious imprecision. Sensitivity analysis excluding two trials classified as "some concerns" or "high risk of bias" showed that ivermectin may decrease hospitalizations (RR 0.67, 95% CI:0.37 to 1.19); RD 18 fewer per 1,000 participants, 95% CI: 34 fewer to 10 more) (S5 Figure in S1 Appendix).

3.8. Symptomatic infection in exposed persons

Four trials including 1974 patients, classified as "high risk of bias", reported on symptomatic infection [29,31,53,54]. Ivermectin may reduce symptomatic infection (RR 0.22, 95% CI:0.09 to 0.53); RD 124 fewer per 1,000 participants, 95% CI: 145 fewer to 75 fewer) (S6 Figure in S1 Appendix). The certainty of the evidence was low because of very serious risk of bias.

3.9. Viral clearance

Thirteen trials with 1628 patients reported on viral clearance [26,28,32,33,34,37,38,40,42,44,46,50,52]. Ivermectin may increase viral clearance (RR 1.19, 95% CI: 1.02 to 1.38); RD 76 more per 1,000 participants, 95% CI: 8 more to 152 more). The certainty of the evidence was low because of serious risk of bias and serious inconsistency (I^2 56%). Sensitivity analysis excluding ten trials classified as "some concerns" or "high risk of bias" showed that ivermectin probably does not increase viral clearance (RR 0.97, 95% CI: 0.79 to 1.19); RD 12 fewer per 1,000 participants, 95% CI: 84 fewer to 76 more) (S7 Figure in S1 Appendix).

3.10. Severe adverse events

Four trials with 824 patients reported on severe adverse events [34,35,41,52]. It is uncertain if Ivermectin increases or decreases severe adverse events (RR 1.04, 95% CI: 0.32 to 3.38); RD 0 more per 1,000 participants, 95% CI: 3 fewer to 12 more). The certainty of the evidence was very low because of serious risk of bias and very serious imprecision. Sensitivity analysis excluding ten trials classified as "some concerns" or "high risk of bias" showed that it is uncertain if ivermectin increases or decreases severe adverse events (RR 0.99, 95% CI: 0.14 to 6.96); RD 0 more per 1,000 participants, 95% CI: 4 fewer to 30 more) (S8 Figure in S1 Appendix).

3.11. Additional analysis

Subgroup and sensitivity analysis did not suggest differential effects according to baseline disease severity, or when ivermectin was administered in combination with other interventions, or when it was compared against hydroxychloroquine or lopinavir-ritonavir, or when different outcome measurements time frames were used (S9 to S30 Figures in S2 Appendix). Visual inspection of the funnel plot for mortality suggested possible publication bias, (S31 Figure in S2 Appendix) however egger's test was not statistically significant ($P = 0.13$). Visual inspection of funnel plots for symptom resolution or improvement and viral clearance did not suggest publication bias, egger's test results $P = 0.48$ and $P = 0.25$ respectively (S32 and S33 Figures in S2 Appendix).

4. Discussion

This systematic review and meta-analysis provide a comprehensive overview of the available evidence on ivermectin for prevention and treatment of COVID-19. Overall, the body of evidence suggests that ivermectin may reduce mortality, may increase symptom resolution or improvement, may decrease hospitalizations, may increase viral clearance, and may decrease symptomatic infection

FOI 26-3132 - Document 5

in exposed individuals. However most trials have serious methodological limitations including lack of allocation concealment and lack of blinding, and reported results varied remarkably from striking benefits to null effects. GRADE assessment resulted in low or very low certainty of the evidence for all the outcomes, due to risk of bias, inconsistency, and imprecision. Visual inspection of funnel plot constructed for mortality outcome suggest possible publication bias which rises additional concerns about the certainty of the evidence on ivermectin's effects.

After excluding trials with significant methodological limitations inconsistency disappeared and results changed substantially. We found low certainty, due to imprecision, that ivermectin may not reduce mortality, nor reduce invasive mechanical ventilation, and moderate certainty evidence that ivermectin probably does not increase viral clearance or symptom resolution or improvement. Regarding hospitalizations, results did not change importantly suggesting that ivermectin may modestly reduce hospitalizations. However, certainty of the evidence remained low due to very serious imprecision. It is uncertain if ivermectin reduces or increases symptomatic infections in exposed individuals or increases severe adverse events as no trials classified as "low risk of bias" were identified, or the certainty of the evidence was very low.

Our systematic review has several strengths. The search strategy was comprehensive with explicit eligibility criteria, and no restrictions on language or publication status. We used a validated tool for risk of bias assessment and performed a thorough assessment providing details of trial limitations and potential important imbalances in baseline participant characteristics. We assessed the certainty of the evidence using the GRADE approach and interpreted the results considering absolute rather than relative effects.

Reporting was poor for a substantial number of included trials. For risk of bias assessment, we adopted a conservative approach and rated as low risk of bias only those trials for which it was clearly reported that no significant methodological limitations existed. Hence, we may have inappropriately classified some well executed trials as "some concerns" or "high risk of bias" due to their suboptimal reporting methods. Although for some trials we intended to contact the authors for clarification, most did not answer.

Multiple systematic reviews assessed ivermectin for COVID-19 [7]. Most of these reviews were already outdated at the time of writing this manuscript [55]. We did not identify studies included in other reviews that were not captured in our search strategy. Only five reviews incorporated a substantial proportion of the studies assessed in our review including a recently published systematic review by the Cochrane collaboration in which the authors excluded studies with high risk of bias or that compared ivermectin against other active interventions [24,56-59]. In agreement with our findings, all these reviews concluded that most of the studies assessing ivermectin for COVID-19 have considerable methodological limitations, and three judged the certainty of the evidence as low to very low for all outcomes [56,57] or not robust enough to justify ivermectin's use [58]. The authors of one systematic review concluded that ivermectin "may have a role in decreasing mortality in mildly/moderately ill COVID-19 patients" although they graded the certainty on ivermectin's effect on mortality as very low [59]. Bryant el at. graded the certainty of the evidence as low or very low for all outcomes except mortality for which they report moderate certainty in important mortality reduction. In contrast to our analysis, they reached this conclusion by not downgrading the certainty of the evidence for inconsistency even though they reported there was significant, not fully explained, heterogeneity in studies' results. In addition, for mortality outcome, they report a sensitivity analysis excluding high risk of bias studies which, in contrast to our findings, did not result in different estimates of effect from the primary analysis. This can be explained by the fact that the authors did not exclude a relevant number of studies with important methodological limitations, that they classified as "unclear" risk of bias [24].

Due to the excessive amount of rapidly published research on COVID-19, often referred to as an "infodemic" [2,3], the scientific community has already faced a similar scenario to the one described for ivermectin in the present review. Small studies with significant methodological limitations suggested benefits for steroids, lopinavir-ritonavir, interferon β-1a and convalescent plasma among others [60–63]. However, those potential benefits were seldom confirmed and mostly discarded by well-designed adequately powered studies [64–67]. The limitations in the body of evidence on ivermectin for COVID-19 does not allow to reach firm conclusions, however the results of our analysis highlight that most of current suggested benefits of ivermectin are based on potentially biased estimates reported by studies with significant methodological limitations. Further research is needed to confirm or reject the effects of ivermectin on patient important outcomes.

There is an urgent need for high quality research both in health emergencies and in health relevant priorities in non-emergency settings. Those involved in evidence production should prioritize quality over quantity and speed to provide trustworthy information that is useful for decision-making. Although countries have capacities to conduct trials, and there exist global standards of quality assurance in clinical trials [68–70], a global coordinating mechanism is needed to streamline and harmonize research findings on an international scale.

5. Conclusions

Ivermectin may not improve clinically important outcomes in patients with COVID-19 and its effects as a prophylactic intervention in exposed individuals are uncertain. Previous reports concluding important benefits associated

FOI 26-3132 - Document 5

with ivermectin are based on potentially biased results reported by studies with substantial methodological limitations. Further research is needed.

Acknowledgments

We would like to thank Victoria Stanford for contributing to the writing of the final version of the manuscript.

Abstract: Drug repositioning is a highly studied alternative strategy to discover and develop anticancer drugs. This drug development approach identifies new indications for existing compounds. Ivermectin belongs to the group of avermectins (AVM), a series of 16-membered macrocyclic lactone compounds discovered in 1967, and FDA-approved for human use in 1987. It has been used by millions of people around the world exhibiting a wide margin of clinical safety. In this review, we summarize the *in vitro* and *in vivo* evidences demonstrating that ivermectin exerts antitumor effects in different types of cancer. Ivermectin interacts with several targets including the multidrug resistance protein (MDR), the Akt/mTOR and WNT-TCF pathways, the purinergic receptors, PAK-1 protein, certain cancer-related epigenetic deregulators such as SIN3A and SIN3B, RNA helicase, chloride channel receptors and preferentially target cancer stem-cell like population. Importantly, the *in vitro* and *in vivo* antitumor activities of ivermectin are achieved at concentrations that can be clinically reachable based on the human pharmacokinetic studies done in healthy and parasited patients. Thus, existing information on ivermectin could allow its rapid move into clinical trials for cancer patients.

Keywords: Ivermectin, cancer, drug repurposing

Introduction

The antiparasitic drug ivermectin was initially approved in humans in 1987 to orally treat onchocerciasis, also known as river blindness, caused by the blackfly-transmitted parasite *Onchocerca volvulus* in poor populations around the tropics, mostly in West and Central Africa [1, 2]. In humans, its use has improved the nutrition, general health and well-being of billions of people worldwide since it was first used to treat onchocerciasis. Not only that, but in veterinary medicine, ivermectin is used to treat billions of livestock and pets around the world, helping to boost production of food and leather products, as well as to keep billions of companion animals, particularly dogs and horses, healthy. Nowadays, ivermectin by its own has produced sales greater than US$1 billion/annum during the past two decades [3] and is annually taken by close to 250 million people [1].

Ivermectin belongs to the group of avermectins (AVM), which is a group of 16-membered macrocyclic lactone compounds discovered in 1967 in the Japanese Kitasato Institute [1, 3] in fermentation broths of actinomycetes cultures with the fungus *Streptomyces avermitilis* [4-6]. AVM family members include, among others, selamectin, abamectin, monoxidectin and ivermectin (**Figure 1**), all of which differ from the antibacterial and antifungal 16-membered macrocyclic lactones by owning a bisoleandrosyloxy substituent at the C13 [3]. Ivermectin is the most commonly employed compound from the AVM group, being a more potent and safer semi-synthetic mixture of the two AVMs 22,23-dihydroavermectin-B_{1a} and dihydroavermectin-B_{1b}, at a reason of 4:1, respectively [1]. Since 1981 ivermectin has been employed for agriculture, veterinary and aquaculture purposes [1], and is recognized as nematocidal, acaracidal and insecticidal [3, 7]. The antiparasitic efficacy of ivermectin is not limited to onchocerciasis, since it is also effective for filarial infections such as those caused by *Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, *Mansonella perstans*, and *Mansonella ozzardi* [7]. It also eradicates gastrointestinal parasites, including

FOI 26-3132 - Document 5

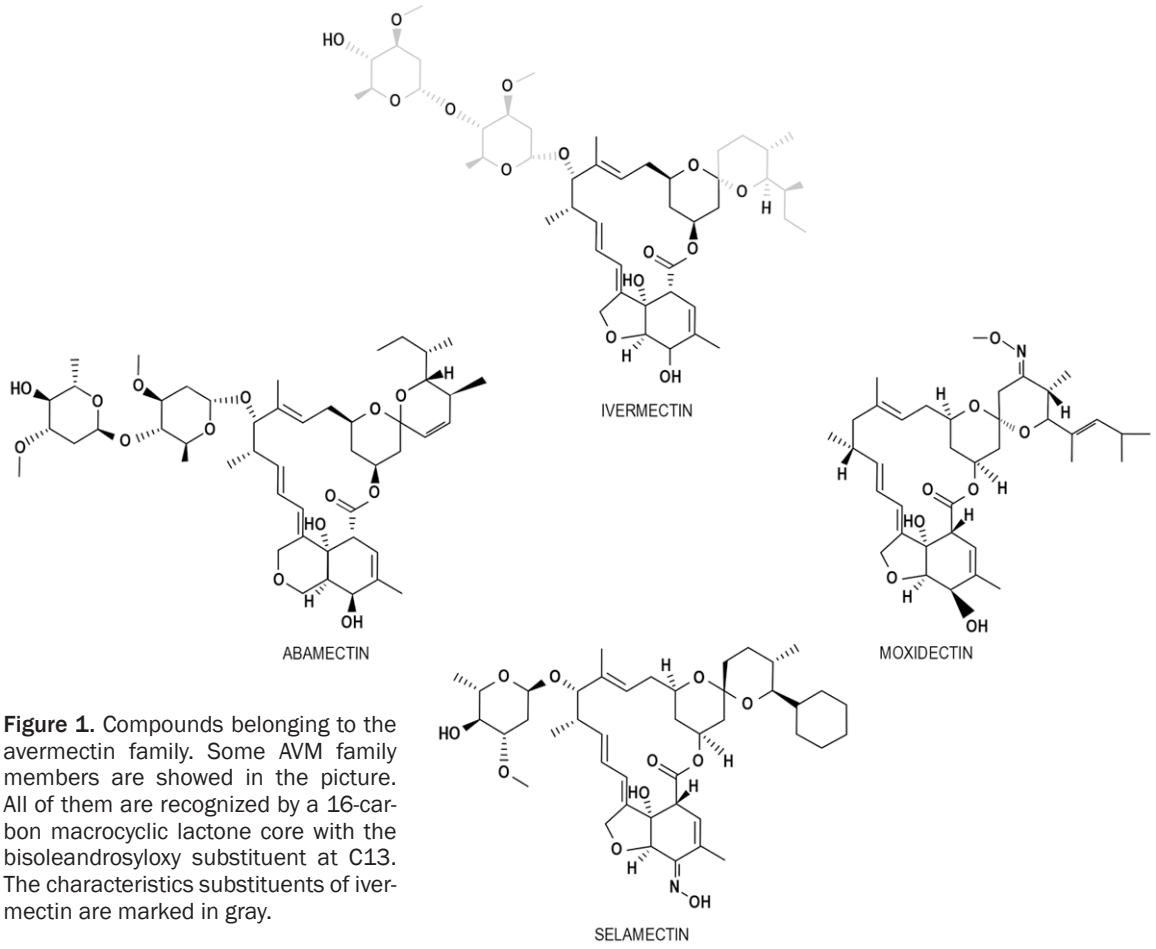

Figure 1. Compounds belonging to the avermectin family. Some AVM family members are showed in the picture. All of them are recognized by a 16-carbon macrocyclic lactone core with the bisoleandrosyloxy substituent at C13. The characteristics substituents of ivermectin are marked in gray.

Ascaris lumbricoides, *Strongyloides stercoralis*, *Enterobius vermicularis*, *Trichuris trichiuria*, and *Ancylostoma duodenale* [7]. Besides, it is employed to treat trypanosomiasis, malaria, leishmaniasis, scabies and head lice [1]. In parasites and helminths, ivermectin, as well as the rest of AVMs, increases the activity of γ-aminobutyric acid (GABA) receptors or glutamate-gated chloride ion channels (Glu-Cl) [3, 4, 6], which blockades the signal between neuron and muscle [3].

In mammals, GABA-sensitive neurons are secured by the blood-brain barrier (BBB) within the central nervous system (CNS), protecting vertebrates against potential harmful effects of AVMs [3, 6]. In support of this statement, subpopulation of collie dogs that have defective function of the multidrug resistance (MDR) protein (commonly a 4 base-pair deletion of the *mdr-1* gene which produces a stop codon), which is an integral part of the BBB and functions as a drug-transport pump in the BBB, have increased neurotoxicity to ivermectin [8]. On the other hand, invertebrates are dose-dependent susceptible due to the widespread allocation of Glu-Cl channels, in whom ivermectin induces the opening of GABA-regulated Cl^- channels that generates an influx of Cl^- [1, 7]. The resulting hyperpolarization impedes the phosphorylation of the regulatory light chain of myosin II by PAK1 [9], promoting paralysis of somatic muscles with concomitant uncoordinated movement, starvation due to inhibition of pharyngeal pumping, and death [1, 3, 5, 7]. Certainly, the affinity of ivermectin for the parasite is 100 times greater than for the mammalian brain, but at least in onchocerciasis, ivermectin action is mostly restricted to the microfilariae stage of *Onchocerca volvulus* [7] as the macrofilariae form does not require pharyngeal pumping to survive [1]. The rate of reduction in microfilarial worms is close to 98% with only two weeks of ivermectin administration, an effect maintained within the next 12 months [1].

FOI 26-3132 - Document 5

Current use and dosage as an antiparasitic drug

In humans, the most used dose of ivermectin for onchocerciasis, strongyloidiasis and enterobiasis ranges between 150 to 200 μg/kg [10-12], while it is used at higher doses of 400 μg/kg for lymphatic filariasis [13]. It is noteworthy the report of a clinical trial on the use of ivermectin for patients with spinal damage and muscle spasms where the drug was administered up to 1.6 mg/kg subcutaneously twice a week for 12 weeks [14].

Toxicity

This compound has a wide margin of safety in ruminants, pigs and equine, as well as in most of the dog breeds [15, 16]. The acute toxicity of ivermectin has been investigated in various species of animals. The signs of toxicity were similar after oral and intraperitoneal administration in rats and mice, and the effects consisted in ataxia, tremors, and reduced activity [17]. In early stages of development, ivermectin at doses of 0.4-0.8 mg/kg in mice, 10 mg/kg in rats, and 3-6 mg/kg in rabbits, increased the incidence of cleft palate, but it was not considered as embryotoxic since the frequency of anomalies was very low [18]. The toxic effects have been related to its interaction with the P-glycoprotein, which limits its access to the CNS. The absence of this protein determines the accumulation of ivermectin in the brain of transgenic mice that do not express it. Finally, in adult Rhesus monkeys that ingested it daily for 16 days at 1.2 mg/kg, no undesirable effects were detected [18].

There are several toxicological reports of ivermectin in different species. The lethal dose 50 (LD50) reported in mice [19] is 25 mg/kg administered orally, whose human equivalent dose (HED) is 2.02 mg/kg. The LD50 increases up to 30 mg/kg when this compound is administered intraperitoneally in mice (HED 2.43 mg/kg). For rats the average lethal dose is 50 mg/kg orally (HED 8.01 mg/kg) and 55 mg/kg intraperitoneally (HED 8.91 mg/kg). In rabbits it is 406 mg/kg in topical application, while in dogs it is 80 mg/kg administered orally (HED 43.24 mg/kg) [20]. Clearly, it seems that the higher the phylogenetic scale the lower toxicity by ivermectin. These data are in accord with the findings in a review paper on avermectins poisoning (14 on suicidal attempt). In this retrospective review, among 18 patients exposed to abamectin and one to ivermectin, 15 were poisoned by oral ingestion. Four were asymptomatic and 8 had minor symptoms with a mean ingestion of 23 mg/kg (range in 4.2-67 mg/kg). Seven patients manifested severe symptoms, such as coma (seven), aspiration with respiratory failure (four), and hypotension (three), after a mean ingestion of 100.7 mg/kg avermectin (15.4 mg/kg for ivermectin and 114.9 mg/kg for abamectin). All 7 seven patients received intensive supportive care; 1 patient died 18 days later as a result of multiple organ failure [21].

In humans it is considered that ivermectin generates low levels of toxicity because its targets are confined within the CNS. Indeed, most patients treated with ivermectin have no side-effects other than those caused by the immune and inflammatory responses against the parasite, such as fever, pruritus, skin rashes and malaise [7, 22], and when present, they appear within 24-48 h after treatment [23]. Certainly, moderate symptoms such as arthralgia, dizziness, fever, skin edema, dyspnea and hypotension may be more related with the microfilarial load in the patient rather than with the intrinsic toxicity of ivermectin [24]. Reports on cases of encephalopathy in patients co-infected with onchocerciasis and lymphatic filariasis after 48 h of treatment with ivermectin can be found in the literature [25], but it is believed that this adverse reaction is due to the obstruction of the microcirculation of the brain by the accumulation of dead or paralyzed parasites, which leads to brain embolism [26].

In conclusion, the immense number of patients who have been treated with ivermectin shows that it is a safe and a well-tolerated drug. Beyond the side effects attributable to the immunological and inflammatory reaction elicited by dying or death parasites, there are sympathetic signs related to ivermectin intoxication, including tremors, mydriasis, sialorrhea, motor incoordination and coma [27].

Pharmacokinetics

The pharmacokinetics of ivermectin have been widely studied in various mammals, including humans; is a fat-soluble compound, with a distribution volumen of 46.9 L; it has a mean peak

Table 1. Pharmacokinetics of ivermectin in healthy and parasited subjects

Condition	Doses (mg/kg)	Route	C_{max} (ng/mL)	T_{max} (h)	AUC (μg/h/mL)
Parasitic infection	0.1-0.2	Oral	52.0	5.2	2.852
Healthy	0.35-0.6	Oral	87.0	4.2	1.444
Healthy	0.7-1.1	Oral	165.2	3.6	2.099
Healthy	1.4-2.0	Oral	247.8	4.2	4.547

plasma level of ~4 h after oral administration with a second peak at 6-12 h because of enterohepatic recycling [1], and possesses an oral clearance of 1.2 L/h [7]. With a plasma protein binding of 93% [7], this drug experiences low biotransformation within the organism [4-6]. The maximum concentration in plasma is reached 4-5 h after its oral administration; its half-life is approximately 19 h and is metabolized in the liver by the cytochrome CYP1A and CYP3A4 complexes, generating 10 metabolites, mostly demethylated and hydroxylated. Its excretion is mainly by feces and only 1% is excreted in the urine [28]. **Table 1** shows the pharmacokinetic data of ivermectin in humans infected with parasites, as well as in healthy humans treated with various doses of ivermectin [28, 29]. According with **Table 1**, the molar concentrations achieved taking into account the total exposure of the drug measured by the area under the curve (systemic exposure) in healthy individuals or patients treated for parasitic diseases are:

3.25 μM/h in parasitized patients with a dose of 0.1-0.2 mg/kg, 1.64 μM in healthy subjects with a dose of 0.35-0.6 mg/kg, 2.4 μM/h in healthy subjects with a dose of 0.7-1.1 mg/kg, and 5.2 μM/h in healthy subjects with a dose of 2 mg/kg.

Drug repurposing in cancer

Drug repurposing, drug redirecting or drug reprofiling is defined as the identification of novel usages for existing drugs. Both development risks and costs, as well as safety-related failure, are reduced with this approach because such drugs have well-known formulation development, *in vitro* and *in vivo* screening, as well as pharmacokinetic and pharmacodynamic profiles. Also, the first clinical phases of many drugs had been completed and can be bypassed to reduce several years of development. Therefore, drug repurposing has the potential to reduce the whole process up to 3-12 years, and consequently, the potential recycle of compounds towards a new indication is an attractive opportunity for patients on need [30]. The relevance of drug repositioning in research is demonstrated with the fact that since the first publication of the subject back to 2004, there are more than 500 papers about it until 2013, at least in PubMed [31]. However, the majority of repositioned agents were discovered before starting with systematic efforts on 2006 to identify drugs with potential additional use, suggesting a serendipitous detection [30, 32, 33]. Currently, other ways to identify compounds with repositioning potential are informed insights and platforms established to identify *in silico* repositioning opportunities [32, 34]. Furthermore, with the recently assembly of the Drug Repurposing Hub, an online repurposing library that systematically classifies a collection of clinically tested compounds from existing databases, now it is possible to easily search and view drugs according to their clinical status, drug indications, or mechanism of action, allowing to rapidly find agents for further evaluation [35].

Important efforts have been made for drug repositioning in cancer. Pantziarka *et al*. have recently summarized on this topic. They report at least 235 non-cancer drugs with proven antitumor activity either *in vitro* or *in vivo*, and among these, 67 (29%) are in the World Health Organization (WHO) list of essential medicines, and 176 (75%) are off-patent [36]. 133 (57%) had human data in cancer patients [36]. Four were listed in clinical guidelines, namely thalidomide, all-trans retinoic acid, zoledronic acid and non-steroidal anti-inflammatory drugs (NSAID) [36]. Of note, at least 3 drugs have shown a survival benefit in randomized trials: cimetidine (colorectal cancer), progesterone (breast cancer) and itraconazole (lung cancer) [36]. Few examples of drug-target networks analyses show that both simvastatin and ketoconazole are anti-proliferative compounds in breast cancer [32], while gene expression profiles suggest that topiramate can be used to treat small-cell lung cancer and that sirolimus can be useful for glucocorticoid-resistant acute

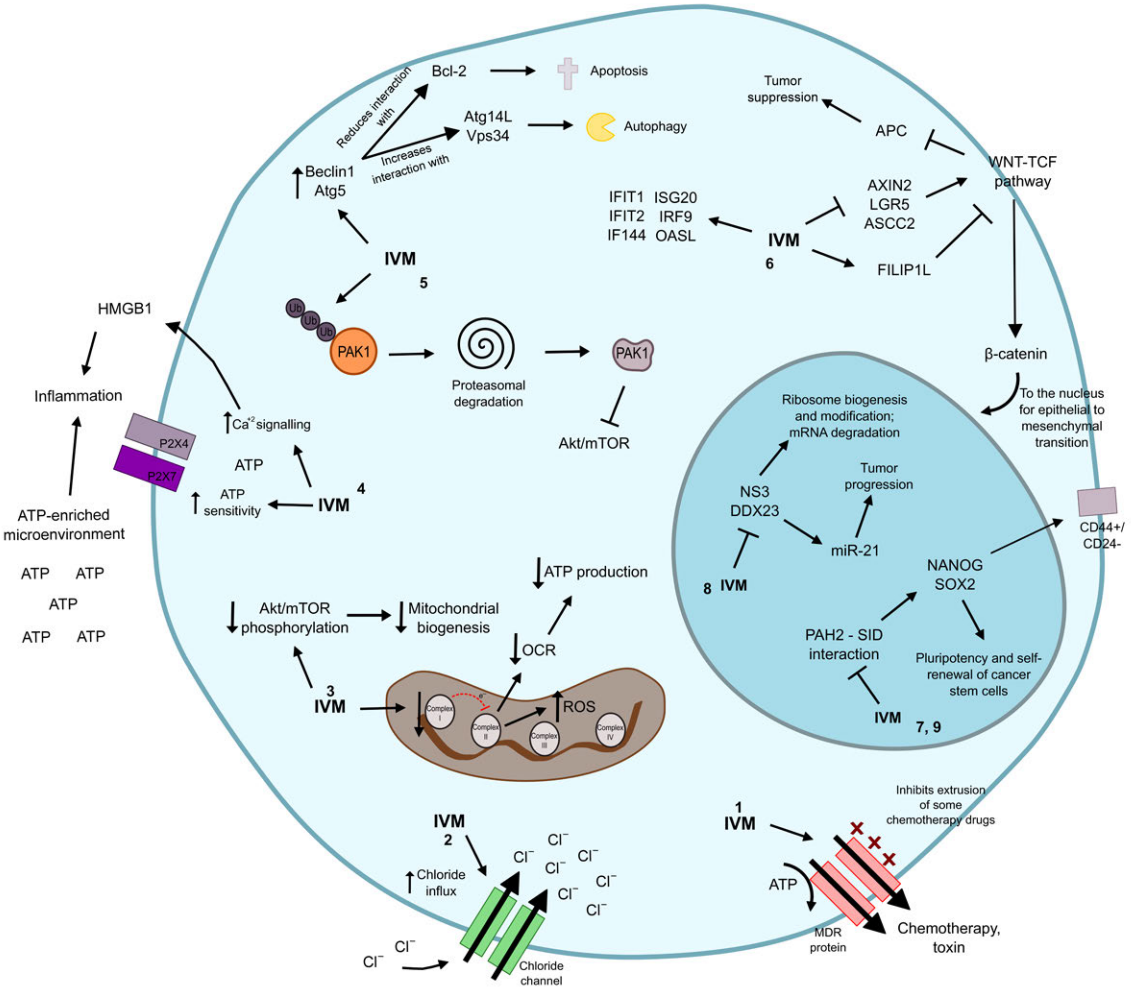

Figure 2. Antitumor mechanisms of ivermectin. 1. Ivermectin inhibits the P-glycoprotein pump, that induces a multidrug phenotype in the cancer cell. 2. Ivermectin acts as an ionophore and up-regulates chloride channels to generate apoptosis and osmotic cell death. 3. By decreasing the function of the mitochondrial complex I, ivermectin limits the electronic movement in the oxidative phosphorylation pathway that stimulates oxygen consumption rate to generate ATP for the cell. Concomitantly there is a reduction in the phosphorylation levels of Akt, impacting in the mitochondrial biogenesis process. Furthermore, alterations in the mitochondrial machinery are related with increased levels of reactive oxygen species that damage DNA. 4. Ivermectin induces ICD through the stimulation of an ATP- and HMGB1-enriched microenvironment, which promotes inflammation. This drug also increases ATP sensitivity and calcium signals in P2X membranal receptors, particularly P2X4 and P2X7, to induce ATP-dependent immune responses. 5. Ivermectin promotes the poly-ubiquitination of the kinase PAK1, which directs it to degradation in the proteasome. Defective PAK1, in turn, inhibits the Akt/mTOR pathway. At the same time, ivermectin stimulates the expression of Beclin1 and Atg5, both related with induction of autophagy and reduces the function of the negative regulator of apoptosis Bcl-2. Together, this generates autophagy and apoptosis. 6. Ivermectin represses AXIN2, LGR5 and ASCL2, all of them positive regulators of WNT-TCF while promotes the repressor of the WNT signaling FILIP1L. Concomitantly, ivermectin promotes the expression of several IFN-related genes, such as *IFIT1*, *IFIT2*, *IF144*, *ISG20*, *IRF9* and *OASL*. 7. Ivermectin modifies the epigenetic signature and the self-renewal activity in the malignant cell due to its ability to mimic the SIN3-interaction that binds to the PAH2 motif of the cancer-associated deregulators SIN3A and SIN3B. SIN3A naturally induces NANOG and SOX2, which are stimulants of stem cell pluripotency. 8. Ivermectin limits the function of the RNA helicases NS3 and DDX23, both of which are related with ribosome biogenesis and post-transcriptional modifications, as well as with mRNA degradation. DDX23 acts as a promoter of miR-21, which is a well-recognized stimulator of tumor progression. 9. Ivermectin inhibitis preferentially the CSC population and up-regulates pluripotency and self-renewal genes NANOG, SOX2 and OCT4. IVM: ivermectin; ATP: adenosine triphosphate; OCR: oxygen consumption rate; ROS: reactive oxygen species.

lymphocytic leukemia [35]. On the other hand, drugs that were first formulated to treat cancer might also be useful to treat non-malignant diseases. That is the case of inhibitors of histone

Table 2. Summary of the antitumor targets of ivermectin

Target	Effect	References
MDR protein	Inhibition	[39]
Chloride channel	Increase of activity	[44]
Akt/mTOR pathway	Inhibition	[47]
P2X7/P2X7 receptors	Activation	[50, 51]
PAK1 protein	Inhibition	[9, 54]
WNT-TCF pathway	Inhibition	[57, 58]
SIN3 domain	Inhibition	[59]
NS3 DDX23 helicase	Inhibition	[64]
Nanog/Sox2/Oct4 genes	Downregulation	[67]

deacetylase enzymes that are approved for T-cell lymphoma, but are prospective targets for malaria, leishmaniasis and trypanosomiasis [37].

Molecular mechanisms of the antitumor effects of ivermectin

Despite the relatively short time on which ivermectin has been investigated as a drug for cancer repositioning, a number of molecular mechanisms of action have been discovered (**Figure 2** and **Table 2**). Among these are the following:

Ivermectin as an inhibitor of the multi-drug resistance (MDR) phenotype

The firsts reports on the potential antitumor activity of ivermectin appeared almost 20 years ago, and these were somehow linked with the recently discovered basis for the MDR phenotype at that time. Gros P *et al*. in 1986 reported the isolation of DNA clones complementary to the cellular messenger RNA transcripts of *MDR* genes, and showed that high-level expression of a full-length complementary DNA clone in an otherwise drug-sensitive cell confers a complete MDR phenotype [38]. Later on, Didier and Loor proved by a short-term assay the P-glycoprotein function inhibition, which measures the restoration of the retention of two P-glycoprotein probes in MDR cells to their parental cells, concluding that ivermectin is also a substrate and an inhibitor of P-glycoprotein [39]. Though not named as ivermectin, avermectin IB1 showed the ability to reduce tumor growth *in vivo* by 50% at day 5 at dose of 1 mg/kg (HED 81 μg/kg) in SHK male mice bearing a solid Ehrlich carcinoma. In addition, at the same dose it inhibits the growth of the carcinoma cell line 755 (C57/BL6 male mice), and the tumor growth inhibition value reached a maximum when avermectin B1 was injected on day 3 after tumor inoculation. Based on the fact that ivermectin inhibits multidrug resistance in tumors, avermectin IB1 was tested with vincristine in the Ehrlich carcinoma, with results indicating that the antitumor effect of vincristine is greatly increased when avermectin 1B1 is administered after vincristine [40]. No further studies have exploited the anti-MDR effect of ivermectin. Nevertheless, the search for novel strategies and/or schedule optimization of MDR inhibitors continues [41], which suggests that there is still room for investigating ivermectin roles in reversing or preventing the development of the MDR phenotype.

Ivermectin as an ionophore drug

The term 'ionophore' was first used in 1967 in reference of the ability of organic molecules to bind metal cations and to form lipid soluble complexes that facilitate their transport across cellular membranes. Thus, ionophores can diffuse back and forth between the extracellular and intracellular spaces, or may remain in the plasma membrane as their transport metal ions between intracellular and extracellular spaces [42]. Ionophore antibiotics act by generating pores in biological membranes that dramatically alter the ionic household of cells. Salinomycin is an example of an ionophore antibiotic which generates ion channel-like structures that exhibit strong selectivity for K^+, but other monovalent cations are also conducted (e.g., Na^+ and H^+) [43]. Traditionally, the cell-killing activity of ionophore antibiotics is thought to originate from profoundly deregulating osmosis, as well as from direct cytotoxic effects of the altered biochemical landscape. It is known that malignant cells tend to upregulate chloride channels, which potentially could mark them as more sensitive to alterations in chloride flux, and that an unbalance in intracellular chloride concentrations affects intracellular Ca^{2+} levels, as well as pH and cell volume, which can lead to apoptosis in the affected cell [44].

In line with these statements, in a screen of a small chemical library of antibiotics and metabolic regulators to identify anti-leukemia compounds, Sharmeen *et al*. found that ivermectin

induces cell death at low micromolar concentrations (IC50 of 10 μM) in HL60, KG1a, and OCI-AML2 acute myeloid leukemia cell lines, as well as in primary patient samples. Cell death was caspase-dependent and interestingly, normal hematopoietic cells were much less sensitive to ivermectin as it did not induce apoptosis at concentrations up to 20 μM. Similar effects were seen when leukemia and normal cells were tested for clonogenicity. They also showed that increased chloride influx correlated with cell death and changes in both cell size and cell hyperpolarization, as these effects were much more marked in sensitive leukemia cells as compared to normal cells. Interestingly, there was a synergistic or additive interaction in OCI-AML2 and U937, but not in normal cells, when they treated with ivermectin plus cytarabine or daunorubicin [44].

Ivermectin as an inductor of mitochondrial dysfunction and oxidative damage

On the basis that anthelmintics or antibiotics may target mitochondria in mammalian cells [45, 46], ivermectin was tested in glioblastoma cell lines to identify whether its antitumor effect occurs via inhibition of mitochondrial biogenesis or function. As expected, ivermectin inhibits in a dose-dependent manner the basal and maximum oxygen consumption rate (OCR), most likely by decreasing the enzyme activity of respiratory complex I but not II, IV or V, and consistent with that, both the membrane potential and electrochemical proton gradient decrease while a significant increase in mitochondrial superoxide and decreased ATP are observed. Furthermore, by establishing a subline of the U87 cell line deficient in mitochondrial respiration it was proved that under these conditions ivermectin was unable to induce cell death, as well as when these cells were co-treated with the antioxidants alfa-tocopherol or mannitol. These effects were tracked down by studying the Akt/mTOR pathway, which at least in part controls mitochondria biogenesis and function. Results showed that ivermectin decreases phosphorylation of Akt (S473), mTOR (S2481) and the ribosomal S6 protein (rS6) in U87, T98G and HBMEC cells, indicating that ivermectin inhibits the Akt/mTOR pathway [47]. The effect of ivermectin upon mitochondria and oxidative damage has been recently corroborated in a study on renal cancer cell lines, where it was demonstrated that renal cancer cells do have higher mitochondrial mass and basal and maximal OCR [48]. As in the Liu *et al*. study, ivermectin in this model also decreased mitochondrial membrane potential as well as basal and maximal respiratory capacities. Of note, ivermectin significantly increased intracellular ROS and 8-OHdG levels, suggesting that the antitumoral effects of ivermectin are related to oxidative stress and DNA damage. This was confirmed by the abolition of the inhibitory effect of ivermectin in these renal cancer cell lines when co-treated with acetyl-L-carnitine (ALCAR) or N-acetyl-L-cysteine (NAC), a stimulant of mitochondrial biogenesis and an antioxidant, respectively [48].

Ivermectin as an inductor of immunogenic cell death (ICD)

Immunogenic cell death (ICD) is characterized by the presence of damage-associated molecular patterns (DAMPs) such as the membranal exposure of calreticulin and the release of both ATP and high-mobility group box 1 (HMGB1) into the extracellular space, which are then recognized by immune cells to elicit antineoplastic activities [49]. Exogenous ATP regulates defense through P1, P2X and P2Y purinergic receptors [50]. However, recently P2X7 overexpression has been correlated with promotion of both tumor growth and metastases [50]. Although within the tumor microenvironment ATPases such CD39 and CD73 degrade ATP to its immunosuppressive form, adenosine, ivermectin can surpass their effect by a potent induction of both HMGB1 and ATP extrusion which, in turn, induces inflammation [50]. Certainly, it has been reported in triple-negative breast cancer cells (TNCB) that ivermectin allosterically potentiates P2X4/P2X7- and caspase-1-mediated ICD due to the stimulation of an ATP-enriched tumor microenvironment, disrupting the balance between the survival and cytotoxic roles of purinergic signaling in malignant cells, which also induces autophagy [50]. One additional work done with human monocyte-derived macrophages corroborated the ivermectin association with PX24 and P2X7 receptors. Such research demonstrated that ivermectin increases ATP sensitivity and delays current deactivation after ATP wash-out in PX24 receptors, which together with the augmentation of ATP-induced currents and Ca^{2+}

signals in P2X7 receptors, suggests that ivermectin may stimulate ATP-dependent immune responses [51]. Altogether, literature indicates that ivermectin could promote and potentiate ICD at the tumor microenvironment.

Ivermectin as an inductor of autophagy

Autophagy, a self-degradative catabolic pathway is characterized by formation of double-membrane autophagosomes, which sequester excess or defective organelles and fuse with lysosomes for degradation of enclosed materials in the lysosome to mobilize energy and nutrients under certain cellular stimuli such as starvation, developmental transitions, hypoxia and/or oxidative stress [52, 53]. Ivermectin in ovarian and glioblastoma cancer cell lines promotes ubiquitination-mediated degradation of the oncogenic kinase PAK1 [1, 47], a key protein in cytoskeletal reorganization and nuclear signaling for tumor growing in more than 70% of all human cancers [1]. PAK1 downregulation in turn blockades the repressor of autophagy Akt/mTOR as evidenced by decreased phosphorylation of Akt, mTOR, p70S6K and 4EBP1 via direct interaction of PAK1 with Akt [54]. In fact, one work with multiple breast cancer cell lines treated with ivermectin showed its autophagy-promoter role by the formation of acidic vesicular organelles, with double-membraned autophagosomes by transmission electronic microscopy, and with the promotion of the expression levels of the autophagy-related proteins Beclin 1 and Atg5 in a dose-dependent fashion. Ivermectin, in turn, increases the interaction of Beclin 1 with positive regulators of autophagy, specifically Atg14L and Vps34, while diminishes its interaction with negative regulators such as Bcl-2 [54]. All together it is demonstrated that the ivermectin autophagic effects in this model results from inhibition of the PAK1/Akt/mTOR pathway.

Ivermectin as an inhibitor of the WNT-TCF pathway

The antiproliferative function of ivermectin has been widely documented. A study aimed to find out drug candidates for repositioning with the ability to block the WNT-TCF signaling, which inactivates the tumor suppressor APC in several sporadic human cancers and stimulates the constitutive activation and translocation into the nucleus of β-catenin during neoplastic transformation [55, 56], revealed that ivermectin at low micromolar concentrations performs anti-WNT-TCF response in cancer cells [57]. The authors showed the efficacy of ivermectin to inhibit BrdU incorporation in colon cancer, glioblastoma and melanoma cell lines, indicating repression in cell proliferation [57]. Besides, they demonstrated upregulation of activated caspase 3 and repression of the positive WNT-TCF targets *AXIN2*, *LGR5*, and *ASCL2* in DLD1 and Ls174T colon cancer cells [57], opening the possibility to use ivermectin to block WNT-TCF-dependent cancers, such as those from breast, skin, lung and intestine [1, 57]. Moreover, after investigating the ivermectin anti-clonogenic activity by analyzing spheroid formation, they showed that pre-treatment of such cell lines with ivermectin diminishes clonal floating spheroids by up to 73%, which together with the repression of the positive cell cycle regulator cyclin D1, suggests a limiting cancer stem cell formation driven by ivermectin [57]. In fact, ivermectin role as an WNT-TCF inhibitor led to use it as a positive control of such pathway in one research that screened a library of plant and microorganism natural compounds, which confirmed ivermectin suppressor activity by transcriptomic analysis that showed an upregulation of the repressor of WNT signaling *FILIP1L* up to 10-fold by the use of this compound [58]. Such study also revealed the increase of the interferon-responsive genes *ISG20*, *IFIT1*, *OASL*, *IRF9*, *IF144*, and *IFIT2*, in colon cancer cells [58]. Interestingly, it has been suggested the employment of interferon to inhibit WNT-TCF pathway [58].

Ivermectin as an epigenetic modulator

Other recognized field of action of ivermectin in cancer involves epigenetic regulation. One work done with the breast cancer cell line MDA-MB-231 reported the functional effect of ivermectin after an *in silico* screen of 2,000 FDA-approved small molecule drugs. The authors evaluated the ability of ivermectin to mimic the SIN3-interaction domain (SID), which naturally binds to the PAH2 motif belonging to the breast cancer-related epigenetic deregulators SIN3A and SIN3B [59]. By nuclear magnetic resonance they demonstrated that ivermectin indeed blocks the PAH2-SID interaction [59]. Furthermore, since SIN3A is part of a complex that positively regulates the stem cell and self-

renewal markers *NANOG* and *SOX2*, the authors analyzed the role of ivermectin to inhibit such genes and proved that in D3H2LN cells at doses of 0.5 μM it reduces *NANOG* and *SOX2* gene expression by 80%, with a decrease between 90-100% in clonogenic tumorsphere growth [59].

Ivermectin as a helicase inhibitor

RNA helicases represent a large family of proteins implicated in many biological processes, including ribosome biogenesis, splicing, translation and mRNA degradation [60]. Members of the DEAD-box family of RNA helicases play important roles in various aspects of RNA processing, including transcription, spliceosome biogenesis, ribosome biogenesis, splicing, nucleocytoplasmic transport, translation and decay [61, 62]. These family members share a conserved core that includes the amino acid sequence D-E-A-D (aspartate-glutamate-alanine-aspartate). They use energy received from ATP hydrolysis to unwind double-stranded RNA, generally act as components of multi-protein complexes, and have diverse functions that depend on their interacting partners. Several DEAD-box RNA helicases are aberrantly expressed in various types of cancer, where they may play important roles in cancer development and/or progression [61, 62]. In 2012, Mastrangelo *et al*. uncovered that ivermectin was an effective inhibitor of the NS3 helicase activity from the Kunjin virus (an Australian variant of the yellow fever virus) by an *in silico* test, and confirmed it by *in vitro* helicase enzymatic assays [63]. On the other hand, a recent study in glioma cell lines has found that the RNA helicase DDX23 regulates the oncogenic miR-21 biogenesis at post-transcriptional level [64], and it is over-expressed in glioma tissues as compared to normal brain, which is associated with poor survival of glioma patients. After the authors assayed a number of drugs known to inhibit viral helicases, they found that ivermectin inhibits the DDX23-mediated potentiation of pri-miR-21 processing that, in turn, decreases the levels of both precursor and mature miR-21, a well-recognized poor prognostic upregulated marker in cancer [65]. The treatment with ivermectin in glioma cell lines both *in vitro* and *in vivo* was able to induce antitumoral effects, which suggests that the antihelicase role of ivermectin can be considered as another mechanism of its anticancer effect.

Ivermectin as a stem-cell cancer inhibitor

In 2009, Gupta *et al*. performed a high-throughput screening to discover selective inhibitors of cancer stem cells (CSCs), and found that salinomycin reduces the proportion of CSCs by >100-fold relative to paclitaxel. Besides, they showed that salinomycin inhibits mammary tumor growth *in vivo*, and that it induces increased epithelial differentiation of tumor cells accompanied by the loss of expression of breast CSC genes [66]. As salinomycin is an antiparasitic drug for veterinary use only, our group searched similar compounds for human use that could also act as selective inhibitors of CSCs. Our results showed that ivermectin has high similarity with salinomycin (similarity of 0.78), and therefore we hypothesized that the antiparasitic drug ivermectin could also have similar biological properties as salinomycin [67]. The results of this study showed that ivermectin has growth inhibitory effects upon MDA-MB-231 cells in the range of 0.2-8 μM, and as predicted, ivermectin preferentially inhibits the viability of CSCs-enriched populations ($CD44^+/CD24^-$) and cells growing in spheroids, as compared to bulk cell population. The opposite pattern was observed with paclitaxel where the non-CSCs ($CD44^+/CD24^+$) were sensitive to paclitaxel at nanomolar concentrations, while the inhibition of the stem cell subpopulation was only observed at higher drug

Table 4. Antitumor effects of ivermectin in vivo

concentrations. According with this, ivermectin reduces the expression of maintenance of the pluripotency and self-renewal markers Nanog, Oct4 and Sox2 at both mRNA and protein levels [67]. A summary of the molecular mechanisms of the antitumor effects of ivermectin are shown in **Table 2** and **Figure 2**.

Antitumor effects of ivermectin, in vitro and in vivo

There are a number of *in vitro* and *in vivo* preclinical studies where ivermectin demonstrates its efficacy against a wide range of malignant conditions, including solid and hematological malignancies. In breast cancer, ivermectin has been studied in MDA-MB-435, MDA-MB-231, MDA-MB-468, MDA-MB-361, MCF-7, HS578T and SKBR3 cell lines where it demonstrates its ability to inhibit cell proliferation, induction of apoptosis, autophagy and reversion of tamoxifen resistance among other effects [51, 55, 60, 67]. These effects are also reported in cancer cell lines from ovarian, prostate, head and neck, colon, and pancreas, as well as in melanoma [9, 45, 51]. Similar results are also observed in a number of murine cancer cell lines including breast, melanoma and colon [51, 60]. Two studies in glioblastoma cell lines show that ivermectin not only induces growth arrest and apoptosis, but induces anti-angiogenic effects [48, 58], whereas two more studies extend these observation upon myeloblastic acute leukemia cell lines [41, 51]. Of interest, the median concentration used for the *in vitro* treatment from all studies referred in **Table 3** was 5 μM (0.01-100 μM) which is clinically achievable according with the pharmacokinetic data in humans shown in **Table 1**. Regarding the *in vivo* evaluation of ivermectin (**Table 4**), this has been done in immune deficient mice using human acute myeloblastic leukemia, glioblastoma, breast and colon carcinoma, as well as in the murine lymphosarcoma cell line MDAY-D2. These studies show more than a 50% reduction in tumor volumes after ivermectin treatment, which varied from 10 to 42 days of treatment by either oral, intraperitoneal or intratumoral routes (more commonly intraperitoneal). The median dose employed was 5 mg/kg (2.4-40 mg/kg), which is equivalent to 0.40 mg/kg in humans, a dose below to the highest dose safely used in human subjects evaluated so far (2 mg/kg) (**Table 1**). Thus, the

in vitro and *in vivo* results with ivermectin strongly suggest that its antitumor effects in cancer patients can be achieved at feasible doses.

Conclusions

The recognition that drug repositioning is a clever opportunity to accelerate the development of cancer drugs is increasing. So far, at least 235 clinically-approved, non-cancer drugs have proven antitumor activity either *in vitro, in vivo*, or even clinically. Among these, ivermectin, an antiparasitic compound of wide use in veterinary and human medicine, is clearly a strong candidate for repositioning, based on the fact that i) it is very safe, causing almost no side-effects other than those caused by the immune and inflammatory responses against the parasite in infected patients, and ii) it has proven antitumor activity in preclinical studies. On the other hand, it is now evident that the use of very selective "unitargeted" drugs is commonly associated to early development of resistance by cancer cells, hence the use of "dirty" or "multitargeted" drugs is important to explore. In this sense, ivermectin has this potential as it modulates several targets such as the multidrug resistance protein (MDR), the Akt/mTOR and WNT-TCF pathways, the purinergic receptors, the PAK-1 protein, certain cancer-related epigenetic deregulators such as SIN3A and SIN3B, RNA helicase activity, while stimulates chloride channel receptors leading to cell hyperpolarization, and down-regulates stemness genes to preferentially target cancer stem-cell like population, at least in breast cancer. Importantly, the *in vitro* and *in vivo* antitumor activities of ivermectin are achieved at concentrations that can be clinically reachable based on the human pharmacokinetic studies done in healthy and parasited patients. Thus, existing information on ivermectin could allow its rapid move into clinical trials for cancer patients.

Tolerance

Summary In Cameroon, a 3-year randomized, double-blind controlled trial was conducted to determine if ivermectin, given at 3-monthly intervals and/or at high doses (800 μg/kg), had a greater effect on adult *Onchocerca volvulus* than standard annual doses of 150 μg/kg. Adverse reactions were recorded and analysed in a logistic regression model with random effects to assess the influence of the dose and rhythm of treatment on their occurrence. After the first dose, 3-monthly treatment was associated with a clearly reduced risk of reactions, especially oedematous swellings, pruritus and back-pain. Oedematous swellings and subjective ocular troubles were found to be associated with high doses of ivermectin. These results reinforce former parasitological conclusions that it would be desirable to evaluate the feasibility and effects on transmission of large-scale 3-monthly treatments with standard doses of ivermectin for onchocerciasis control. Owing to the unexpected ocular reactions, the use of high doses to counteract any future resistance of *O. volvulus* to ivermectin should be considered with caution.

1. Introduction

In 1993, the WHO estimated that 18 million people suffered from onchocerciasis, over 95% of them in sub-Saharan Africa and the rest in six Latin American countries and the Yemen (WHO, 1995). Control of onchocerciasis in Africa is currently based on mass administration of ivermectin (Mectizan®, Merck & Co., Inc., Whitehouse Station, NJ, USA) at an annual dose of 150 μg/kg to all eligible persons in communities where the disease is hyper or

mesoendemic. In Latin America, the same dosage is given on a 6-monthly basis.

At 150 μg/kg annually, ivermectin does not kill the adult *Onchocerca volvulus* which, after 3–6 months of embryostasis, resume production of microfilariae (mf) (Duke et al., 1991). When repeated the treatments seem to cause an irreversible decline in mf production of 30% per treatment (Plaisier et al., 1995), but this would not prevent the intensity of transmission from increasing again some time after the distribution, thus preventing control of the parasite (Winnen et al., 2002).

We undertook a double-blind, randomized controlled trial in Cameroon, to evaluate if higher and/or more frequent doses of ivermectin would have a greater effect on the adult worms and mf of *O. volvulus* than standard doses. Of four groups of patients, the reference group received the standard dose of 150 μg/kg annually (Group 150 × 1); the other three received respectively: 150 μg/kg 3-monthly (Group 150 × 4); high doses (400 μg/kg then 800 μg/kg) annually (Group 800 × 1); and the same high doses 3-monthly (Group 800 × 4). We aimed to investigate if more frequent or higher doses would have greater impact on the adult worms and mf thus leading to a shortening of treatment campaigns.

The design and parasitological results of this trial have been published elsewhere (Gardon et al., 2002) with the conclusion that 3-monthly treatments, whether at 150 μg/kg or at high doses, increased the mortality of adult *O. volvulus* by some 30% and diminished considerably the fertility of the females; and that 3-monthly treatments reduced the concentrations of mf in the skin much more than did annual treatments. The present paper describes the adverse systemic reactions that were encountered during this trial.

2. Methods

2.1. Study area and design

The study took place in the Republic of Cameroon, in 20 villages in the Mbam River valley (a tributary of the Sanaga River), where onchocerciasis was hyperendemic (Macé et al., 1997). Initially it involved 657 men aged 18–60 years, each presenting at least two palpable, presumably *O. volvulus* nodules, but otherwise in good health.

In May 1994, a pre-treatment nodule was excised from each man followed by a suppressive dose of 150 μg/kg ivermectin to avoid the possibility of severe reactions developing after the first dose in those on the high-dose schedules. Each patient was then randomly allotted to one of the four treatment groups. The trial proper began in August 1994 and ended in August 1997, when a second nodule was removed from each patient to assess the effect of the each regimen on the adult worms. As no treatment was given in August 1997, the 3 year follow-up corresponded to three doses of ivermectin (and nine of placebo) for the groups treated annually, and 12 doses of ivermectin for the groups treated 3-monthly.

When the trial started, the highest dose permitted by Merck & Co., Inc. was 400 μg/kg. Six months later, when the results of Awadzi et al. (1995, 1999) became available, we were allowed to increase the high-dose regimens from 400 to 800 μg/kg. Thus our high-dose patients treated annually received one dose of 400 μg/kg and two doses of 800 μg/kg, and those on the 3-monthly regimen received two doses at 400 μg/kg and ten doses of 800 μg/kg. Including the clearing dose (150 μg/kg) given 3 months before the trial proper began, the patients treated annually at 150 μg/kg received a total of 600 μg/kg; and those on high dosage a total of 2150 μg/kg. In the groups treated 3-monthly, those on 150 μg/kg received a total of 1950 μg/kg, and those on high dosage 8950 μg/kg.

2.2. Treatment given and adverse reactions recorded

The trial was conducted double-blind, thanks to Merck & Co. which provided indistinguishable gelatin capsules, containing either ivermectin or placebo. At the outset, each patient was given a plastic name card, identifying him to the medical team for ivermectin treatment or consultation about reactions. Ivermectin was given in the morning under the strict control of one of the investigators. Each patient received his correct dose of ivermectin or placebo given in five gelatin capsules, pre-prepared by the pharmacist in a packet with the patient's name and photograph attached. Neither the patients nor those giving out the drug knew what dose any patient was receiving.

In the afternoon of each treatment day (D0) and on each of the following three days (D1–D3), a medical team moved from village to village, at appointed times, to be at the disposal of patients who presented adverse reactions. The patients were asked to come to well-defined places for free palliative treatment as necessary. Each was instructed to seek another consultation if his reaction to treatment had not settled within 24–48 hours. A member of each treated patient's family was

instructed to inform the team in the event of a domiciliary visit being necessary.

During the first six treatment rounds, full details of all reactions were 'narratively' recorded; but, from the treatment round in November 1995, experience allowed us to keep records on the basis of a list of 12 reactive symptoms and signs or groups thereof (see Tables 1–3). Fever was diagnosed by touch. For analysis, all the complaints recorded before November 1995 were recoded so as to be included in one or other of these 12 symptoms.

2.3. Statistical analysis

When a patient complained of more than one type of reaction at any given round, each reaction was included for analysis. This was so either when a patient showed ≥2 reactions on a given day, or when he came more than once (i.e. on different days), each time with a different sign or symptom. When the patient came more than once for the same sign, only one complaint was considered for analysis.

The first step in the analysis involved comparing the mean number of consultations as a whole, and the mean number of consultations for a given symptom, using the non-parametric test of Kruskal–Wallis. Then, a logistic regression analysis was performed, in which the risk of occurrence of each adverse reaction in the 'non-standard' treatment groups was compared with the risk in the reference group (150 × 1). In this analysis, we took into account the fact that the adverse reactions presented by any one patient at any one treatment round, or over the whole course of the trial, could not be considered as independent events. To take account of the excess variation introduced by this 'individual effect', we used a logistic regression model with random effects. Odds ratios (OR), with their 95% CIs, were calculated for each group and each reaction.

The next step in the analysis was to evaluate the way in which the risk of occurrence of a given symptom at a given round was dependent on the rhythm of treatment, and on the dose. In this analysis, the reference categories were the annual ivermectin treatment and the doses of placebo. As in the previous analysis, we used a logistic regression model with random effects. This analysis allowed us to evaluate, simultaneously and within a single model, the relationship between the dosage level and the interval between dosings, and to adjust the one in relation to the other.

Finally, to focus the analysis on the effect of high doses of ivermectin, we compared the impact of the dose given, after having discarded the treatment rounds in which the patients received placebo; thus no longer using the placebo as the reference, but instead using the standard 150 μg/kg dose.

3. Results

3.1. General information

Of the 657 patients allocated initially to one of the four treatment groups, only 643 actually participated in the first treatment in August 1994. Comparisons of the means of their ages, heights, weights, numbers of palpable nodules and *O. volvulus* microfilarial densities showed that the four groups did not differ significantly (Gardon et al., 2002). After 3 years, 572 patients completed the protocol and received the twelfth and last treatment in May 1997. Three months later, 541 of them submitted to further skin snips and the excision of a second palpable nodule. Over the whole trial, 7237 treatments were given, i.e. 2808 doses of placebo; 2226 of ivermectin at 150 μg/kg; and 2203 of high-level ivermectin (475 at 400 μg/kg and 1728 at 800 μg/kg).

3.2. Causes of exclusion from the cohorts and serious reactions

By August 1997, 24/643 patients, who took their first treatment in August 1994, had died in the interval (seven in Group 150 × 1; eight in Group 800 × 1; two in Group 150 × 4; and seven in Group 800 × 4). None of these deaths was related to treatment (see details in Gardon et al., 2002). Between August 1994 and August 1997, 78 other patients were excluded from the trial: 17 on medical grounds and 61 because they had moved away or missed one treatment round. The proportions of patients lost (overall or for each of the above three specific reasons) did not differ significantly between groups.

No patient developed a serious adverse reaction, none required hospitalization, and, no-one withdrew from the trial because of an adverse reaction.

3.3. Risk of mild adverse reactions in the trial as a whole

Mild adverse reactions began very soon after taking the gelatin capsules. Of 1129 consultations for adverse reactions, 367 (32.5%) took place in the afternoon following treatment the same morning (D0); and 449 (39.8%), 195 (17.3%) and 118 (10.5%) took place on the following three days (D1–D3). This distribution over time was similar in all four treatment groups ($P = 0.69$).

Table 1 Number of consultations for, and risk of occurrence of, various adverse reactions in each of the four treatment groups

Dosage group	150 × 1	800 × 1	150 × 4	800 × 4
Total no. of doses	1878	1965	1783	1750
Occurrence of at least one symptom	283	292 0.96 (0.64–1.44)	255 0.91 (0.59–1.40)	299 1.17 (0.74–1.85)
Total no. of symptoms	456	513	402	452
Sundry aches and pains	23	25 1.07 (0.52–2.18)	13 0.61 (0.27–1.37)	18 0.85 (0.4–1.83)
Joint pains	34	18 0.44* (0.21–0.94)	29 0.85 (0.42–1.70)	32 1.03 (0.52–2.04)

Cutaneous eruptions	15	17 1.07 (0.44–2.60)	23 1.61 (0.69–3.76)	25 1.79 (0.77–4.14)
Subjective ocular troubles	18	31 1.62 (0.72–3.64)	18 1.04 (0.45–2.42)	50 3.30** (1.58–6.96)
Asthenia	33	24 0.71 (0.36–1.42)	34 1.16 (0.59–2.76)	26 0.84 (0.42–1.69)
Abdominal troubles	15	15 0.95 (0.41–2.18)	6 0.42 (0.15–1.20)	4 0.29* (0.09–0.95)
Giddiness	18	8 0.44 (0.16–1.17)	15 0.91 (0.39–2.17)	17 1.03 (0.43–2.46)
Others	12	17 1.34 (0.60–3.02)	14 1.24 (0.53–2.87)	8 0.71 (0.27–1.84)

The odds ratios (95% CI) were calculated using treatment with 150 μg/kg as the reference category.
*$P < 0.05$.
**$P = 0.0017$.

During the 3 years of treatment, the mean number of consultations per patient was the same in each of the four treatment groups: i.e. 1.8 (SE = 2.4) for 150 × 1; 1.8 (SE = 2.9) for 800 × 1; 1.7 (SE = 2.3) for 150 × 4; and 1.9 (SE = 3.0) for 800 × 4 ($P = 0.92$). Over the whole trial, the risk in the non-standard treatment groups of presenting at least one adverse symptom or sign after taking the treatment, was comparable to that observed in the reference group (Table 1), with ORs of 0.96, 0.91, and 1.17. The same applied to each of the individual symptoms, almost all of which appeared with similar frequencies in all four groups. Only arthralgia seemed slightly less frequent in the group 800 × 1 (OR = 0.44, 95% CI 0.21–0.94); whereas abdominal pains were less frequent (OR = 0.29, 95% CI 0.09–0.95), and subjective ocular troubles (transitory blurring of vision, itching or pain of the eye, and in several cases dyschromatopsia) more frequent (OR = 3.30, 95% CI 1.58–6.96) in the group 800 × 4 than in the reference group.

3.4. Changes in the risk of mild adverse reactions over time

Although the results presented above demonstrate only small differences between the four groups, taking the 3 year trial as a whole, things were very different when each treatment round is considered separately. The incidence of adverse reactions diminished steadily over the course of the trial. Overall, they affected 28.6% of patients after the first round of treatment, 20.0% during the course of the first year of treatment, 12.5% in the course of the second year and 8.0% during the third year.

Table 2 Symptoms recorded and the risk of their happening as a function of the ivermectin dosage regimen

	No. of events	Dosage interval		Dose			
		3-monthly[a]		150 μg/kg[b]		800 μg/kg[b]	
		OR (*P*)	95% CI	OR (*P*)	95% CI	OR (*P*)	95% CI
Any one symptom	1129	0.36 (<0.001)	0.25–0.52	4.27 (<0.001)	3.21–5.67	6.30 (<0.001)	4.69–8.46
Sundry pains	79	0.46 (0.021)	0.24–0.89	1.60 (0.19)	0.79–3.23	2.22 (0.018)	1.14–4.30
Joint pains	113	0.88 (0.70)	0.47–1.66	1.57 (0.18)	0.81–3.02	2.09 (0.028)	1.08–4.02
Back and waist pain	134	0.33 (<0.001)	0.18–0.61	2.36 (0.002)	1.36–4.10	2.53 (<0.001)	1.48–4.33
Headache	354	0.64 (0.066)	0.40–1.03	1.95 (0.001)	1.30–2.91	1.84 (0.003)	1.24–2.74
Fever	136	0.38 (<0.001)	0.22–0.66	2.85 (<0.001)	1.62–4.98	3.31 (<0.001)	1.95–5.61
Pruritus	423	0.34 (<0.001)	0.24–0.49	6.04 (<0.001)	4.20–8.68	6.55 (<0.001)	4.63–9.28
Oedematous swellings	121	0.11 (<0.001)	0.067–0.20	77.08 (<0.001)	23.0–257.9	131.4 (<0.001)	39.6–436.0
Cutaneous eruptions	80	0.58 (0.10)	0.31–1.12	6.42 (<0.001)	2.78–14.84	3.19 (<0.001)	3.19–16.55
Subjective ocular troubles	117	0.61 (0.11)	0.34–1.11	2.67 (0.008)	1.29–5.56	8.57 (<0.001)	4.46–16.47
Asthenia	117	0.69 (0.23)	0.38–1.26	2.54 (0.003)	1.39–4.66	1.85 (0.059)	0.98–3.52
Abdominal troubles	40	0.42 (0.093)	0.15–1.16	0.78 (0.63)	0.28–2.17	0.92 (0.86)	0.35–2.43
Giddiness	58	1.15 (0.75)	0.47–2.81	1.46 (0.41)	0.59–3.63	1.07 (0.89)	0.40–2.85
Others[c]	51	0.47 (0.042)	0.22–0.97	2.77 (0.015)	1.22–6.26	2.00 (0.10)	0.87–4.63

The odds ratios (OR) and their 95% confidence intervals (95% CI) were calculated using regression models with random effects.
[a] Reference category: annual interval.
[b] Reference category: dose of placebo.
[c] Insomnia, feeling cold, cramps, nausea, anorexia, paresthesiae, pains in the chest, etc.

This fall-off was observed in all the groups, but in those that received ivermectin annually, it was associated with a recrudescence only when the patients received ivermectin, i.e. at rounds 5 and 9. In both groups treated annually, the frequency of adverse reactions was higher after round 5 than after round 9. After round 5, the proportions of consultations in the groups 150 × 1 and 800 × 1 were 24.5 and 30.9%, respectively; in the groups 150 × 4 and 800 × 4, they were 17.8 and 22.6% (comparison between the four groups: $P = 0.060$). Likewise, after round 9, the proportions of consultations in the groups 150 × 1 and 800 × 1 were 18.0 and 21.5% respectively; in the groups 150 × 4 and 800 × 4, they were only 9.0 and 12.5% (comparison between the four groups: $P = 0.014$).

When the various symptoms are considered separately, this variability over time was particularly noticeable with regard to itching, which was also the most frequent secondary symptom encountered. Taking the study as a whole, the risk of itching developing after a round of treatment seemed to be almost the same in all groups including the reference group, with ORs of 1.24, 1.13, and 1.09 in the groups 800 × 1, 150 × 4 and 800 × 4, whereas in reality the frequency of itching varied greatly as a function of the dosage rhythm (Figure 1). In fact, in the groups treated annually there was a strong recrudescence of itching after rounds 5 and 9, which was the price to be paid for the much lower number of consultations requested after those rounds at which the placebo was administered.

3.5. Study of the respective effects of dosage and of the rhythm of ivermectin treatment on the occurrence of reactions

Analysis shows that taking ivermectin every 3 months was associated with a clearly reduced risk of adverse reactions (OR = 0.36, 95% CI 0.25–0.52), regardless of the dose (Table 2). When considering the various symptoms separately, the analysis shows that the reduction of risk associated with 3-monthly treatments was especially noticeable with regard to oedema (OR = 0.11, 95% CI 0.07–0.20), pruritus (OR = 0.34, 95% CI 0.24–0.49) and back- or waist-pain (OR = 0.33, 95% CI 0.18–0.61). In addition, the risk of joint pains, headache, rash, subjective ocular troubles, asthenia, intestinal troubles and giddiness seemed to be independent of the rhythm of ivermectin treatment.

When compared to treatment with placebo, ivermectin dosage was associated with a marked increase in adverse reactions, whether it was given at the standard dose of 150 μg/kg (OR = 4.3, 95% CI 3.2–5.7) or at high doses (OR = 6.3, 95% CI 4.7–8.5). The manifestations with the highest occurrence after ivermectin treatment were itching, rash, oedematous swellings and fever; and, amongst them, swellings appeared to be more frequently associated with high-dose treatment (OR = 131.4, 95% CI 39.6–436.0) than with standard doses (OR = 77.1, 95% CI 23.0–257.9). Besides these signs, which are classically reported in many studies, the analysis showed that ivermectin treatment was also associated with a risk of occurrence of subjective ocular problems (blurring of vision, changes in colour vision, etc.). In contrast, giddiness and abdominal problems seemed to be independent of the treatment regimen. Throughout the three years of the trial, 2808 doses of placebo were given and the adverse reactions most frequently observed after these treatments were headache (3.7%), pruritus (3.0%), back and waist pain (1.6%), sensation of fever (1.4%), asthenia (1.1%) and joint pain (1.1%).

If one eliminates the placebo dosings from the analysis, one can compare the impact of high

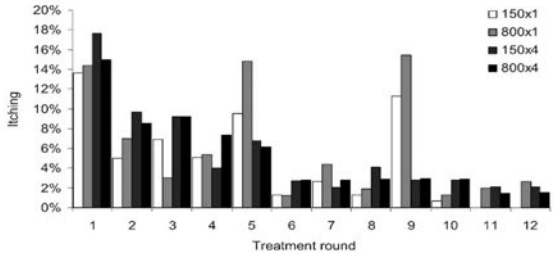

Figure 1 Development over time of the frequency of itching after treatment in the four treatment groups.

Table 3 Symptoms recorded and the risk of their happening as a function of the treatment regimens

	3-monthly treatment[a]		Dose 800 μg/kg[b]	
	OR (*P*)	95% CI	OR (*P*)	95% CI
Any one symptom	0.35 (<0.001)	0.25–0.50	1.24 (0.22)	0.88–1.75
Sundry pains	0.44 (0.012)	0.24–0.83	1.37 (0.32)	0.74–2.55
Joint pains	0.87 (0.65)	0.47–1.61	1.19 (0.56)	0.67–2.10
Back and waist pain	0.32 (<0.001)	0.19–0.56	1.12 (0.68)	0.65–1.94
Headache	0.63 (0.040)	0.41–0.98	1.03 (0.89)	0.67–1.58
Fever	0.38 (<0.001)	0.22–0.65	1.18 (0.53)	0.70–2.02
Pruritus	0.33 (<0.001)	0.24–0.47	1.14 (0.47)	0.81–1.60
Oedematous swellings	0.012 (<0.001)	0.067–0.19	1.76 (0.039)	1.03–2.96
Cutaneous eruptions	0.60 (0.15)	0.30–1.21	1.14 (0.70)	0.58–2.23
Subjective ocular troubles	0.58 (0.070)	0.32–1.05	3.22 (<0.001)	1.76–5.87
Asthenia	0.69 (0.18)	0.40–1.19	0.72 (0.22)	0.43–1.21
Abdominal troubles	0.40 (0.066)	0.15–1.06	1.11 (0.83)	0.43–2.89
Giddiness	1.13 (0.78)	0.47–2.73	0.72 (0.41)	0.33–1.57
Others[c]	0.47 (0.039)	0.23–0.96	0.74 (0.41)	0.37–1.51

The odds ratios (OR) and their 95% confidence intervals (95% CI) were calculated using regression models with random effects.
[a] Reference category: annual interval.
[b] Reference category: dose of ivermectin at 150 μg/kg.
[c] Insomnia, feeling cold, cramps, nausea, anorexia, paresthesiae, pains in the chest, etc.

versus normal dosings (Table 3). In these circumstances, 3-monthly dosage was still associated with a marked decrease in the risk of developing adverse reactions, when compared with annual treatments (OR = 0.35, 95% CI 0.25–0.50). Of the different adverse manifestations, only oedematous swellings (OR = 1.8, 95% CI 1.0–3.0) and subjective ocular problems (OR = 3.2, 95% CI 1.8–5.9) were more frequent after high doses than after the standard dose.

4. Discussion

The safety of ivermectin treatment has allowed it to be used by the African Programme for Onchocerciasis Control (APOC) in mass community-directed treatment with ivermectin (CDTI). The only areas where mass ivermectin treatments against onchocerciasis are associated with problems concerning the management of adverse reactions are those where onchocerciasis is co-endemic with loiasis. In communities where the prevalence of *Loa loa* microfilaraemia is >20%, and the proportion of persons at high risk of severe *Loa*-encephalopathic reactions is sufficiently high, specific measures to prevent and control such unfortunate eventualities are essential (Boussinesq et al., 2001; Gardon et al., 1997). In the present trial, we avoided recruiting persons from communities with such high prevalence of *Loa* microfilaraemia.

Our trial was designed to evaluate the potential macrofilaricidal activity of ivermectin against *O. volvulus*, and the safety of normal and higher doses of ivermectin given at shorter intervals than in the regimen currently used as part of APOC. The examinations of nodules and skin snips after 3 years of repeated treatments led to two main results. The first was that 3-monthly treatments increase the mortality of adult female worms and have an increased sterilizing effect on those females that remain alive. Because of these effects, as well as the direct microfilaricidal action of ivermectin, 3-monthly treatments maintain the concentrations of mf in the skin at much lower levels than annual treatments. The second, and perhaps surprising, result was that high doses (800 μg/kg) produce little marginal parasitological benefit as compared with standard doses of 150 μg/kg. These observations lead us to recommend the use of ivermectin at 150 μg/kg 3-monthly rather than once a year.

Our results regarding adverse reactions reinforce the former conclusions, mainly based on parasitological arguments. First, throughout the 3 year trial, no severe adverse reaction was recorded; nor did we observe any case of orthostatic hypotension such as those reported from West Africa by Awadzi et al. (1990). The adverse reactions recorded during our trial were always transitory and responded readily to symptomatic treatment with analgaesics or antihistamines over 24–72 h. Only occasionally were corticosteroids necessary. Second, analysis

of the respective roles of dosage level and rhythm of treatment have demonstrated that taking ivermectin every 3 months is associated with a clearly reduced risk of adverse reactions, and that this decrease is particularly marked for the frequent and inconvenient reactions of oedema, itching and backache. Lastly, although we have shown that the dosage level seems to have little or no impact on the majority of reactions, two worrying manifestations, namely oedematous swellings and subjective ocular troubles, were more frequent after high doses than after the standard dose of 150 μg/kg.

In onchocerciasis the adverse reactions of ivermectin are linked to the death of mf in the skin or in the network of lymphatic capillaries, vessels and nodes, and to the resulting inflammatory reactions. Many studies have shown that the severity of such reactions is proportional to the degree of microfilaridermia (e.g. De Sole et al., 1989; Prod'hon et al., 1991), and that, under treatment, they tend to diminish year by year along with the *O. volvulus* microfilarial skin load. In our trial, this was particularly obvious in those groups treated with ivermectin at 3-monthly intervals.

One may wonder why, in our trial, the risk of occurrence of some reactions was related to the dose received, whereas others were not. The pathophysiology of post-ivermectin reactions is not fully understood, but is clearly associated with various immune responses (Njoo et al., 1993, 1994), including, particularly, eosinophil sequestration and activation/degranulation (Cooper et al., 1999, 2000). Recent results have also suggested that the *Wolbachia* bacterial endosymbiont of *O. volvulus* plays a role in mediating the inflammatory responses after treatment (Brattig et al., 2001; Keiser et al., 2002). In the present study, most of the symptoms seemed to occur at similar frequency, whatever the dose of ivermectin given. As indicated by Awadzi et al. (1995), this is probably because 'the Mazzotti reaction is a response to the death of microfilariae; and as near complete elimination is achieved with the standard dose, additional reaction is unlikely at higher doses'. However, we observed that the oedematous swellings were more frequent after high doses; this may possibly have resulted from the action of ivermectin on worms (probably males or possibly third or fourth-stage larvae or immature females) moving about outside the nodules. The issue of the higher frequency of subjective ocular symptoms after high doses will be addressed elsewhere, together with the results of two series of detailed ophthalmological examinations; but at present we have no explanation for these phenomena.

We have shown that high doses may be the cause of unexpected oedematous swellings, and especially of subjective ocular side reactions. In future, these findings should be taken into account if increasing the dose of ivermectin, to counteract any tendency of *O. volvulus* to develop a resistance to this drug, is considered. It should also be kept in mind, with regard to current trials evaluating the effects and safety of moxidectin, a close structural relative of ivermectin, but one, which has a considerably longer persistence in plasma.

All these results are consistent with our former conclusions (Gardon et al., 2002) that 3-monthly treatments with standard doses of ivermectin would have a great beneficial effect on communities suffering from onchocerciasis, and that this regimen should be further tested in the field to evaluate its feasibility under CDTI and its effect in reducing transmission of *O. volvulus*.

Ethical clearance
Ethical agreement to the trial was received from the Cameroonian Ministry of Public Health and from Merck & Co., Inc.

Conflicts of interest statement
The authors have no conflicts of interest concerning the work reported in this paper.

Acknowledgements

We thank Pr. Joseph Mbédé (former Minister of Public Health), who provided ethical clearance for this study; Dr Philippe Gaxotte (Merck & Co.) for his help in providing the capsules; and the patients who participated in the trial. The study was supported by the River Blindness Foundation.

Zinc: an essential but elusive nutrient[1–3]

Janet C King

ABSTRACT

Zinc is essential for multiple aspects of metabolism. Physiologic signs of zinc depletion are linked with diverse biochemical functions rather than with a specific function, which makes it difficult to identify biomarkers of zinc nutrition. Nutrients, such as zinc, that are required for general metabolism are called *type 2 nutrients*. Protein and magnesium are examples of other type 2 nutrients. Type 1 nutrients are required for one or more specific functions: examples include iron, vitamin A, iodine, folate, and copper. When dietary zinc is insufficient, a marked reduction in endogenous zinc loss occurs immediately to conserve the nutrient. If zinc balance is not reestablished, other metabolic adjustments occur to mobilize zinc from small body pools. The location of those pools is not known, but all cells probably have a small zinc reserve that includes zinc bound to metallothionein or zinc stored in the Golgi or in other organelles. Plasma zinc is also part of this small zinc pool that is vulnerable to insufficient intakes. Plasma zinc concentrations decline rapidly with severe deficiencies and more moderately with marginal depletion. Unfortunately, plasma zinc concentrations also decrease with a number of conditions (eg, infection, trauma, stress, steroid use, after a meal) due to a metabolic redistribution of zinc from the plasma to the tissues. This redistribution confounds the interpretation of low plasma zinc concentrations. Biomarkers of metabolic zinc redistribution are needed to determine whether this redistribution is the cause of a low plasma zinc rather than poor nutrition. Measures of metallothionein or cellular zinc transporters may fulfill that role. *Am J Clin Nutr* 2011;94(suppl):679S–84S.

INTRODUCTION

Zinc was shown to be an essential nutrient for rats and mice in the 1930s, for pigs in 1955, and for humans in 1963 (1). In the past 40 y, much has been learned about zinc's essential biochemical and physiologic functions. Although it is a dietary trace element, it is one of the most abundant elements within cells. Approximately 95% of the body zinc is within the cells. A complex, extensive system for cellular zinc homeostasis maintains cellular zinc concentrations within a narrow range.

Even though considerable progress has been made in understanding the regulation of cellular zinc metabolism, there still is much we do not know. The lack of a good indicator of zinc status is a primary limitation. The signs of zinc depletion are diverse and cannot be attributed to a defect in a specific function. Until now, efforts to identify a marker of zinc status have focused predominantly on the response to changes in dietary zinc intake. However, studies of cellular zinc metabolism show that shifts in zinc-dependent functions are frequently linked to intracellular zinc fluctuations. This suggests that cellular zinc metabolism needs to be assessed along with whole-body zinc homeostasis to fully understand zinc status.

This article is divided into 3 parts: an overview of zinc's essential functions, a discussion of *why* assessing zinc status is so elusive, and a summary of cellular and whole-body potential biomarkers of zinc nutrition. Excessively high zinc intakes undoubtedly also alter these biomarkers, but given the limited information on the zinc metabolic response to excessive intakes, that aspect is not addressed in this article.

ZINC ESSENTIALITY

The physiologic effects of zinc deficiency are associated with a number of diverse biochemical changes rather than with a specific function as is the case for other trace elements such as iron and selenium. In general, zinc is essential for normal metabolism. Given its ubiquitous nature and high intracellular concentrations, it is not surprising that zinc has 3 very basic functions: catalytic, structural, and regulatory (2).

Zinc is a catalyst for >50 different enzymes when the same enzyme from different sources (plant, animal, microbial) is counted only once (2). An enzyme is classified as a zinc metalloenzyme if removal of zinc causes a decrease in activity without affecting the protein and if adding back zinc restores enzyme activity. A direct link between zinc deficiency symptoms and the function of an individual enzyme or enzymes has not been identified in complex organisms. Such a direct link is unlikely because it would occur only if the zinc-dependent enzyme were acting at a rate-limiting step in a critical biochemical pathway. For example, alkaline phosphatase is a zinc-dependent enzyme whose activities decline with low zinc intakes. But, it has not been possible to relate the signs and symptoms of zinc depletion with a change in alkaline phosphatase activity.

The discovery of the zinc finger motif in frogs in 1985 established a structural role for zinc (2). Zinc fingers have 4 cysteines within the general structure of the protein that allows zinc to be bound in a tetrahedral complex. Some zinc fingers have histidine substituted for cysteine. Zinc fingers occur in a variety

of proteins, including those involved in cellular differentiation or proliferation, signal transduction, cellular adhesion, or transcription. Zinc is also involved in maintaining the structure of enzymes such as CuZn superoxide dismutase where copper is at the active site and zinc maintains enzymatic structure. The extent to which dietary zinc intake influences the function of zinc finger proteins is not well known. However, given the abundance of zinc fingers, these structures contribute to the overall zinc requirement and provide a rationale for the tight homeostatic control of zinc metabolism.

The third basic zinc function is regulation of gene expression (2). The basic components include a metal-binding transcription factor (MTF) and a metal response element (MRE) in the promoter of the regulated gene. The MTF acquires zinc in the cytosol or nucleus and then interacts with the MRE to stimulate transcription. MTF-1 is thought to regulate numerous genes either negatively or positively depending on the cellular zinc status (2). It is thought that dietary zinc can be transported into the cells and interact with MTF-1, facilitating translocation to the nucleus for MRE binding and stimulating transcription. This may be the mechanism whereby adaptive changes in lipid peroxidation, apoptosis, immunity, and neuronal function occur with zinc depletion.

These general zinc biochemical functions have not been related to the physiologic effects of zinc depletion. This is because these basic biochemical zinc functions do not provide a complete picture of cellular zinc metabolism and function. Zinc transporters also play a key role in moving zinc to various organelles, thereby regulating cellular function. For example, the secretion of neurotransmitters, such as glutamate from neuronal synaptic vesicles, requires zinc and explains the relation between zinc and cognitive function (3). Also, zinc is required for packaging insulin into pancreatic granules and its subsequent secretion. Thus, zinc transporters also contribute to metabolic regulation by moving zinc into and out of organelles, thereby influencing gene transcription or the secretion of essential hormones or neurotransmitters.

Two classes of zinc transporters have been identified (2, 3). The ZIP (SLC 39) family of transporters move zinc into the cytoplasm from extracellular space or cellular organelles. A total of 14 ZIP transporters have been identified. The ZnT (SLC 30) family of transporters move zinc and other metal ions, such as iron, from the cytoplasm into the lumen of the intracellular organelles or to the outside of the cell. Thus, the ZnT proteins work in opposition to the ZIP transporters. A total of 10 ZnT transporters have been identified (2, 3). Examples include ZnT3, which is found in the synaptic vesicles of neurons, and ZnT8, which is found in the secretory granules of pancreatic β cells. Zinc transporters play a major role in cellular zinc trafficking, thereby regulating zinc function. Although the discovery of zinc transporters has expanded our understanding of zinc metabolism, much remains to be learned. For example, what do all of the 24 zinc transporters do and how is their expression altered to help maintain cellular zinc homeostasis?

WHY IS ZINC STATUS ELUSIVE?

Most nutrients are required for specific metabolic functions rather than for metabolism in general as is the case for zinc (4). When a deficiency of nutrients with specific functions occurs, tissue nutrient concentrations decline and a defect in one or more specific metabolic pathways develop, causing the onset of specific clinical or biochemical signs. The diagnosis of a deficiency of nutrients with specific functions is relatively straightforward. All one has to do is measure the nutrient concentration in an appropriate, convenient tissue; test the metabolic pathways where the defect lies; or simply recognize the specific clinical sign. Nutrients with specific functions are referred to as "type 1 nutrients." Examples of specific indicators of type 1 nutrient deficiencies include microcytic anemia for iron, beriberi for thiamine, pellagra for niacin, scurvy for vitamin C, and macrocytic anemia for folic acid.

Type 2 nutrients are required for multiple general metabolic functions and therefore respond to insufficient intakes quite differently (4). Examples include nitrogen, essential amino acids, magnesium, potassium, and zinc. The first response to an insufficient intake of type 2 nutrients is a marked reduction in endogenous losses and possibly a metabolic adaptation to reduce the need for functions that have a high demand, such as growth or immunity. For example, if a type 2 nutrient deficiency occurs in a growing animal, a marked decline in growth occurs within days, which is soon followed by nonspecific signs of metabolic or clinical dysfunction. General dysfunction—ie, malaise or apathy—is rapid because there is no body store or reserve of type 2 nutrients that lasts for more than a couple of days in growing animals.

Zinc is a classic example of a type 2 nutrient. An inadequate zinc intake in experimental animals or humans causes an avid reduction of excretory losses to conserve zinc (5). Endogenous fecal losses decrease markedly within a couple days. With severe zinc depletion ($<$1 mg dietary zinc/d), urinary losses also decline (6). If the decline in fecal and urinary losses fails to reestablish zinc balance, additional metabolic adjustments occur to mobilize zinc from a small, vulnerable pool for zinc function. Tissue catabolism may also occur to release zinc. Experimental animals fed diets providing $<$3 parts per million (ppm) zinc develop a cyclical food intake pattern in which anorexia and food ingestion fluctuate over a 4–5-d period (7). During the anorexic period, muscle is catabolized, and zinc along with protein, potassium, and other muscle components are released. Flanagan (8) showed that cyclic food intake permits longer survival in rats fed a zinc-deficient diet. Rats tube-fed a zinc-deficient diet thrived for 6–7 d and then became seriously ill, whereas rats fed the deficient diet ad libitum and that then underwent cyclical food intakes stopped growing after 3 d, but they remained relatively healthy for $\approx$10 d.

Because zinc losses are markedly reduced with severe depletion, the total amount of zinc lost is small. For example, men subsisting on a virtually zinc-free diet for 4–9 wk lost a total of $\approx$95 mg ($\approx$1460 μmol) zinc, which represents $\approx$5% of total body zinc (5). In a 5-wk severe-zinc-depletion study, zinc losses totaled $\approx$40 mg ($\approx$615 μmol), or $\approx$2% of body zinc (9). Clinical symptoms of zinc depletion—ie, skin lesions, diarrhea, and sore throats—were evident in both studies. This shows that the vulnerable zinc pool is very small, and it is sufficient only to support body needs for several weeks when the diet lacks zinc. The corollary of this small zinc reserve is that the response to zinc repletion is extremely rapid. Within a matter of days, the clinical picture changes: enzymes are resynthesized (7), a growth response is observed in children (10), and skin lesions are reversed (11). This rapid reversal of clinical symptoms with small

FOI 26-3132 - Document 5

increases in dietary zinc occurs because there is no significant loss of tissue zinc with depletion. There is no large depleted pool that must be replaced before clinical symptoms improve. Instead, only enough is needed to replete a very small, vulnerable pool (4).

It is important to remember that all nutrients excreted as a consequence of muscle catabolism due to zinc deficiency must be replaced during the repletion period. If, for example, an anorexic child with zinc deficiency is supplemented with zinc, he will regain his appetite and, if quality foods are available, his intake of protein, potassium, and intrinsic dietary zinc will increase. However, if the diet staple is a low-quality cereal food, he may not consume sufficient amounts of the other type 2 nutrients lost and the growth response may be limited. The growth response of stunted children given supplemental zinc varies widely in studies done around the world (12). This may reflect an insufficient intake of other type 2 nutrients, such as protein and potassium, during the zinc supplementation trial.

POTENTIAL DIAGNOSTIC BIOMARKERS OF ZINC NUTRITION

Unique features of type 2 nutrients

Aggett (13) defined nutritional status as the ratio of the tissue nutrient need to tissue nutrient availability. If need is greater than availability and the ratio is less than one, nutritional status is inadequate. This definition assumes that a decline in nutritional status is associated with a reduction in tissue nutrient concentration. This is true for type 1 nutrients where a low tissue nutrient concentration causes a decline in one or more specific functions (4). Type 2 nutrients respond differently to dietary insufficiency because their tissue pools are fixed and vary little with reduced intakes. Instead, a small, vulnerable body pool exists that must be sustained by a continual dietary supply. When intakes are insufficient for maintaining balance, this small pool is depleted quickly, often within days in growing animals or weeks in adult humans, giving rise to nonspecific symptoms of nutrient depletion, such as reduced growth, skin lesions, or infection. Because zinc is a type 2 nutrient, the response to zinc depletion and repletion is extremely rapid (4).

Homeostatic response to acute zinc depletion

Studies in animals and humans show that symptoms of severe zinc depletion occur rapidly and recover quickly with repletion (5, 7, 9, 14). For example, growth ceased after 4 d of a zinc-deficient diet (≈1 ppm) in weanling rats (7). In children, a rapid growth response was observed during zinc repletion (15). Also, the onset of clinical signs of zinc depletion occurred rapidly in adult men who consumed zinc-deficient diets (16, 17). A description of the clinical lesions observed in a study of 8 men who consumed a diet virtually free of zinc, the time of onset, and plasma zinc concentration at that time are shown in **Table 1** (17). Only one subject (12) had no health problems, and subject 5 developed only a sore throat without any skin lesions. The plasma zinc concentrations of these 2 men at the end of depletion (day 35 or 36) tended to be higher than that of the other men, ≈49 μg/dL. Three subjects (subjects 2, 3, and 5) complained of sore throats on day 26 of depletion. Toward the end of depletion (day 33 or 40), 6 subjects (subjects 1–4, 10, 11) had developed canker sores of the mouth and nostrils and a rash on their faces. Subjects 1 and 11 also had rashes in the scrotal area. Plasma zinc concentrations had dropped below 35 μg/dL when the skin rashes occurred. After only 6 d of repletion with 12.2 mg zinc/d, all symptoms had vanished. When the first sign of skin lesions occurred (day 28), whole-body zinc losses totaled 42 mg (≈645 μmol or ≈2–3% of whole-body zinc); at the end of depletion, after ≈40 d, total losses averaged 45 mg, showing the marked effect of the decline in excretory losses on total body zinc loss during extended time on the poor diet (16). It appears, therefore, that the vulnerable pool mobilized with zinc deficiency before clinical signs of zinc depletion are evident is <2% of body zinc. Given this limited reserve of only ≈40 mg zinc to maintain function when the diet is insufficient, it is not surprising that zinc endogenous losses rapidly approach zero in an attempt to maintain the pool and tissue zinc homeostasis with a marked reduction in intake.

TABLE 1
Time of appearance of clinical signs of zinc depletion and plasma zinc concentrations

Subject no.	Day of depletion	Plasma zinc	Clinical signs
		μg/dL	
1	32	8.0	Rash on face, canker sores in mouth, rash in scrotal region, fungal infection on feet
2	26	22.2	Sore throat
	32	17.2	Mouth canker sores, facial rash
3	25	<59.7[1]	Sore throat
	34	19.1	Mouth and nasal canker sores
4	37	24.0	Mouth canker sores
	40	15.8	Facial rash with purulent drainage
5	26	<49.0[1]	Sore throat
	35	48.7	Sore throat
10	34	35.5	Mouth canker sores
11	36	27.6	Nasal canker sores
			Rash in scrotal region, lesion on penis
12	36	48.6	No problems
	40	39.7	No problems

[1] Plasma zinc was not measured on this day. The value given is the previous measurement.

Zinc pools sensitive to zinc deficiency

Cellular organelles

The location or locations of the small, vulnerable zinc pool sensitive to zinc depletion has not been established. Components of the small, vulnerable zinc pools are probably found in all tissues (3, 15). In yeast, which does not have zinc efflux systems, excessive zinc is transported into intracellular organelles for storage and release in times of need. This storage organelle is called a zincosome (3). In mammalian cells, it appears that a small reserve of zinc is stored in the Golgi and in the endoplasmic reticulum. To maintain cellular zinc homeostasis, the ZnT (SLC30) transporters efflux zinc into those organelles or across the plasma membrane (3).

Cellular metallothionein

Cellular metallothionein is another means whereby cells can "park" zinc temporarily for future needs (4). Metallothionein is a cysteine-rich, intracellular, metal-binding protein (18). Although metallothionein has a higher affinity for copper and cadmium than for zinc, it normally exists in vivo in the zinc form. Up to 7 zinc molecules can bind to one metallothionein molecule. Four major metallothionein isoforms exist: MT-1 and MT-2 are located throughout the body, MT-3 is found primarily in the brain, and MT-4 is most abundant in stratified tissues (19). MT-2a is the most predominant form in human tissues. The highest concentrations of metallothionein are found in the liver, kidney, intestine, and pancreas (18). Gut and pancreatic metallothionein concentrations respond readily to changes in dietary zinc, suggesting that metallothionein helps maintain zinc homeostasis in these tissues. For example, high concentrations of intestinal zinc induce metallothionein synthesis and limit zinc absorption by sequestering it in the intestinal wall. The role of metallothionein in enhancing zinc absorption with low zinc intakes is uncertain. However, a decline in pancreatic and renal metallothionein occurs with low zinc intakes and facilitates the decline in fecal and urinary zinc losses (18).

Liver metallothionein concentrations respond promptly to tissue injury, infection, inflammation or neoplastic disease (18, 20, 21). In an inflammatory state, hepatic metallothionein content can increase as much as 100-fold within 2–4 h. This sharp rise in hepatic metallothionein causes hepatic uptake of plasma zinc to facilitate the acute stress response associated with inflammation.

Although the largest concentrations of metallothionein are in the liver, kidney, intestine, and pancreas, smaller quantities are located in all tissue cells. Because metallothionein gene expression is regulated by zinc and because it is one of the strongest cellular zinc binding proteins, it is likely that metallothionein also provides a way for cells to maintain a small zinc reserve (2, 18, 20, 21). Furthermore, the release of zinc from metallothionein when needed causes metallothionein to be degraded, freeing the zinc for metabolic functions.

Plasma zinc

Plasma zinc is a pool of zinc readily available for uptake by tissues when needed, and it is a component of the small, vulnerable zinc reserve. Studies in men show that plasma zinc mass declines rapidly with severe deficiency, decliningfrom 3.4 mg to 1.2 mg in 5 wk (9). The important role of plasma zinc, which serves as a source of zinc for essential tissue functions with low intakes, is shown by its high fractional turnover rate. Normally, the total amount of zinc in plasma is replaced ≈150 times/d; this increases to ≈200 times/d with severe zinc deficiency (9). The decline in plasma zinc concentrations during severe depletion is highly correlated with zinc balance; the higher the loss of body zinc, the greater the rate of plasma zinc decline (22). With moderate dietary zinc restriction (3–5 mg/d), the plasma zinc response is subtle, and shows no change to a slight decrease in zinc because the amount and rate of whole-body zinc loss is lower (23). A comprehensive evaluation of the relation between dietary zinc and plasma zinc concentrations shows that plasma concentrations decrease sharply when intakes are <2–3 mg/d but rise slightly and continuously with higher intakes, reaching a peak at ≈25–30 mg/d (23). It is interesting that zinc absorption also seems to plateau at intakes >20 mg/d. Supplementation with 10 or 20 mg zinc in healthy adult men increased plasma zinc concentrations within 5 d, but concentrations also declined to baseline levels within 5 d of discontinuing zinc supplementation (24).

Although plasma zinc concentrations are sensitive to zinc nutrition, they is not a specific measure of zinc nutrition. This is because plasma zinc is mobilized as a result of metabolic redistribution as well as poor zinc nutrition. Plasma zinc readily decreases with metabolic redistribution induced by endotoxemia, infection, carcinoma, steroid use, and after a meal (4, 25). This decline represents a redistribution of zinc from the small, vulnerable pool to the tissues, not a change in zinc nutrition.

Plasma zinc is primarily bound to albumin (70%) with the remainder bound tightly to α_2-macroglobulin (18%) and other proteins or amino acids, especially histidine and cysteine (23). Hypoalbuminemia is frequently associated with hypozincemia (4), and it is argued that this is due to reduced concentrations of plasma zinc–binding sites that could confound the interpretation of the decline in plasma zinc concentrations. However, even when plasma albumin is low, only ≈1 of every 50 albumin molecules is associated with a zinc atom, making it difficult to see how a reduction in albumin could lead to a significant reduction in zinc (4). On the other hand, a marginal zinc status could lead to a reduction in albumin synthesis.

Food intake, plasma volume expansion (pregnancy, overhydration), and steroid or oral contraceptive use all cause a decline in plasma zinc concentrations. A careful assessment of the individual's health status at the time of the blood draw can help determine whether the plasma zinc concentration is low due to one of these conditions. Ruling out the influence of a subclinical infection as a cause of low plasma zinc concentrations is more difficult. Measurements of proteins that are elevated in response to tissue injury or infection—eg, C-reactive protein or α_1-acid glycoprotein—are frequently performed to determine whether infection is present (26). However, these measures of infection are not directly related to plasma zinc concentrations because the stage and severity of infection both influence the change in plasma zinc. Also, the nutritional status of the host will affect the influence of infection on plasma zinc concentrations. The cytokine response to infection is reduced in malnourished animals and humans, suggesting that infection may have a smaller effect on plasma zinc concentrations in malnourished individuals (26).

FOI 26-3132 - Document 5

Theoretically, metallothionein may be the key to diagnosing metabolic zinc redistribution due to infection, trauma, or stress (4). Metallothionein can be detected in plasma and erythrocytes by a radioimmunoassay (27, 28). Hepatic metallothionein concentrations rise with inflammation or stress, which also causes a rise in plasma metallothionein but not erythrocyte metallothionein (20, 21). Thus, in a metabolic state causing tissue zinc redistribution, plasma zinc concentrations will be low and metallothionein concentrations will be high, but erythrocyte metallothionein will be normal (16). If the plasma zinc pool is reduced due to poor zinc nutrition in the absence of infection, both plasma and erythrocyte metallothionein should be low.

This potential procedure for determining if low plasma zinc is due to poor nutrition or metabolic distribution has not been validated experimentally. But, preliminary studies are promising. Human studies have shown that both plasma and erythrocyte metallothionein concentrations are sensitive to dietary zinc (21, 27). However, the effects of infection or stress on plasma and erythrocyte metallothionein concentrations in the presence of low or adequate zinc nutrition need to be evaluated in humans.

Exchangeable zinc pool

Using zinc isotopes and a model-based compartmental analysis, Miller et al (29) and Jackson et al (30) have defined an exchangeable zinc pool (EZP) that exchanges rapidly with plasma zinc. Some, but not all, studies have shown a relation between dietary zinc and the size of the EZP (31, 32). During severe zinc depletion in adult men, EZP size declined nearly as much as the plasma zinc (60% compared with 65%), suggesting that it is part of the small, vulnerable pool susceptible to zinc depletion but not more sensitive than plasma zinc concentrations. Measurements of the effect of infection or stress on the size of the EZP have not been done. But it is likely that EZP size will decline with metabolic zinc redistribution due to stress because plasma zinc is a component of the EZP measure. Presently, EZP size is not used widely as a biomarker of zinc nutrition because it is not more responsive to changes in dietary zinc than is plasma zinc and because its measurement requires the use of expensive stable isotopes and access to a mass spectrometer for analysis.

CONCLUSIONS

Although much has been learned about cellular and whole-body zinc homeostasis and metabolism, a sensitive, specific biomarker of zinc nutrition has not been identified. Given that zinc is required for multiple general metabolic functions, it is unlikely that a specific biomarker of zinc nutrition exists. Nevertheless, the sensitivity of a small, vulnerable zinc pool to dietary zinc provides a means of identifying zinc under- and possibly overnutrition. Plasma zinc is a component of the small, vulnerable zinc pool, and it is a sensitive marker of zinc nutrition. Unfortunately, plasma zinc concentration is subject to metabolic redistribution as well as insufficient dietary zinc. Research is needed to identify biomarkers of zinc metabolic redistribution. Indicators of shifts in the metabolism of cellular zinc pools (zinc transporters or metallothionein) appear to be promising.

Doxycycline Inhibits TGF-β1–Induced MMP-9 via Smad and MAPK Pathways in Human Corneal Epithelial Cells

Hyun-Seung Kim,[1,2] *Lihui Luo,*[1] *Stephen C. Pflugfelder,*[1] *and De-Quan Li*[1]

Purpose. To evaluate the effects of TGF-β1 and doxycycline on production of gelatinase MMP-9 and activation of Smad, c-Jun N-terminal kinase (JNK), extracellular-regulated kinase (ERK), and p38 mitogen-activated protein kinase (MAPK) signaling pathways in human corneal epithelial cells.

Methods. Primary human corneal epithelial cells were cultured to confluence. The cells were treated with different concentrations of TGF-β1 (0.1, 1, or 10 ng/mL), with or without TGF-β1–neutralizing mAb (5 μg/mL), SP600125 (30 μM), PD98059 (40 μM), SB202190 (20 μM), or doxycycline (5–40 μg/mL) for different lengths of time. Conditioned media were collected from cultures treated for 24 to 48 hours to evaluate the MMP-9 production by zymography and activity assay. Total RNA was isolated from cells treated for 6 to 24 hours to evaluate MMP-9 expression by semiquantitative RT-PCR and Northern hybridization. Cells treated for 5 to 60 minutes were lysed in RIPA buffer for Western blot with phospho-specific antibodies against Smad2, JNK1/2, ERK1/2, or p38.

Results. TGF-β1 increased expression, production, and activity of MMP-9 by human corneal epithelial cells in a concentration-dependent fashion. TGF-β1 also induced activation of Smad2, JNK1/2, ERK1/2, and p38 within 5 to 15 minutes, with peak activation at 15 to 60 minutes. Doxycycline markedly inhibited the TGF-β1–induced production of MMP-9 and activation of the Smad, JNK1/2, ERK1/2, and p38 signaling pathways. Its inhibitory effects were of a magnitude similar to SP600125, PD98059, and SB202190, specific inhibitors of the JNK1/2, ERK1/2, and p38 pathways, respectively.

Conclusions. These findings demonstrated that doxycycline inhibits TGF-β1–induced MMP-9 production and activity, perhaps through the Smad and MAPK signaling pathways. These inhibitory effects may explain the reported efficacy of doxycycline in treating MMP-9–mediated ocular surface diseases. (*Invest Ophthalmol Vis Sci.* 2005;46:840–848) DOI:10.1167/iovs.04-0929

The important role of matrix metalloproteinases (MMPs) has been recognized in ocular surface diseases including wound healing, dry eye, sterile corneal ulceration, recurrent epithelial erosion, corneal neovascularization, pterygium, and conjunctivochalasis.[1–6] Among these, gelatinase B (MMP-9) has been found to be of central importance in extracellular matrix remodeling after wounding of the corneal surface and has been implicated in the pathogenesis of sterile corneal ulceration, dry eye–associated epitheliopathy, and other ocular diseases.[7–10] The expression of MMP-9 is known to be modulated by cytokines and growth factors that induce cellular responses by activating a variety of intracellular signaling cascades. The pro-inflammatory cytokines IL-1β and TNF-α, as well as transforming growth factor (TGF)-β have been reported to play a role in the regulation of MMP-9 production and activity in human corneal epithelial cells.[11]

TGF-β is known to play a vital role in tissue remodeling during inflammatory responses. TGF-β has been found to stimulate the expression of MMP-9 in endothelial cells, fibroblasts, and epithelial cells, including the corneal epithelium.[11–14] The diverse cellular responses elicited by TGF-β are triggered by activation of serine/threonine kinase TGF-β receptors and are transduced through multiple intracellular signal pathways. After ligand binding, the type II TGF-β receptor recruits the type I receptor, which is then phosphorylated by the type II receptor. The activation of the type I receptor triggers the phosphorylation of cytoplasmic proteins, including the novel Smad pathway, that are directly implicated in the transmission of the intracellular signal.[15] Many of the signaling responses induced by TGF-β are mediated by Smad proteins, but certain evidence has suggested that TGF-β can also signal independently of Smads.[16] TGF-β can activate mitogen-activated protein kinase (MAPK) signaling pathways including c-Jun N-terminal kinase (JNK), extracellular-regulated kinase (ERK), and p38 MAPK, and the specific pathway used appears to vary with and depend on the cell type and tissue function.[17,18] The signaling pathways that mediate the regulatory effect of TGF-β on MMP-9 are not understood.

Doxycycline, a long-acting semisynthetic tetracycline, is well recognized for its therapeutic efficacy in treating MMP-mediated ocular surface diseases, such as rosacea, and sterile corneal ulceration.[19,20] Doxycycline has been found to inhibit MMP-9 activity in human endothelial cells,[21] skin keratinocytes,[22] and cancer cells.[23,24] Doxycycline was reported to significantly decrease serum MMP-9 levels (50%) after 6 months of oral administration after myocardial infarction.[25] Doxycycline has been reported to decrease the activity of MMP-9 in conditioned media of cultured human corneal epithelial cells,[26] but the effects and mechanisms of doxycycline on TGF-β–induced MMP-9 production are not known.

This study investigated the effects of doxycycline on TGF-β1–induced production of MMP-9 and activation of the Smad2, JNK, ERK, and p38 MAPK signaling pathways in human corneal epithelial cells.

Materials and Methods

DMEM/Ham's F12, amphotericin B, phenol, DNA or RNA size markers, and a random primer DNA labeling kit were purchased from Invitro-

gen-Gibco (Grand Island, NY); fetal bovine serum (FBS) from Hyclone (Logan, UT); recombinant human TGF-β1 and TGF-β1 neutralizing monoclonal antibody (mAb) from R&D Systems (Minneapolis, MN); activity assay kits (Biotrak) for MMP-9 and chemiluminescence reagents (ECL Plus) from Amersham Pharmacia Biotech (Piscataway, NJ); EDTA-free protease inhibitor cocktail tablet from Roche Applied Sciences (Indianapolis, IN); the bicinchoninic (BCA) protein assay kit from Pierce Chemical (Rockford, IL); SP600125, PD98059, and SB202190 from Calbiochem (Darmstadt, Germany); rabbit polyclonal antibodies against ERK or p38 from Cell Signaling (Beverly, MA); phospho-specific mAbs for JNK, ERK, and p38 and rabbit antibodies against JNK and phospho-Smad2 from Santa Cruz Biotechnology (Santa Cruz, CA); polyvinylidene difluoride (PVDF) membranes from Millipore (Bedford, MA); nitrocellulose membranes from Schleicher and Schuell (Keene, NH); the PCR kit (GeneAmp) from Applied Biosystems (Foster City, CA); PCR purification and gel extraction kits (QIAquick) from Qiagen (Valencia, CA); [α-^{32}P]-dCTP from Du Pont NEN (Boston, MA); and film and intensifying screens (XAR-5 and BioMax MS-1) from Eastman Kodak (Rochester, NY). All plastic ware was from BD Biosciences (Franklin Lakes, NJ). Doxycycline, cholera toxin subunit A, hydrocortisone, and all other reagents were from Sigma-Aldrich (St. Louis, MO).

Primary Cultures of Human Corneal Epithelial Cells

Human corneal epithelial cells were cultured from explants taken from human donor corneoscleral rims, provided by the Lions Eye Bank of Texas, using a previously described method.[26,27] In brief, corneoscleral rims were trimmed, the endothelial layer and iris remnants were removed, and each limbal rim was dissected into 12 equal segments. Two segments were placed in each well of six-well culture plates, and each explant was covered with a drop of FBS overnight. The explants were then cultured in hormone supplemented medium, containing equal amounts of DMEM and Ham's F12, supplemented with 5% FBS, 0.5% dimethyl sulfoxide, 2 ng/mL epidermal growth factor (EGF), 5 μg/mL insulin, 5 μg/mL transferrin, 5 ng/mL selenium, 0.5 μg/mL hydrocortisone, 30 ng/mL cholera toxin A, 50 μg/mL gentamicin, and 1.25 μg/mL amphotericin B, at 37°C in 95% humidity and 5% CO_2. The medium was renewed every 2 to 3 days. Epithelial phenotype of these cultures was confirmed by characteristic morphology and immunofluorescent staining with cytokeratin antibodies (AE-1/AE-3). Subconfluent cultures (12–14 days) were washed four times with PBS and switched to serum-free medium (the same just medium described, but without FBS) for 24 hours before treatment.

Cell Treatment

Except for the control groups that were continually cultured in serum-free medium alone, the cultures were treated with TGF-β1 at different concentrations (0.1, 1.0, or 10 ng/mL), with or without the TGF-β1-neutralizing mAb (5 μg/mL), SP600125 (30 μM, a JNK/SAPK pathway inhibitor), PD98059 (40 μM, a ERK MAPK pathway inhibitor), SB202190 (20 μM, a p38 MAPK pathway inhibitor), or doxycycline (5–40 μg/mL) for different lengths of time. For gelatin zymography and MMP-9 activity assays, the same volume of the serum-free medium (1.2 mL) was added to each well of corneal epithelial cultures (~5×10^5 cells/well). The conditioned medium after 24 to 48 hours of treatment was collected and centrifuged, and the supernatants were stored at −80°C before use. The adherent cells were lysed in phosphate-buffered saline (PBS, pH 7.3), containing 1.5 M NaCl and 0.039% Triton X-100 for the BCA protein assay. The cellular protein concentration in each well was used to adjust the volume of the conditioned medium used for gelatin zymography and MMP-9 activity assays. For MMP-9 gene expression analysis, the corneal epithelial cells after treatment for 6 hours were lysed in 4 M guanidium solution and subjected to total RNA extraction. The cells treated for shorter times (5, 15, 30, and 60 minutes) were lysed in RIPA lysis buffer, containing 50 mM Tris-HCl, 150 mM NaCl, 1% NP-40, 0.5% sodium deoxycholate, 2 mM sodium fluoride, 2 mM EDTA, 0.1% SDS, and an EDTA-free protease inhibitor cocktail tablet, for Western blot analysis. These experiments were performed at least three times using separate sets of cultures that were initiated from different donor corneas.

Gelatin Zymography

To determine the relative concentration and activity of gelatinases in the conditioned media from corneal epithelial cultures receiving various treatments, SDS-PAGE gelatin zymography was performed with a previously reported method.[28] Briefly, 8 to 10 μL of each conditioned medium was used, and the volume was adjusted by cellular protein concentrations. The media supernatants were treated with SDS-PAGE sample buffer without boiling or reduction. Samples were fractionated in an 8% polyacrylamide gel containing gelatin (0.5 mg/mL) by electrophoresis at 100 V for 90 minutes at 4°C. The gels were soaked in 0.25% Triton X-100 for 30 minutes at room temperature to remove the SDS, and incubated in a digestion buffer (50 mM Tris-HCl [pH 7.4], 150 mM NaCl, 10 mM $CaCl_2$, 2 μM $ZnSO_4$ and 0.01% Brij-35) containing 5 mM phenylmethylsulfonyl fluoride (PMSF), a serine protease inhibitor, at 37°C overnight, to allow proteinase digestion of its substrate. The gels were then stained with 0.25% Coomassie brilliant blue R-250 in 40% isopropanol for 2 hours, and destained with 7% acetic acid. Gelatinolytic activities appeared as clear bands of digested gelatin against a dark blue background of stained gelatin.

MMP-9 Activity Assay

The total activity levels of MMP-9 protein in supernatants of the corneal epithelial cultures were determined using MMP-9 activity assay systems (Biotrak) according to manufacturer's protocol. This assay primarily measured the activity of latent MMP-9, because the active form of MMP-9 in the media was almost undetectable. In brief, 100 μL each pro-MMP-9 standard (0.5–32 ng/mL), culture supernatant sample, or assay buffer (for blanks) was incubated at 4°C overnight in microtiter wells precoated with anti-MMP-9 antibody. Any MMP-9 present in these solutions bound to the wells. Other components of the sample were removed by washing four times with 0.01 M sodium phosphate buffer (pH 7.0) containing 0.05% Tween-20. To measure the total activity of MMP-9, bound pro-MMP-9 was activated with 50 μL of 1 mM *p*-aminophenylmercuric acetate (APMA) in assay buffer at 37°C for 2 hours. Detection reagent (50 μL) was then added to each well and incubated at 37°C for 6 hours. Active MMP-9 was detected though activation of a modified prodetection enzyme and the subsequent cleavage of its chromogenic peptide substrate. The resultant color was read at 405 nm in a microtiter plate reader. The activity of MMP-9 in a sample was determined by interpolation from a standard curve.

RNA Isolation and Semiquantitative RT-PCR

Total RNA was isolated from corneal epithelial cell cultures by acid guanidium thiocyanate-phenol-chloroform extraction according to a previously described method.[29] The PCR primers for MMP-9 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were designed from published human gene sequences (Table 1). The semiquantitative reverse transcription–polymerase chain reaction (RT-PCR) was performed to evaluate the expression of these MMP-9 genes by corneal epithelial cells with a housekeeping gene, GAPDH, as an internal control.[11] In brief, the first-strand cDNAs were synthesized from 1 μg of total RNA at 42°C for 30 minutes. PCR amplification was performed in a DNA thermal cycler (model 9700; Applied Biosystems, Inc.) using the following program: denaturation for 2 minutes at 95°C followed by 20 to 40 cycles of denaturation for 1 minute at 95°C, annealing for 1 minute at 60°C, and extension for 1 minute at 72°C, with a final extension for 7 minutes at 72°C. Semiquantitative RT-PCR was established by terminating reactions at intervals of 20, 24, 28, 32, 36, and 40 cycles for each primer pair to ensure that the PCR products formed were within the linear portion of the amplification curve. The fidelity of the RT-PCR product was verified by comparing the size of the

amplified products to the expected cDNA bands and by sequencing the PCR products.

Probe Preparation and Northern Hybridization

Human cDNA probes (552-bp fragment of MMP-9 and 498 bp of GAPDH) were purified from the RT-PCR products by electrophoresis through a 1.5% low-melting-point agarose gel, with a PCR purification kit (QIAquick; Qiagen) and gel extraction kit, per the manufacturer's protocol. Northern hybridization was performed with a previously described method.[29] In brief, total RNA for each group at 20 μg/lane was electrophoresed through 1.2% agarose containing formaldehyde, transferred to nitrocellulose membranes, and hybridized with a ^{32}P-labeled cDNA probe at 2 to 4 $\times$ 10^6 cpm/3 to 8 ng/mL in the hybridization solution. After visualizing the hybridization product on the x-ray film, the ^{32}P-label on the membrane was stripped by washing the membranes twice at 65°C for 1 hour in 5 mM Tris-HCl (pH 8.0), 0.2 mM EDTA, 0.05% sodium pyrophosphate, and 0.1$\times$ Denhardt's solution. The membranes were then rehybridized with GAPDH probe, which served as a loading control.

Western Blot Analysis

The cells treated for 5 to 60 minutes were lysed in RIPA buffer, and appropriate volumes (25–30 μL) of cell extracts, adjusted to represent the same amount of total cellular protein (50 μg), were electrophoresed under reducing condition at 4°C in a 4% to 15% gradient polyacrylamide gel. After electrophoretic transfer to a PVDF membrane at 100 V for 1 hour at 4°C, the membranes were blocked with 5% nonfat milk in TTBS (50 mM Tris [pH 7.5], 0.9% NaCl, and 0.1% Tween-20) for 1 hour at RT. The primary antibody (i.e., phospho-specific antibodies against Smad2, JNKs, ERKs, or p38) in TTBS containing 5% nonfat milk was placed on each membrane and incubated at RT for 60 minutes with agitation. After three washings with TTBS over 15 minutes, the second antibody, conjugated with horseradish peroxidase (HRP), was applied and the signals on the membranes were detected by chemiluminescence reagents (ECL Plus; Amersham Pharmacia Biotech) and imaged with a digital image station (2000R; Eastman Kodak).

RESULTS

Effects of TGF-β1 and Doxycycline on MMP-9 Production and Activity

The protein levels of MMP-9 were determined by gelatin zymography and MMP-9 activity assay in the serum-free conditioned medium from corneal epithelial cultures. As shown in Figures 1A and 1B, zymography revealed that TGF-β1 stimulated 92-kDa MMP-9 protein production in a concentration-dependent manner by corneal epithelial cells treated with increasing concentrations of TGF-β1 (0.1, 1.0, and 10 ng/mL) for 24 hours. TGF-β1 at 1 ng/mL markedly stimulated MMP-9 production and the strongest stimulation was observed with 10 ng/mL. This stimulation at 1 ng/mL TGF-β1 was abolished by 5 μg/mL TGF-β1 neutralizing mAb or 10 μg/mL doxycycline (Fig. 1A). In contrast, the bands of 72-kDa gelatinase A (MMP-2) were essentially unchanged. The bands in zymograms from three experiments were scanned, and the quantified data showing the relative change (*x*-fold) in MMP-9 protein are summarized in Figure 1B. Doxycycline at a concentration of 10 μg/mL completely abolished the stimulation of MMP-9 by 1 ng/mL TGF-β1.

The MMP-9 activity assays confirmed the zymography results. As shown in Figure 1B, MMP-9 activities in the conditioned media from TGF-β1 (0.1, 1.0, or 10 ng/mL) treated epithelial cultures were 1.97 $\pm$ 0.20, 4.09 $\pm$ 0.10, and 4.65 $\pm$ 0.25 ng/mL (mean $\pm$ SD, n = 3) respectively, significantly higher than the control group (0.82 $\pm$ 0.09 ng/mL). MMP-9 activity in the conditioned media was significantly increased to 4.99- and 5.67-fold (both $P < 0.05$) by TGF-β1 at concentrations of 1 and 10 ng/mL, respectively. The upregulation of MMP-9 by 1 ng/mL TGF-β1 was inhibited 54.7% by 10 μg/mL doxycycline ($P < 0.05$), but MMP-9 stimulated by the higher dose of TGF-β1 (10 ng/mL) was not inhibited by this pharmacologic dose of doxycycline.

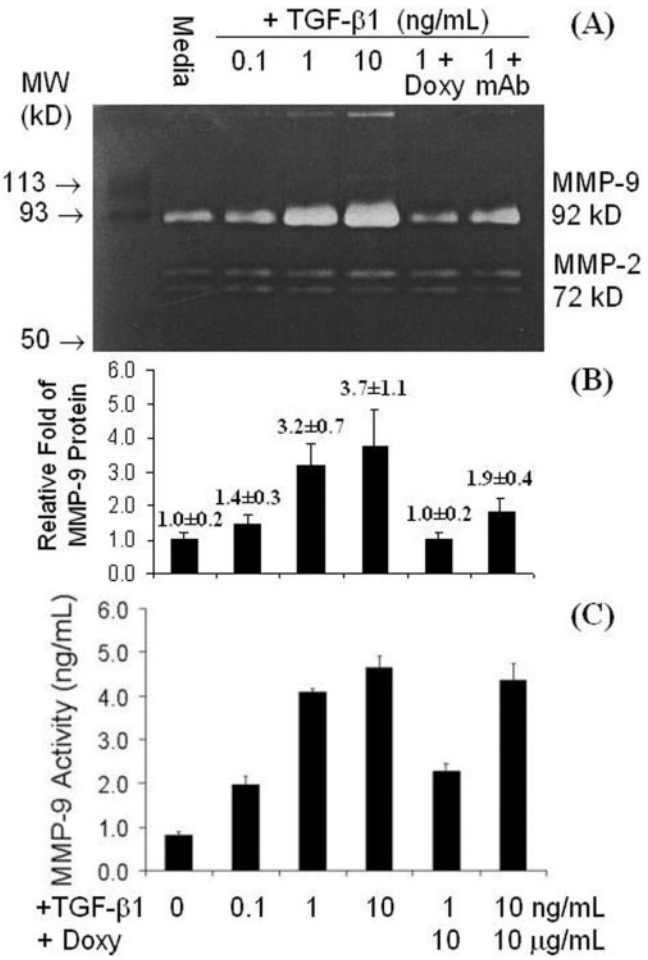

FIGURE 1. Zymography (**A**, **B**) and MMP-9 activity assay (**C**) showing MMP-9 production and activity in the conditioned media of human corneal epithelial cells treated by TGF-β1 (0.1–10 ng/mL), alone or with TGF-β1 (1 ng/mL) plus doxycycline (10 μg/mL) or a neutralizing mAb (5 μg/mL) against TGF-β1. The bands in zymograms from three experiments were scanned and quantified. Data showing relative change of MMP-9 protein (*x*-fold) are summarized in (**B**).

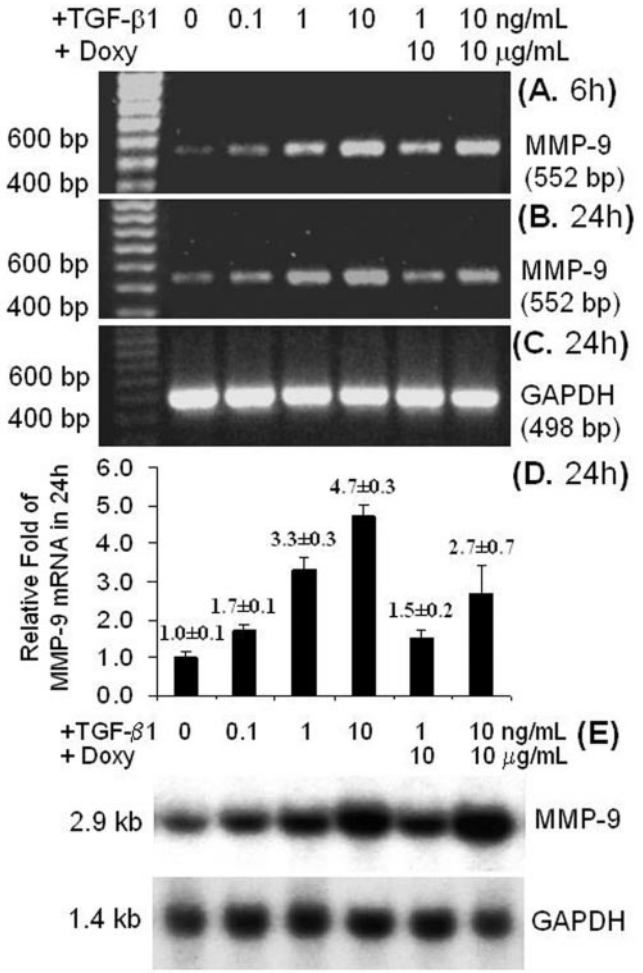

FIGURE 2. Semiquantitative RT-PCR (**A**–**D**) and Northern blot (**E**) showing the regulation of MMP-9 mRNA in human corneal epithelial cells by TGF-β1 and doxycycline at 6 (**A**, **E**) and 24 hours (**B**–**D**). The scanned and quantified data of RT-PCR profiles treated for 24 hours from three experiments (**B**, **C**) are summarized in (**D**), showing the relative change (*x*-fold) of MMP-9 mRNA after normalization by GAPDH mRNA.

Effects of TGF-β1 and Doxycycline on MMP-9 mRNA Expression

Semiquantitative RT-PCR analysis revealed that MMP-9 mRNA was expressed by normal corneal epithelial cells. The MMP-9 transcripts were upregulated in a concentration-dependent manner after 6 (Fig. 2A) and 24 hours (Fig. 2B) of treatment with increasing concentrations (0.1, 1.0, 10 ng/mL) of TGF-β1 when compared with constantly expressed levels of GAPDH mRNA (Fig. 2C), which served as an internal control. The addition of doxycycline did not affect the levels of MMP-9 mRNA at 6 hours, but did inhibit MMP-9 expression at 24 hours (Fig. 2B). The scanned and quantified data of RT-PCR profiles of cultures treated for 24 hours from three experiments (Figs. 2B, 2C) are summarized in Figure 2D, which shows the relative *x*-fold change of MMP-9 mRNA after normalization by GAPDH mRNA. The results show that 1 ng/mL TGF-β1 increased MMP-9 mRNA by 3.3-fold, whereas doxycycline decreased this stimulation by 78.3% to 1.5-fold. Northern hybridization disclosed that a single 2.9 kb band of MMP-9 transcript was expressed by cultured corneal epithelial cells (Fig. 2E). The size of this transcript is consistent with previous reports.[30] The expression of MMP-9 mRNA was stimulated in a concentration-dependent manner by treatment with different doses (0.1, 1.0, and 10 ng/mL) of TGF-β1. In contrast, the 1.4-kb band of GAPDH transcripts was unaltered by exposure to TGF-β1. The addition of doxycycline did not affect the levels of MMP-9 expression at 6 hours (Fig. 2E), which agreed with RT-PCR results.

Effects of TGF-β1 and Doxycycline on Activation of Smad Pathway

Phosphorylated Smad2 protein (60 kDa) was detected in corneal epithelial cells by Western blot using a phospho-specific polyclonal antibody. As shown in Figure 3A, 10 ng/mL TGF-β1 activated phosphorylation of Smad2 by 5 minutes after exposure and activation peaked at 30 minutes. TGF-β1 concentration dependently induced Smad2 phosphorylation, which was detected after treatment with a low concentration of TGF-β1 (0.1 ng/mL) and peaked at 10 ng/mL. Doxycycline at 10 μg/mL markedly inhibited the activation of Smad2 induced by 1 ng/mL TGF-β1 (Fig. 3B).

Effects of TGF-β1 and Doxycycline on Activation of MAPK Pathways

The activation of MAPK signaling pathways in corneal epithelial cells was detected by Western blot using phospho-specific antibodies. As shown in Figure 4A, 10 ng/mL TGF-β stimulated phosphorylation of JNK1 (46 kDa) and JNK2 (54 kDa) as early as 5 minutes, peaking at 15 minutes. TGF-β1 at 0.1, 1, and 10 ng/mL concentration dependently induced p-JNK1/2 when compared with constant levels of total JNK1/2. SP600125, a specific inhibitor of the JNK pathway, markedly inhibited the activation of JNK1/2 induced by 1 ng/mL TGF-β1, but did not decrease levels of total JNK1/2 (Fig. 4B). Doxycycline showed an inhibitory effect on the TGF-β1–induced activation of JNK1/2, especially at a 10-μg/mL concentration, which was similar to the inhibitory effect produced by SP600125 (Figs. 4B, 4C). Activation of 46-kDa p-JNK1 appeared more pronounced than 54-kDa p-JNK2, suggesting that p-JNK1 may be the major isoform of JNK that is activated by TGF-β1.

As shown in Figure 5A, Western blot revealed that 10 ng/mL TGF-β1 activated phosphorylation of ERK1/2 as early as 15 minutes, peaking at 60 minutes in the time course tested. TGF-β1, at 0.1, 1, and 10 ng/mL, concentration dependently

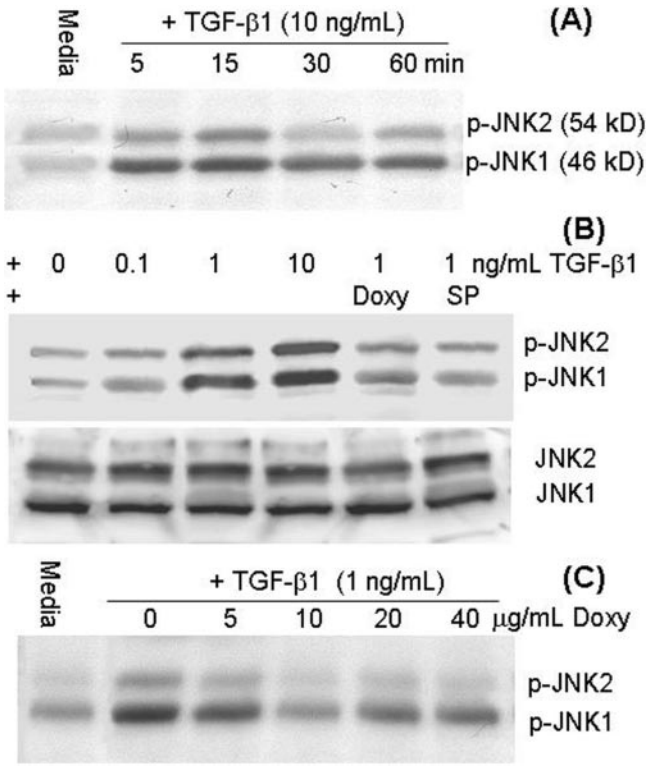

FIGURE 4. Western blot showing the time course (**A**) and dose–response (**B**) of p-JNK1 and p-JNK2 activated by TGF-β1 and inhibited by (**B**) 10 and (**C**) 5 to 40 μg/mL doxycycline (Doxy) and 30 μM SP600125 (SP) in human corneal epithelial cells.

induced p-ERK1/2 when compared with relatively constant levels of total ERK1/2. PD98059, a specific inhibitor of the ERK pathway, markedly inhibited the activation of ERK1/2 induced by 1 ng/mL TGF-β1, but did not inhibit total ERK1/2 (Fig. 5B). Doxycycline at a 5- to 40-μg/mL concentration dependently inhibited the TGFβ1-induced activation of ERK1/2 (Fig. 5C). The inhibitory effect of doxycycline on p-ERK1/2 was similar to PD98059 (Fig. 5B) All figures show that the 42-kDa band of p-ERK2 was stronger than 44-kDa p-ERK1, which may suggest that p-ERK2 was the major isoform of ERK is activated by TGF-β1.

TGF-β1 also induced activation of p38 MAPK in corneal epithelial cells. Western blot showed that 10 ng/mL TGF-β1 activated phosphorylation of p38 as early as 5 minutes, and the reaction peaked at 60 minutes in the time course tested (Fig. 6A). TGF-β1 concentration dependently induced p-p38 at a low concentration of 0.1 ng/mL, with peak activation at 10 ng/mL. In contrast, levels of total p38 remained constant. SB202190, a specific inhibitor of p38 MAPK pathway, markedly inhibited p38 phosphorylation induced by 1 ng/mL TGF-β1, but did not affect levels of total p38. Doxycycline at, 5 to 40 μg/mL, concentration dependently inhibited the TGFβ1–induced activation of p-38 (Fig. 6C). The inhibitory effect of doxycycline on p-p38 was similar to SB202190 (Fig. 6B).

These MAPK pathway inhibitors not only blocked the phosphorylation of the JNKs, ERKs, or p38, then also markedly inhibited MMP-9 production by corneal epithelial cells. SP600125, PD98059, and SB202190 almost abolished the production and activity of MMP-9 stimulated by TGF-β1 (1 ng/mL) in the cultures treated for 24 (Fig. 7A) and 48 (Fig. 7B) hours. SB202190 showed stronger inhibition of TGF-β1–induced MMP-9 than did SP600125 and PD98059, perhaps because SB202190 at 20 μM inhibits both the p38 and JNK pathways.[31,32] Doxycycline, at 5 to 40 μg/mL, concentration dependently inhibited the TGF-β1–ed production of MMP-9 (Fig. 7C). The inhibitory effect of doxycycline at 10 μg/mL on TGF-β1–stimulated MMP-9 production was similar to that of SP600125 and PD98059, whereas it was slightly weaker than that of SB202190 at 24 and 48 hours.

DISCUSSION

Stimulation of MMP-9 Expression, Production and Activity by TGF-β1

In mammals there are three isoforms of TGF-β (TGF-β1, -β2, and -β3), which are functionally similar and interchangeable under many conditions, although they may possess unique functions.[33–35] All three TGF-β isoforms are expressed by ocular surface fibroblasts and epithelial cells.[29,35–38] Among them, TGF-β1 and -β2 are abundantly present in human tears, which are secreted by lacrimal glands and are produced by the epithelial and inflammatory cells that reside on the ocular surface.[29,38,39] TGF-β1 is the predominant isoform, particularly in its latent inactive form, that may be activated by proteases during inflammation and wound healing.[40–43] In this study, we used TGF-β1 to investigate its effects on regulation of MMP-9 production by primary cultured human corneal epithelial cells.

The role of TGF-β1 in regulating MMP-9 has not been well understood, and previous studies have reported conflicting results. TGF-β1 has been reported to reduce the production of gelatinases (MMP-2 and -9) and enhance the expression of the tissue inhibitors of MMP (TIMP-1 and -3) in human lung fibroblasts[33] and myometrial smooth muscle cells.[44] TGF-β1 has also been found to stimulate production of MMP-9 in keratinocytes,[14] odontoblasts,[45] human fibroblasts,[13] and oral tumor

cells.[46] These observations suggest that the effect of TGF-β1 on MMP-9 may be species specific, tissue or cell-type specific, and temporally and spatially specific. We have observed by zymography that TGF-β1 stimulates MMP-9 production.[11] In the current study, we demonstrated that TGF-β1 concentration dependently increased protein production and mRNA expression of gelatinase MMP-9 in cultured human corneal epithelial cells (Figs. 1, 2). This TGF-β1–stimulated MMP-9 expression may mediate epithelial cell migration during wound healing and involve the pathogenesis of ocular surface diseases such as corneal ulceration and dry eye.[47–49]

Activation of Smad and MAPK Pathways by TGF-β1

Ligands of the TGF-β superfamily are known to be unique, in that they signal through transmembrane receptor serine-threonine kinases, rather than through tyrosine kinases. The receptor complex couples to a signal transduction pathway involving a novel family of proteins, the Smads.[50] Receptor-activated Smads (Smad2 and -3) are directly phosphorylated by activated TGF-β receptors and form heteromeric complexes with Smad4 that translocate into the nucleus and modulate the transcription of target genes.[51–54] In many TGF-β-regulated genes, Smad-binding sequences are located adjacent to AP-1-recognition sites.[55,56] Although transcriptional responses can result from direct Smad binding to DNA, more commonly, functional interaction of Smads with transcriptional cofactors and coactivators or corepressors is necessary.

MAPK cascades are also a group of protein serine/threonine kinases that are activated in response to a variety of extracellular stimuli and mediate signal transduction from the cell surface to the nucleus.[57] The kinetics of this response convincingly argue that it is a primary effect of receptor kinase activation, and the use of dominant negative type II TGF-β receptors demonstrates that the same TGF-β receptor complex is coupling to the MAPK pathways as it is to the Smad pathway.[17] It is likely that there are transcriptional responses that are uniquely Smad dependent, uniquely MAPK dependent, or interdependent on the interaction between the two. The Smad pathway is a nexus for cross talk with other signal transduction pathways and for modulation by many different interacting proteins. TGF-β receptors activate Smad-independent pathways that not only regulate Smad signaling, but also allow Smad-independent TGF-β responses.[58] Different biological responses to TGF-β1 depend to various degrees on activation of either or both of these two pathways.

MMP-9 has been observed to be regulated by TGF-β,[11,13,14] and protein kinases belonging to the MAPK family, ERK, JNK, and p38 pathways are found to involve the regulation of MMP-9 production.[59–61] The regulatory mechanisms responsible for the expression of MMP-9 by TGF-β1, however, are still poorly understood. Only a few reports have shown that TGF-β1 stimulates MMP-9 production through the Ras-ERK1/2 MAPK pathway in transformed keratinocytes.[62] In this study, TGF-β1 concentration dependently activated the phosphorylation of 60-kDa Smad2 as early as 5 minutes, with peak activity at 30 minutes. This finding is supported by a recent study showing that TGF-β–induced MMP-13 production is triggered by Smad2 protein in human osteoarthritic chondrocytes.[63] In this study, we also showed that TGF-β1 concentration dependently activates JNK1/2, ERK1/2, and p38 MAPK pathways (Fig. 4–6). The requirement for activation of these MAPK pathways in the TGF-β1–induced MMP-9 production was supported by experiments using MAPK specific inhibitors, SP600125, PD98059, and SB202190, which blocked activation of JNK/SAPK, ERK,

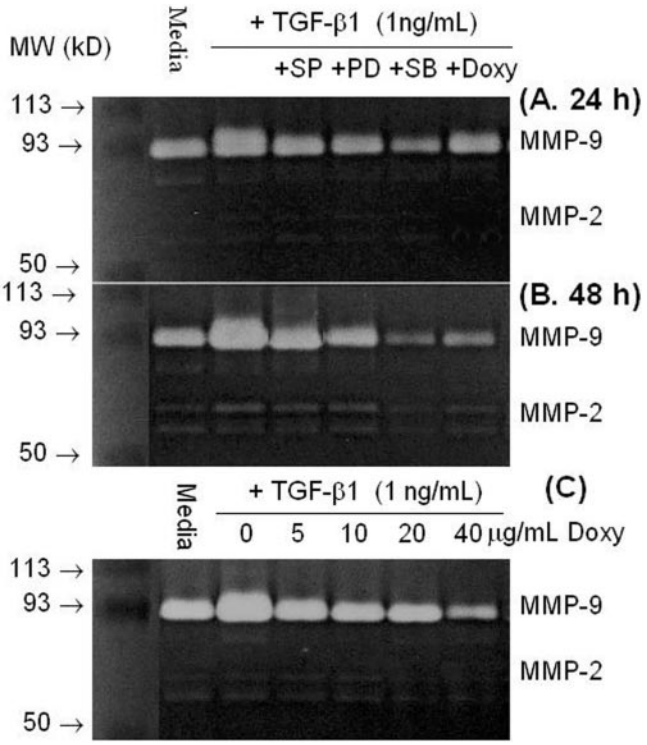

FIGURE 7. Representative zymograms showing MMP-9 production in the conditioned media of human corneal epithelial cells treated with TGF-β1 (1 ng/mL), with or without 30 μM SP600125 (SP), 40 μM PD98059 (PD), 20 μM SB202190 (SB), or 10 μg/mL doxycycline (Doxy) for (**A**) 24 or (**B**) 48 hours or 5 to 40 μg/mL doxycycline for (**C**) 24 hours.

FOI 26-3132 - Document 5

and p38, respectively, and also inhibited TGF-β1–induced MMP-9 production (Fig. 7). These findings demonstrate that the Smad2, JNK, ERK, and p38 pathways are involved in MMP-9 production in human corneal epithelial cells.

TGF-β1–induced activation of the ERK and JNK pathways has been found to regulate Smad phosphorylation, which facilitates both its activation by the TGF-β receptor complex and its nuclear accumulation.[64,65] Activation of MAPK pathways by TGF-β may also affect transcription responses through direct effects on Smad-interacting transcription factors allowing convergence of TGF-β–induced Smad and MAPK pathways. The dual ability of TGF-β to activate Smads and MAPK signaling has a potential role in TGF-β–induced epithelial-to-mesenchymal transdifferentiation, which depends in part on the ERK and/or p38 MAPK pathways.[16,66,67] Although this convergence often results in synergy, these pathways may also counteract each other. In this study, the relationship between the TGF-β–induced Smad and MAPK pathways was not established, and it needs further studies in the future.

Inhibition of TGF-β1–Induced MMP-9 by Doxycycline through Smad and MAPK Pathways

Doxycycline, a member of the tetracycline family, is well recognized for its therapeutic efficacy in treating ocular surface diseases, such as rosacea and sterile corneal ulceration.[19,20] Doxycycline has also been reported to inhibit the activity of MMPs, including MMP-9.[22,24,26] We have experienced clinical success in treating patients with rosacea-associated corneal epithelial erosions with doxycycline.[68] We also reported that doxycycline at a nontoxic dose, markedly decreases the production and activity of MMP-9 stimulated by IL-1β and TNF-α in cultured human corneal epithelial cells,[11,26] but the effects and mechanism of doxycycline on TGF-β–stimulated MMP-9 have not been not elucidated.

In this study, we provide evidence that doxycycline, at pharmacologically achievable nontoxic doses, concentration dependently inhibits MMP-9 protein production and mRNA expression stimulated by TGF-β1 at a concentration of 1 ng/mL, which is in the range of in vivo physiological and pathologic levels, in cultured corneal epithelial cells, as shown by zymography, activity assay, semiquantitative RT-PCR, and Northern hybridization (Fig. 1, 2). These results are supported by previous reports that doxycycline inhibits the activity of 92-kDa gelatinases in bone-metastasizing cells,[69] human skin keratinocytes,[22] and corneal epithelial cells.[11,26] We further demonstrated that doxycycline inhibits TGF-β1–induced activation of Smad2, JNK1/2, ERK1/2, and p38 MAPKs and that these inhibitory effects are similar or equal to those of SP600125, PD98059, or SB202190, the inhibitors of the JNK1/2, ERK1/2, and p38 MAPK pathways, respectively (Figs. 4–6). Therefore, doxycycline inhibits TGF-β1–induced MMP-9 production and activity, perhaps through the Smad and the three MAPK pathways.

In conclusion, TGF-β1 concentration dependently increases the expression, production, and activity of MMP-9 through activation of both Smad and MAPK signaling pathways in human corneal epithelial cells. Doxycycline dose dependently inhibits this TGF-β1–stimulated MMP-9 by blocking the activation of Smad, as well as the JNK, ERK, and p38 MAPK pathways. These findings may explain the reported efficacy of doxycycline in treating sterile corneal ulceration and other ocular surface diseases in which TGF-β1 may play a role in pathogenesis.

(Accepted for publication 3 August 1995)

SUMMARY

Minocycline has been shown to have an anti-inflammatory effect in patients with rheumatoid arthritis (RA). Since there is evidence that RA is a T cell-mediated disease, we investigated the effect of minocycline on human T cell clones derived from the synovium of an RA patient. The T cells, when activated via the T cell receptor (TCR)/CD3 complex, were suppressed functionally by minocycline, resulting in a dose-dependent inhibition of T cell proliferation and reduction in production of IL-2, interferon-gamma (IFN-γ) and tumour necrosis factor-alpha (TNF-α). Besides an inhibition of IL-2 production, minocycline exerted its effect on T cell proliferation by induction of a decreased IL-2 responsiveness. We showed that the chelating capacity of minocycline plays a crucial role in the inhibitory effect on T cell function, since the inhibitory effect on T cell proliferation could be annulled by addition of exogenous Ca^{2+}. However, minocycline did not markedly influence the typical TCR/CD3-induced intracellular Ca^{2+} mobilization. Taken together, the results clearly indicate that minocycline has immunomodulating effects on human T cells.

Keywords tetracyclines minocycline T cell function immunosuppression

INTRODUCTION

Tetracyclines are reported to have an ameliorative effect in arthritis in animals. Minocycline, a tetracycline derivative, decreased the incidence and severity in the collagen and adjuvant models of chronic arthritis in rats [1]. Additionally CMT, a chemically modified tetracycline without antibacterial activity, in combination with a non-steroidal anti-inflammatory drug, prevented bone loss in rats with adjuvant arthritis [2].

Rheumatoid arthritis (RA) is a chronic joint disease in man. In the pathogenesis of RA, T cells are held responsible for the initiation and perpetuation of ongoing synovial inflammation (for review, see [2]), which may lead to cartilage and joint destruction brought about by enzymes, especially matrix metalloproteinases.

Two open clinical studies have suggested a beneficial effect of minocycline in patients with RA [4,5]. In a double-blind placebo-controlled trial minocycline suppressed the laboratory parameters of disease activity, especially the acute-phase reactants, although the effects on clinical signs and symptoms were less pronounced [6].

Tetracyclines are predominantly known for their antimicrobial features. However, two other properties of minocycline should be considered to account for the observed phenomena in patients treated with minocycline: tetracyclines inhibit the activity of matrix metalloproteinases [7], and are immunomodulatory. In animals, tetracyclines have been shown to suppress the DTH, the rejection of transplants [8–11] and levels of serum immunoglobulin [9,12]. Furthermore, *in vitro* tetracyclines inhibited the proliferative response of human peripheral blood mononuclear cells (PBMC) to mitogens [13–16].

We studied the effect of minocycline on T cell activation, in particular in T cell clones derived from a patient with RA. In the present study, the T cells were activated by triggering the T cell receptor (TCR)/CD3 complex, which results in the generation of the second messengers inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). Subsequently, IP_3 induces a rapid rise of intracellular free calcium ($[Ca^{2+}]_i$), whereas DAG activates protein kinase C, which together lead to the synthesis of IL-2, an autocrine growth factor of T cell proliferation. The effect of minocycline on several aspects of T cell activation were studied in more detail.

MATERIALS AND METHODS

Reagents

Minocycline HCl, kindly provided by D. G. Lederle (Etten-Leur, The Netherlands), and doxycycline HCl, kindly provided by Pfizer (Capelle a/d IJssel, The Netherlands) were obtained in

Correspondence: C. L. Verweij PhD, Department of Rheumatology, University Hospital Leiden, Building 1, C4-R, PO Box 9600, 2300 RC Leiden, The Netherlands.

powder form. Minocycline HCl was dissolved in culture medium (Iscove's modified Dulbecco's medium (IMDM; GIBCO, Grand Island, NY) supplemented with antibiotics (penicillin 100 U/ml, streptomycin 100 μg/ml; Boehringer Mannheim, Mannheim, Germany), and fetal calf serum (FCS, 10%; GIBCO)) at a concentration of 100 μg/ml. Doxycycline HCl was dissolved in 0·02 N HCl at a concentration of 1 mg/ml and further diluted in culture medium. The antibiotic solutions were freshly prepared on the day of use and diluted to the appropriate concentrations. The concentrations used in the experiments ranged from 0·8 to 50 μg/ml. Anti-CD3 MoAbs (OKT3) were obtained from Cilag (Herenthals, Belgium). Recombinant (r) IL-2 was obtained from Cetus (Gouda, The Netherlands). Indo-1/AM was obtained from Molecular Probes (Junction City, OR).

Cell cultures

T cell clones (two $CD4^+$ (N16, N18) and one $CD8^+$ (N17)) were derived from the synovium of a patient with rheumatoid factor-positive classical RA. The cloning procedure has been described in detail [17]. In short, fragments of synovial tissue were placed in 24-well tissue culture plates (Costar 3524; Cambridge, MA) in culture medium and 5% v/v T cell growth factor (TCGF). After approximately 1 week, growing cells were separated from the tissue fragments and cloned by limiting dilution in a feeder cell mixture consisting of irradiated (30 Gy) allogeneic PBMC (10^6/ml), OKT3 ascites (10^{-5} dilution), and 5% v/v TCGF. Clones were expanded and restimulated every 7 days with a feeder cell mixture. In between the clones were maintained in culture in the presence of 5% v/v TCGF.

Proliferation experiments

Overnight 96-well tissue culture plates (Greiner, Alphen a/d Rijn, The Netherlands) were coated at room temperature with anti-CD3 MoAb (0·1 μg/ml; 0·1 ml/well) diluted in PBS. Before use the plates were washed three times with PBS. Cloned T cells were washed free of TCGF and plated at a concentration of 2×10^5 cells/well. The cells were incubated in the presence or absence of the drug for 48 h at 37°C, 5% CO_2. Twenty-four hours after initiation of the experiment, ^{3}H-thymidine (20 μCi/ml; 0·05 ml/well) was added. The cells were harvested with a Skatron AS semiautomatic cell harvester on filter paper discs. The rate of DNA synthesis was measured by liquid scintillation counting of the air-dried discs in a 1217 Rackbeta liquid scintillation counter. Experiments were performed in triplicate.

Cytokine production experiments

Washed cloned T cells (1×10^6 or 2×10^6 cells/well) were stimulated with plastic-immobilized anti-CD3 MoAb (0·1 μg/ml; 0·5 ml/well) in 24-well tissue culture plates with or without the drug for 24 h at 37°C, 5% CO_2. Cell-free culture supernatants were stored at −20°C.

Interferon-gamma assay

For the determination of interferon-gamma (IFN-γ) an ELISA [18] (kindly provided by Dr P. Van der Meide, Rijswijk, The Netherlands) was used. Briefly, microtitre plates were coated with anti-IFN-γ MoAb (MD2) for 3 h at 37°C. The test samples and rIFN-γ standards were incubated overnight at room temperature. The next day biotinylated anti-IFN-γ MoAb (MD1) was added, followed by the addition of streptavidin conjugated to horseradish peroxidase (HRP; Zymed, Sanbio, Uden, The Netherlands). For developing the assay, orthophenylenediamine (OPD; Sigma, St Louis, MO) in phosphate buffer pH 5·6, activated with H_2O_2, was used. The reaction was stopped with 10% H_2SO_4. All reagents and samples were diluted in PBS with 0·05% Tween (PBS–T) and 1% new born calf serum (NBCS) and between the incubation steps plates were washed three times with PBS–T. Optical densities (OD) were read in a Titertek Multiscan Plus at 492 nm. The sensitivity was 0·2 ng/ml.

Tumour necrosis factor-alpha assay

For the determination of tumour necrosis factor-alpha (TNF-α) an ELISA [19] (kindly provided by Dr W. Buurman, Maastricht, The Netherlands) was used. Briefly, immuno-Maxisorb plates were coated overnight at 4°C with 0·125 μg/well of the anti-human TNF-α MoAb 61E71 in PBS. Non-specific binding was prevented by incubation of the plates for 1 h at room temperature with bovine serum albumin (BSA; Organon Teknika, Oss, The Netherlands) 1% (w/v) in PBS. The test samples and rTNF-α standards were incubated for 2·5 h at room temperature. Subsequently, the plates were incubated with a rabbit polyclonal anti-human TNF-α immunoglobulin, followed by a peroxidase-conjugated goat anti-rabbit IgG. Next, the plates were washed three times with distilled water containing 0·1% Tween, and developed with ABTS activated with H_2O_2. The reaction was stopped with 2% oxalate acid. Reagents and samples were diluted in PBS–0·1% BSA (w/v). Finally, OD were read at 405 nm, using a Titertek Multiscan Plus. The sensitivity was 10 pg/ml.

IL-2 assay

IL-2 was determined by an ELISA (Boehringer Mannheim), according to the manufacturer's description. The sensitivity of the ELISA was 62·5 pg/ml.

Determination of IL-2 receptor

For determination of IL-2R (CD25) expression flow cytometric analysis was used. Per sample, 2×10^5 cells were incubated with anti-Tac MoAb (the hybridoma producing anti-Tac was obtained from the American Type Culture Collection (ATCC, Rockville, MD)) for at least 30 min on ice. After two washes with ice-cold PBS containing 1% (w/v) BSA, cells were incubated with FITC-conjugated goat anti-mouse IgG (Nordic Immunological Labs, Tilburg, The Netherlands) diluted 1:40 in PBS–1% BSA. Cells were washed twice and analysed on a FACStar (Becton Dickinson, Mountain View, CA). The experiment was performed in duplicate on two separate occasions.

Measurement of intracellular free calcium

$[Ca^{2+}]_i$ was measured as described before [20]. In short, prewarmed Jurkat cells (5 min at 37°C, 10×10^6/ml) were resuspended in HEPES medium (NaCl (133 mM), KCl (6 mM), $MgSO_4$ (1 mM), $CaCl_2$ (1 mM), potassium phosphate (1 mM), glucose (5·5 mM), HEPES (20 mM), and human albumin (0·5% w/v), pH 7·4) and loaded with 1 μM Indo-1/AM during 45 min at 37°C. Subsequently, the cells were washed, resuspended at 10×10^6 cells/ml in the HEPES medium and kept at room temperature. Fluorescence measurements were performed at

FOI 26-3132 - Document 5

37°C in stirred suspensions after dilution of the cells to 1×10^6/ml. Calibration of Indo-1 fluorescence as a function of $[Ca^{2+}]_i$ was determined as follows: to saturate all trapped Indo-1 with Ca^{2+}, 5 μM digitonin was added to the cell suspension. Subsequently, the Indo-1 signal was quenched by adding 0·5 mM Mn^{2+}. $[Ca^{2+}]_i$ was calculated as described [21], using 250 nM as the K_d for the Indo-1/Ca^{2+} complex.

Viability

Cell viability was determined by trypan blue exclusion and measurement of lactate dehydrogenase activity and the concentration of β_2-microglobulin in the supernatant. Lactate dehydrogenase activity was determined on a BM/Hitachi 747 (Boehringer Mannheim, Almere, The Netherlands) using an ultraviolet method according to the manufacturer's instructions. Levels of β_2-microglobulin were determined by IMx β_2-microglobulin assay (Abbott Labs, Santa Clara, CA), which is a microparticle enzyme immunoassay. The assay was performed according to the manufacturer's instructions. The sensitivity of the test is 5 $\mu g/l$.

Statistical analysis

The effect of the drug was expressed as percentage inhibition, which is defined as (1 − (effect in the presence of the drug/effect in the absence of the drug)) × 100%.

Non-parametric tests were used to determine statistically significant differences.

The correlation coefficient between the effects of the different doses of minocycline and doxycycline was estimated by means of the intraclass correlation coefficient. This was calculated using multivariate analysis of variance (MANOVA) with dose as a within-subjects factor.

RESULTS

Minocycline inhibits TCR/CD3-induced proliferation in $CD4^+$ and $CD8^+$ synovial T cell clones

In one $CD8^+$ (N17) and two $CD4^+$ (N16, N18) synovial T cell clones proliferation was induced with plastic-immobilized anti-CD3 MoAb in the presence or absence of minocycline. Minocycline inhibited the proliferation of each T cell clone in a dose-response manner (Fig. 1).

Cell viability, as measured with trypan blue staining, was >80% with all drug concentrations tested. Accordingly, no significant differences in lactate dehydrogenase release could be measured in the presence of minocycline at concentrations of 25 and 50 μg/ml. Moreover, the production of the constitutively expressed protein β_2-microglobulin was measured to investigate the viability of the cells. In unstimulated T cells (1×10^6 cells) the total β_2-microglobulin concentration was 85 ± 27 ng/ml (mean ± s.d.). A slight increase in β_2-microglobulin production to 111 ± 32 ng/ml was observed when T cells were stimulated via the TCR/CD3 complex for 24 h; in the presence of 25 μg/ml minocycline the production of β_2-microglobulin, being 94 ± 26 ng/ml, was always more than the amount of β_2-microglobulin produced by resting T cells.

Since minocycline affected all three clones to the same extent, we continued our experiments with one representative clone (N18).

Minocycline inhibits TCR/CD3-induced IL-2, IFN-γ and TNF-α production by a $CD4^+$ synovial T cell clone

Stimulation of the $CD4^+$ T cell clone N18 by anti-CD3 MoAb coated to tissue culture plates induced the production of IL-2, IFN-γ and TNF-α. Minocycline inhibited IL-2 production in a dose-dependent manner. Minocycline at a concentration of 25 μg/ml inhibited IL-2 production 26 ± 7·5% (mean ± s.e.m.) (Fig. 2). Minocycline also inhibited IFN-γ and TNF-α production in a dose-response manner. The maximal percentage inhibition was 23·9 ± 3·1% and 21·5 ± 5% for IFN-γ and TNF-α production, respectively, at a concentration of 25 μg/ml minocycline (Fig. 2).

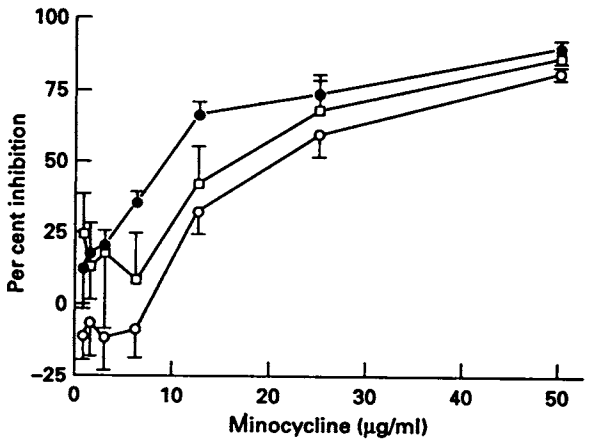

Fig. 1. The effect of minocycline on anti-CD3-induced proliferation of synovial T cell clones (○, N16; □, N17; ●, N18). The symbols reflect mean ± s.e.m. of at least three experiments. The results are presented as percentage inhibition of control in the absence of minocycline. The control ranged from 12 351 to 45 729, from 17 132 to 72 985, and from 10 118 to 64 794 ct/min for N16, N17 and N18, respectively.

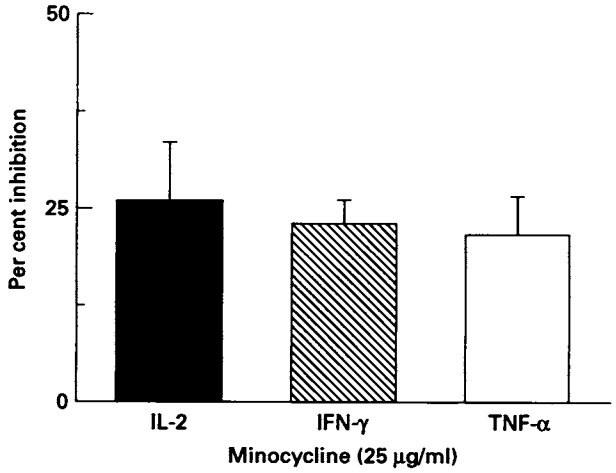

Fig. 2. The effect of minocycline on anti-CD3-induced IFN-γ and tumour necrosis factor-alpha (TNF-α) production by cloned T cells (N18). Shown are mean ± s.e.m. of three, five and six experiments for IL-2, IFN-γ and TNF-α, respectively, in the presence of 25 μg/ml minocycline. The results are described as percentage inhibition of induced production in the absence of minocycline. The production of the individual cytokines ranged from 625 to 7820 pg/ml for IL-2, from 92 to 1197 ng/ml IFN-γ, and from 7 to 40 ng/ml for TNF-α.

FOI 26-3132 - Document 5

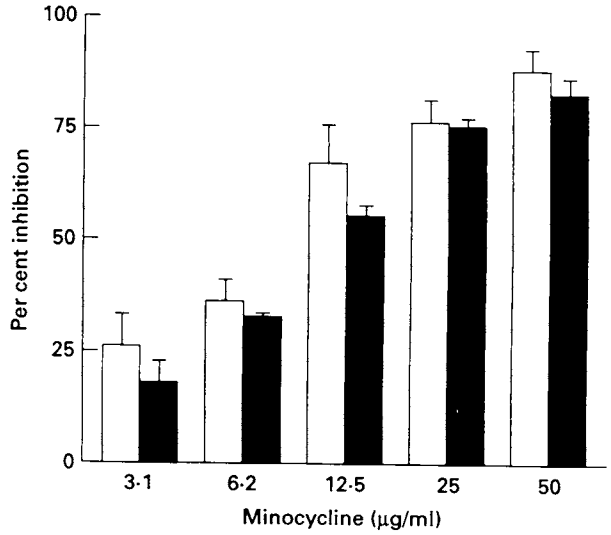

Fig. 3. Inhibition of anti-CD3-induced proliferation in cloned T cells (N18) by minocycline could not be restored by the addition of exogenous recombinant (r)IL-2. Shown are mean ± s.e.m. of three experiments. The results are described as percentage inhibition of control. The control ranged from 10 903 to 68 458 and from 16 158 to 56 641 ct min for 0 and 10 U ml IL-2, respectively. □ and ■ represent, respectively, addition of 0 and 10 U ml rIL 2.

Minocycline inhibits IL-2 responsiveness in synovial T cell clones

Next, we determined whether the inhibitory effect of minocycline on T cell proliferation could be bypassed by the addition of IL-2. The $CD4^+$ T cell clone is known to express IL-2R and to respond to IL-2 addition by proliferation. However, the addition of rIL-2 (0·1, 1 or 10 U/ml) did not bypass the inhibitory effect of minocycline on TCR CD3-induced proliferation in cloned T cells (Fig. 3). In proliferation experiments in which cloned T cells were stimulated with rIL-2 (20 U ml) in the absence or presence of minocycline, an inhibition of T cell proliferation by minocycline in a dose-dependent manner was seen (Fig. 4).

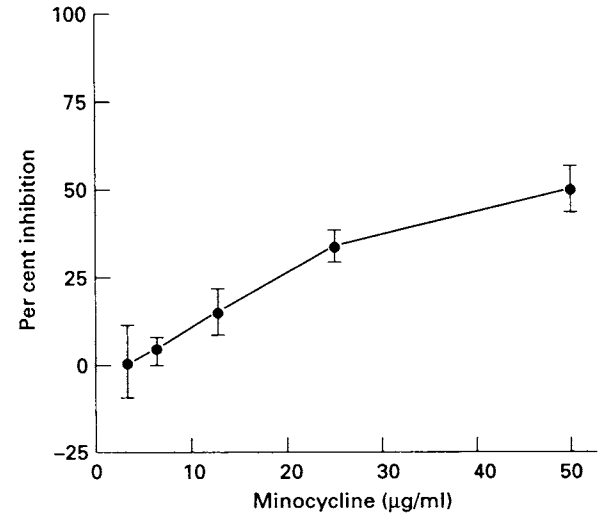

Fig. 4. The effect of minocycline on IL-2-induced proliferation in cloned T cells (N18). The symbols represent mean ± s.e.m. of three experiments. The results are described as percentage inhibition of control. The control ranged from 44 385 to 75 895 ct min.

To investigate whether inhibition of IL-2 responsiveness was caused by down-regulation of the expression of the IL-2R α chain (CD25) by minocycline, cloned synovial T cells were stimulated with anti-CD3 MoAb in the presence or absence of minocycline for 24 h and subsequently analysed for IL-2R expression using anti-Tac MoAb. In the absence of minocycline 86–92% of T cells were positive for IL-2R (mean fluorescence intensity ranging from 518 to 544) against 86–96% in the presence of 50 μg/ml minocycline (mean fluorescence intensity ranging from 437 to 542).

Doxycycline, like minocycline, inhibits TCR/CD3-induced T cell proliferation and IFN-γ production

To study whether the effect on T cell activation was a more general property of tetracyclines, another tetracycline derivative, i.e. doxycycline, was studied also. Doxycycline and minocycline have corresponding biochemical characteristics with regard to lipid solubility and chelating capacity.

Both drugs inhibited anti-CD3-induced proliferation in a concentration-dependent way and to the same extent (MANOVA, $r = 0{\cdot}65$; $P = 0{\cdot}064$) (Fig. 5a). The inhibitory capacity of doxycycline and minocycline towards TCR/CD3-induced IFN-γ production was similar (MANOVA, $r = 0{\cdot}71$; $P = 0{\cdot}001$) (Fig. 5b). Similar to minocyclin we observed no toxic effects of doxycycline on T cell functioning in the presence of the concentrations tested.

The inhibitory effect of minocycline on proliferation is partially reversible

When cloned synovial T cells were preincubated with minocycline at a concentration of 50 or 12·5 μg/ml for 24 h at 37 C, 5% CO_2, subsequently harvested, washed, counted, adjusted to cell number and finally incubated on plates coated with anti-CD3 MoAb, we also observed inhibition of T cell proliferation. However, the inhibitory effect of preincubation with 50 or 12·5 μg ml minocycline was less, namely 30% and 19%, than the inhibitory effect of direct incubation with minocycline, being 76% and 35% (Fig. 6).

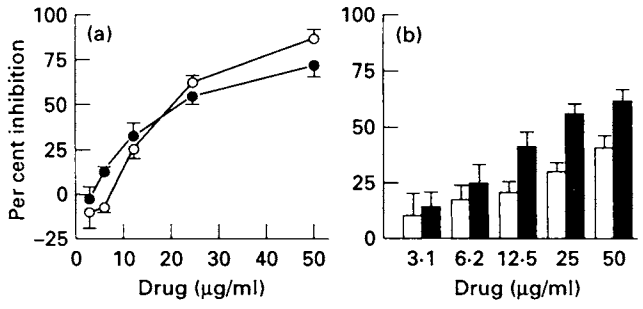

Fig. 5. The effect of doxycycline and minocycline on anti-CD3-induced proliferation (a) and IFN-γ production (b) by cloned T cells (N18). The symbols reflect the mean ± s.e.m. values of three and five separate experiments for proliferation and IFN-γ production, respectively. The results are described as percentage inhibition of control. The control values for the proliferation ranged from 17 122 to 44 431 ct min and for IFN-γ production from 220 to 1560 ng ml. ○, □, Minocycline; ●, ■, doxycycline.

FOI 26-3132 - Document 5

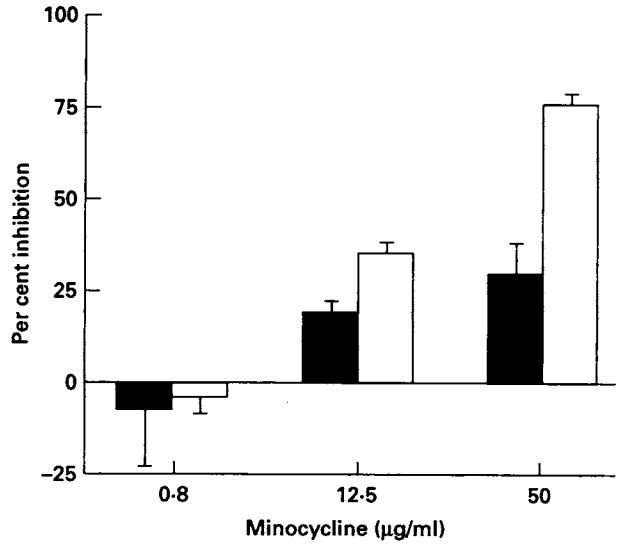

Fig. 6. The inhibitory effect of minocycline on T cell proliferation was partially reversible. Cloned T cells (N18) were preincubated with or without minocycline for 24 h at 37°C, 5% CO_2. Afterwards the cells were harvested, washed, counted, adjusted to cell number, and proliferation was induced with anti-CD3 MoAb (0·1 μg/ml). As controls, cells which had been preincubated without minocycline were incubated with minocycline. Symbols represent mean ± s.e.m. of four separate experiments. Results are described as percentage inhibition relative to proliferation in the absence of minocycline, which ranged from 12 976 to 40 040 ct/min. □, Proliferation experiments in the presence of minocycline; ■, proliferation experiments after preincubation with minocycline.

Addition of Ca^{2+} restores the inhibition of TCR/CD3-induced proliferation by minocycline

Since minocycline is a compound with chelating capacity [22], we studied whether Ca^{2+} plays a role in the inhibition of TCR/CD3-induced proliferation by minocycline.

Therefore, exogenous Ca^{2+}, ranging from 1·6 to 9·6 mM, was added to cloned synovial T cells, stimulated with plastic-immobilized anti-CD3 MoAb in the absence or presence of minocycline. The inhibitory effect of minocycline was partially abolished at low concentrations of Ca^{2+} in the culture medium and totally abolished at high concentrations of Ca^{2+} in the culture medium (Fig. 7a,b).

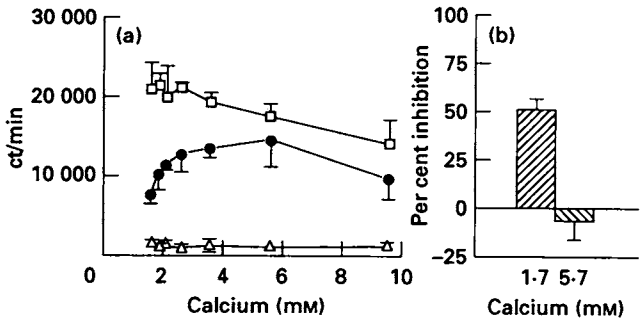

Fig. 7. Addition of Ca^{2+} restored the inhibition of anti-CD3-induced proliferation by minocycline. (a) Ca^{2+} was added in proliferation experiments of cloned T cells (N18). (Δ, Proliferation in medium without anti-CD3 stimulus; □, proliferation induced with plastic-immobilized anti-CD3 (0·1 μg/ml); ●, anti-CD3-induced proliferation in the presence of 25 μg/ml minocycline.) (b) Percentage inhibition by 25 μg/ml minocycline compared with control in the presence of a low and high concentration of Ca^{2+} in the culture medium. The results (mean ± s.e.m.) of four independent proliferation experiments are demonstrated.

Minocycline does not affect TCR/CD3-induced rises in $[Ca^{2+}]_i$ in Jurkat cells

To study whether minocycline affected $[Ca^{2+}]_i$ mobilization upon TCR/CD3 triggering, we studied Jurkat T cells, which are generally used as a model for resting T cells and particularly for studying $[Ca^{2+}]_i$ mobilization [23]. In a series of experiments (n = 10) on three separate occasions the basal $[Ca^{2+}]_i$ of 58 ± 24 nM increased after anti-CD3 stimulation to 222 ± 186 nM, followed by a plateau of 93 ± 26 nM. When minocycline (25 μg/ml) was present in the experiments (n = 9) the basal $[Ca^{2+}]_i$ was 115 ± 31 nM, increased to 222 ± 136 nM, and was followed by a plateau of 168 ± 75 nM. Minocycline did not influence the typical $[Ca^{2+}]_i$ response, but increased the basal and plateau levels of $[Ca^{2+}]_i$ ($P < 0·05$).

DISCUSSION

The present study shows that minocycline exerts immunomodulatory effects on human T cells.

Tetracyclines have apart from their immunomodulatory features, other properties that validate their usage as a treatment modality in RA. For instance, tetracyclines inhibit the enzyme activity of metalloproteinases [7], including synovial collagenases [24]. Therefore, cartilage and bone breakdown may be decreased as a result of treatment with tetracyclines. Concordantly, prophylactic treatment with oral doxycycline reduced the severity of canine osteoarthritis [25]. In addition, tetracyclines inhibit the activity of phospholipase A_2 [26], suppress the function of neutrophils [27,28] and scavenge oxygen radicals [29], which may result in an anti-inflammatory effect. Diminishing of joint destruction and inflammation may have a beneficial effect in RA.

In the literature, tetracyclines have been shown to inhibit the proliferative response of human T cells in monocyte-dependent, mitogen-stimulated assay systems [13–16]. Whether or not minocycline directly affects T cell proliferation *per se* is difficult to conclude on the basis of these studies in complex cell systems, especially since tetracyclines have been reported to influence monocyte functioning [30]. The present study investigated the effect of minocycline on T cells selectively and showed that minocycline affected both TCR/CD3 as well as IL-2-induced proliferation, which was due to a negative effect on IL-2 production and on IL-2 responsiveness. Besides an inhibitory effect on IL-2 production, minocycline also negatively influenced the production of the other early induced cytokine gene products IFN-γ and TNF-α [31]. Similar results were obtained with peripheral blood T cells, whereas minocycline exerted stimulatory effects on cytokine production by monocytes (Kloppenburg and Verweij, unpublised observations). These findings indicate that minocycline affects cell function in a cell-specific manner.

Since T cell-targeted therapy, including thoracic duct drainage, total lymph node irradiation, lymphocytapheresis and cyclosporin A, exerts beneficial effects in RA, compounds with immunosuppressive properties are generally considered to

FOI 26-3132 - Document 5

be interesting candidates for treatment in RA. However, despite the effect of minocycline on T cell function *in vitro*, the effect of minocycline treatment in patients with RA was not very strong [5]. That not all T cell-targeted therapies lead to a beneficial effect in RA has also been observed in recent work of our group on the treatment of early RA with CD4 MoAbs in a placebo-controlled trial [32,33]. Despite a decline in the number of circulating $CD4^+$ cells and in histological scores for CD3, CD4, CD45RO, CD45RA, and CD38, no clinical improvement has been seen.

Tetracyclines are chelators of divalent cations [23], which may account for several features of tetracyclines. Addition of divalent cations (Ca^{2+}) *in vitro* overcomes the inhibition of metalloproteinase activity [7] and the suppression of neutrophil functions [29,34] by tetracyclines. In the present study we show that the inhibitory effect of minocycline on T cell proliferation could be overcome by addition of Ca^{2+}. The inhibitory effect was found to be higher in the continued presence of minocycline than after preincubation with the drug. Together, these findings suggest that the chelating activity of minocycline is important for the inhibition of T cell proliferation. The chelating effect of tetracyclines may possibly interfere with T cell proliferation in two ways. First, tetracylines have been shown to bind to DNA by calcium bridges [35], which may account for the inhibition of T cell proliferation. Moreover, in the association curve of DNA and tetracyclines an optimum is observed for the amount of calcium that binds to DNA [35]. Possibly, the addition of extra calcium changed the composition of the calcium–tetracycline complexes in such a way that these complexes bound less efficiently to DNA and therefore did not induce inhibition of T cell proliferation. Second, minocycline may interfere with early signal transduction, since minocycline has been shown to negatively influence the early activated genes upon TCR/CD3 stimulation (Fig. 2). Triggering of the TCR/CD3 complex results in an increased $[Ca^{2+}]_i$ which is obligatory for T cell proliferation [23,36]. The chelating capacity of minocycline may prevent the increase in $[Ca^{2+}]_i$. However, our results have demonstrated no inhibitory effect of minocycline on $[Ca^{2+}]_i$ mobilization following anti-CD3-induced T cell activation, but in contrast have shown an increase in the value of basal $[Ca^{2+}]_i$. On the other hand, these results agree with an *in vitro* study in osteoclasts showing a transient elevation of $[Ca^{2+}]_i$ after application of minocycline [37]. Accordingly, T cells from rats, treated orally with minocycline, have shown an increase in $[Ca^{2+}]_i$ upon concanavalin A stimulation *in vitro* compared with T cells from untreated rats [38].

In the present study minocycline has been shown to affect the IL-2 responsiveness of T cell clones. In the literature minocycline has been reported to inhibit the mitogen-induced up-regulation of IL-2R in peripheral T cells [16]. Synovial T cell clones, used in the present study, express IL-2R constitutively, and minocycline did not down-regulate the expression of these receptors. Thus, a diminished IL-2R expression can not explain the observed inhibition of proliferation.

In general, prediction of *in vivo* potency of drugs on the basis of *in vitro* results is limited. Serum concentrations of minocycline after a normal oral dose regimen (initial oral dose of 200 mg followed by 100 mg every 12 h thereafter) ranged from 2·3 to 3·5 μg/ml [39]. T cell function *in vitro* was found to be inhibited at a concentration of 12·5 μg/ml minocycline or higher. Since minocycline has a high degree of lipid solubility, this compound is widely distributed in the body. This results in tissue concentrations that exceed serum concentrations [40]. Moreover, lipid-soluble tetracyclines have been reported to accumulate in leucocytes [9,41,42]. In agreement with the latter are the *in vitro* studies that demonstrated that lipid-soluble tetracyclines are more potent inhibitors of mitogen-induced proliferation than non-lipid-soluble ones [13–16].

The coronavirus disease-19 (COVID-19) is caused due to the infection by a unique single stranded enveloped RNA virus, severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2). The COVID-19 has claimed many lives around the globe, and a promising solution to end this pandemic is still awaited. Till date neither an exact antiviral drug nor a vaccine is available in the market for public use to cure or control this pandemic. Repurposed drugs and supportive measures are the only available treatment options. This systematic review focuses on different treatment strategies based on various clinical studies. The review discusses all the current treatment plans and probable future strategies obtained as a result of a systematic search in PubMed and Science Direct database. All the possible options for the treatment as well as prophylaxis of COVID-19 are discussed. Apart from this, the article provides details on the clinical trials related to COVID-19, which are registered under ClinicalTrials.gov. Potential of drugs based on the previous researches on SARS-CoV, MERS-CoV, Ebola, influenza, etc. which fall under the same category of coronavirus are also emphasized. Information on cell-based and immunology-based approaches is also provided. In addition, miscellaneous therapeutic approaches and adjunctive therapies are discussed. The drug repurposing options, as evidenced from various *in vitro* and *in silico* models, are also covered including the possible future solutions to this pandemic.

Keywords: COVID-19, SARS-CoV-2, vaccine, convalescent plasma therapy, drug repurposing

INTRODUCTION

Coronavirus disease-19 (COVID-19) is a rapidly transmitted respiratory disease that has recently attracted the worldwide public health attention since its declaration as a pandemic by the World Health Organization (WHO) on March 11, 2020 (WHO, 2020). Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), the novel coronavirus responsible for COVID-19, primarily attacks the human respiratory system. Several upsurges of coronaviruses have previously occurred, like the severe acute respiratory syndrome (SARS) and the Middle East respiratory syndrome (MERS); both syndromes were considered as significant public health warnings (De Wit et al., 2016). In December 2019, some patients in China were diagnosed with pneumonia of an undetermined underlying cause (Bogoch et al., 2020; Lu H. et al., 2020). Early reports anticipated the start of a new coronavirus

upsurge that was named by the WHO as COVID-19, on February 11, 2020. The high rate of human-to-human transmission of COVID-19 infection resulted in the necessity of patients' isolation and a great urge for social distancing (Rothan and Byrareddy, 2020; Zhao et al., 2020).

Severe acute respiratory syndrome coronavirus-2 is the most recently discovered species of the coronaviruses (CoV) that infects humans, and it is categorized as a new strain of beta CoV. The genetics of the virus revealed above 80% similarity to SARS-CoV and above 50% to the MERS-CoV that originated in bats (Lu R. et al., 2020; Nadeem et al., 2020). Studies have been conducted to find a reservoir host or intermediate transmitter of the newly emerging virus. Early reports assume that two snake species as major reservoir of COVID-19. But, no evidences have been confirmed for animals other than bats and mammals as coronavirus reservoirs (Bassetti et al., 2020; Ji et al., 2020). Human-to-human transmission has been regarded as a likely mode of COVID-19 infection based on disease spreading within families and among people who were not exposed to animals (Graham Carlos et al., 2020; Helmy et al., 2020). Human-to-human transmission has been suggested to happen by unmediated contact or via droplets that outspread by coughing or sneezing from a person infected with the virus. Accordingly, the WHO has advised for keeping a distance of 1.5–2 m between people to reduce the likelihood of infection by nose or mouth droplets. However, the possibility of virus conveyance by airborne droplets over a distance of 2 m has been suggested by recent studies (Setti et al., 2020; van Doremalen et al., 2020).

The commonly identified clinical symptoms of COVID-19 disease are fever, dry cough, shortness of breath and excessive tiredness. Minor signs comprise of headache, sputum production, diarrhea, and lymphopenia (Borah et al., 2020; Ren et al., 2020). The symptoms, as mentioned earlier, are mostly revealed after an incubation period of about five days (Li Q. et al., 2020). A chest computed tomography (CT) scan in people with COVID-19 presents the clinical features of pneumonia (Huang et al., 2020). However, there are additional abnormal manifestations, including acute respiratory distress, severe cardiac side effects, and the presence of ground glass like opacities were found in sub-pleural areas of lungs in many cases. These opacities are likely to cause systemic and localized immune reactions that result in an elevated inflammatory response. Sorrowfully, the treatment of some cases with interferon did not exhibit promising clinical effects. Instead, the pulmonary opacities showed progression with consequent worsening of the condition (Dong D. et al., 2020; Lei et al., 2020). Recently it was found that the disease exhibits a broad spectrum of clinical signs and symptoms. Various case studies reported the involvement of all the vital organs of the body including heart, lungs, GIT, liver, kidneys, and central nervous system (CNS). In severe cases multisystem involvement can be seen and might lead to worse clinical outcomes as well as increased mortality (Gavriatopoulou et al., 2020).

No exact antiviral drug or vaccine against COVID-19 has been discovered yet. The only available option, other than using symptom alleviating agents, is utilizing broad-spectrum antiviral drugs comprising protease inhibitors and nucleoside analogs in an attempt to attenuate the viral infection (Lu, 2020). Amongst the antivirals that are recently recorded as having some effects against COVID-19 are oseltamivir (anti-flu drug), lopinavir/ritonavir (anti-human immunodeficiency virus; anti-HIV), and ganciclovir (Costanzo et al., 2020). High efficacy of the broad-spectrum antiviral remdesivir, which has been utilized for controlling the Ebola virus and the antimalarial agents like chloroquine and hydroxychloroquine, are also reported for controlling COVID-19 infection (Kumar et al., 2020; Ledford, 2020). Moreover, there are so many other molecules that are under development and testing. This article aims at reviewing the present and possible therapeutic options for the management of this emerging and widely spreading pandemic.

METHOD

We systematically searched the researches, reviews, and case reports in PubMed and Science Direct database, using the keywords COVID-19 and treatment, and selected the relevant articles. Some of the cross-references were also accessed. After selecting the potential agents for the COVID-19 treatment, again a search was conducted using the drug name AND COVID. The search is refined by the term "2020." The paper includes all the possible treatment strategies as well as all clinical trials for treatment or prevention of COVID-19 which are registered in NIH ClinicalTrials.gov.

MECHANISM OF COVID-19 INFECTION AND POSSIBLE DRUG TARGETS

The spike glycoprotein on the viral envelope is a major determinant of entry of virus to host cells by binding with its cellular receptor, angiotensin converting enzyme 2 (ACE-2). The viral infectivity and fusion are due to a significant proteolytic cleavage episode, and through clathrin-dependent as well as independent endocytosis. Once entered into the cells, the viruses release RNA which will synthesize two polyproteins and structural proteins, and starts replication. Then, the formation of nucleocapsid takes place by the combination of genomic RNA and nucleocapsid protein. Finally, the vesicles with viral particles combine with plasma membrane and discharge the viruses (Li X. et al., 2020). Different therapeutic agents against COVID-19 target at one or more different stages of the replication cycle. The mechanism of replication COVID-19 inside host cell and possible drug targets are shown in **Figure 1**.

Various studies reported moderate to severe "cytokine storms" in severe patients. The "cytokine storm" which in turn leads to acute respiratory distress syndrome (ARDS), occurs due to the effects of combined action of several immunoactive molecules (Coperchini et al., 2020). This seems to be one of the most hazardous and life-threatening episodes in COVID-19. After binding to alveolar epithelial cells, the virus activates innate as well as the adaptive immune system. Following the SARS-CoV-2 infection macrophages are released as a response to inflammatory signals by type 2 cells. Cytokines are released by macrophages that in turn results in the release of more immune cells to the injury

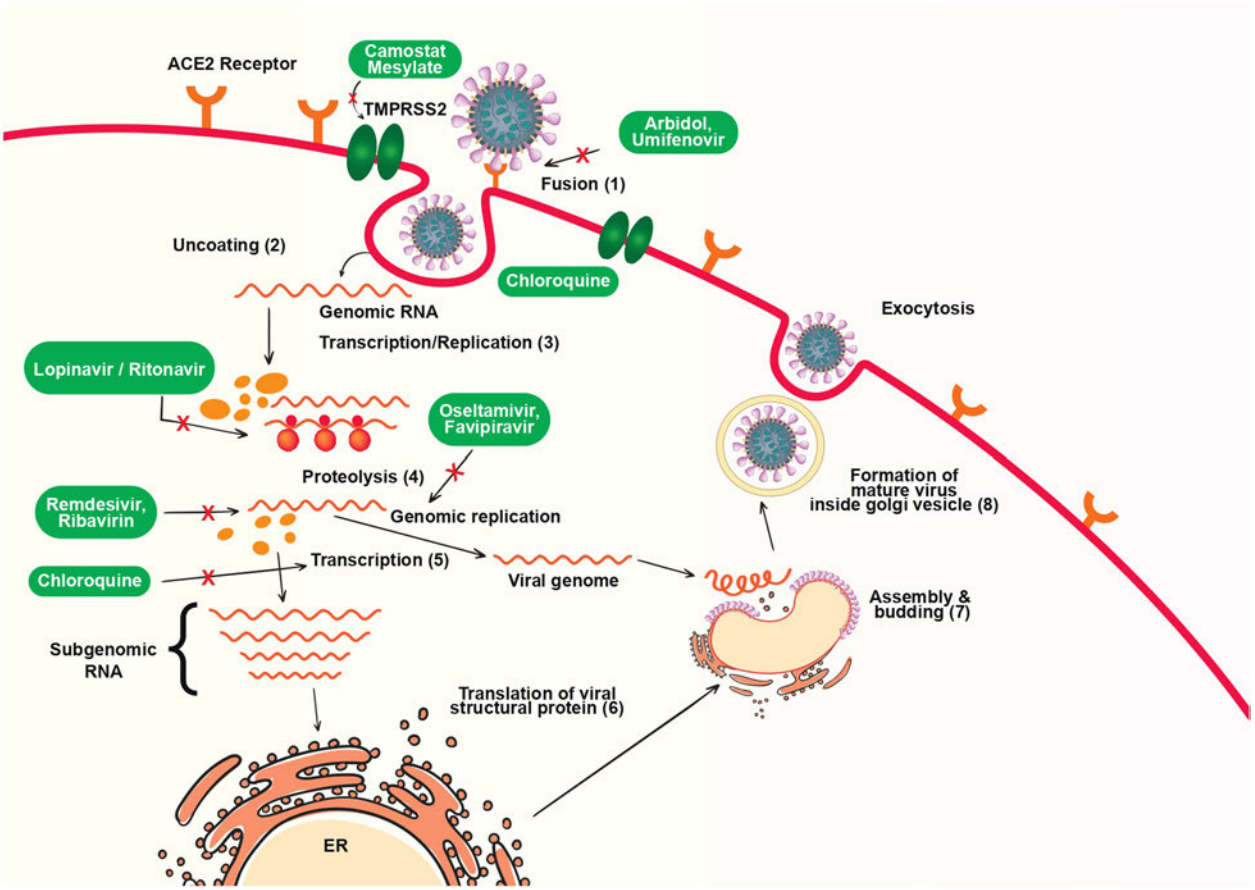

FIGURE 1 | Replication of SARS-CoV-2 and possible drug targets.

site. Cytokines cause vasodilatation also. Fluid accumulation in alveoli causes the damage of surfactant, and thus alveolar collapse which in turn affects the gas exchange. Further recruitment of neutrophils results in the release of reactive oxygen species (ROS) for destroying the infected cells. Also, the extensive release of cytokines occurs including interleukin-6 (IL-6), resulting in subsequent increase in the vascular permeability. This further leads to the entry of a large number of blood cells and fluid into the lungs, and causes dyspnea and respiratory failure (Zhang C. et al., 2020). The hyper-inflammation and cytokine storm syndrome is responsible ARDS and multi-organ failure. An illustration showing the effect of COVID-19 infection on the lungs is shown in **Figure 2**.

CURRENT TREATMENT STRATEGIES

Identifying effective therapeutic agents to fight this pandemic is urgently needed in this scenario (Li H. et al., 2020). A simplified classification of therapeutic options against COVID-19 is presented in **Figure 3**.

Drug repurposing is the only fastest approach to find potential candidates as a preventive or therapeutic measure for this new deadly pandemic (Ekins et al., 2020). Trials with ivermectin and hydroxychloroquine are examples of such an approach. At the same time, a large number of current researches are based on the testing of proven antiviral agents for related infections caused by SARS-CoV as well as MERS-CoV. The latter approach of the use of existing antiviral agents with proven efficiency against coronaviruses seems to be more promising. This argument could be justified by the fact that SARS-CoV-2 also belong to the same class of beta coronaviruses like SARS-CoV and MERS-CoV. Details of clinical trials on drug candidates against COVID-19 are presented in **Table 1**.

Antiviral Agents

Remdesivir

Remdesivir is an investigational antiviral agent and also the first drug under clinical trial in the United States as an experimental cure for COVID-19 (Holshue et al., 2020). It possesses broad spectrum of action against different RNA viruses, such as MERS-CoV. Remdesivir and chloroquine are shown to be very efficient in the control of novel coronavirus infection *in vitro* (Li Q. et al., 2020). To understand the mechanism of inhibition, in a recent study, the MERS-CoV non-structural proteins were co-expressed in insect cells as a part of the polyprotein. The research demonstrated that remdesivir acts by inhibiting the

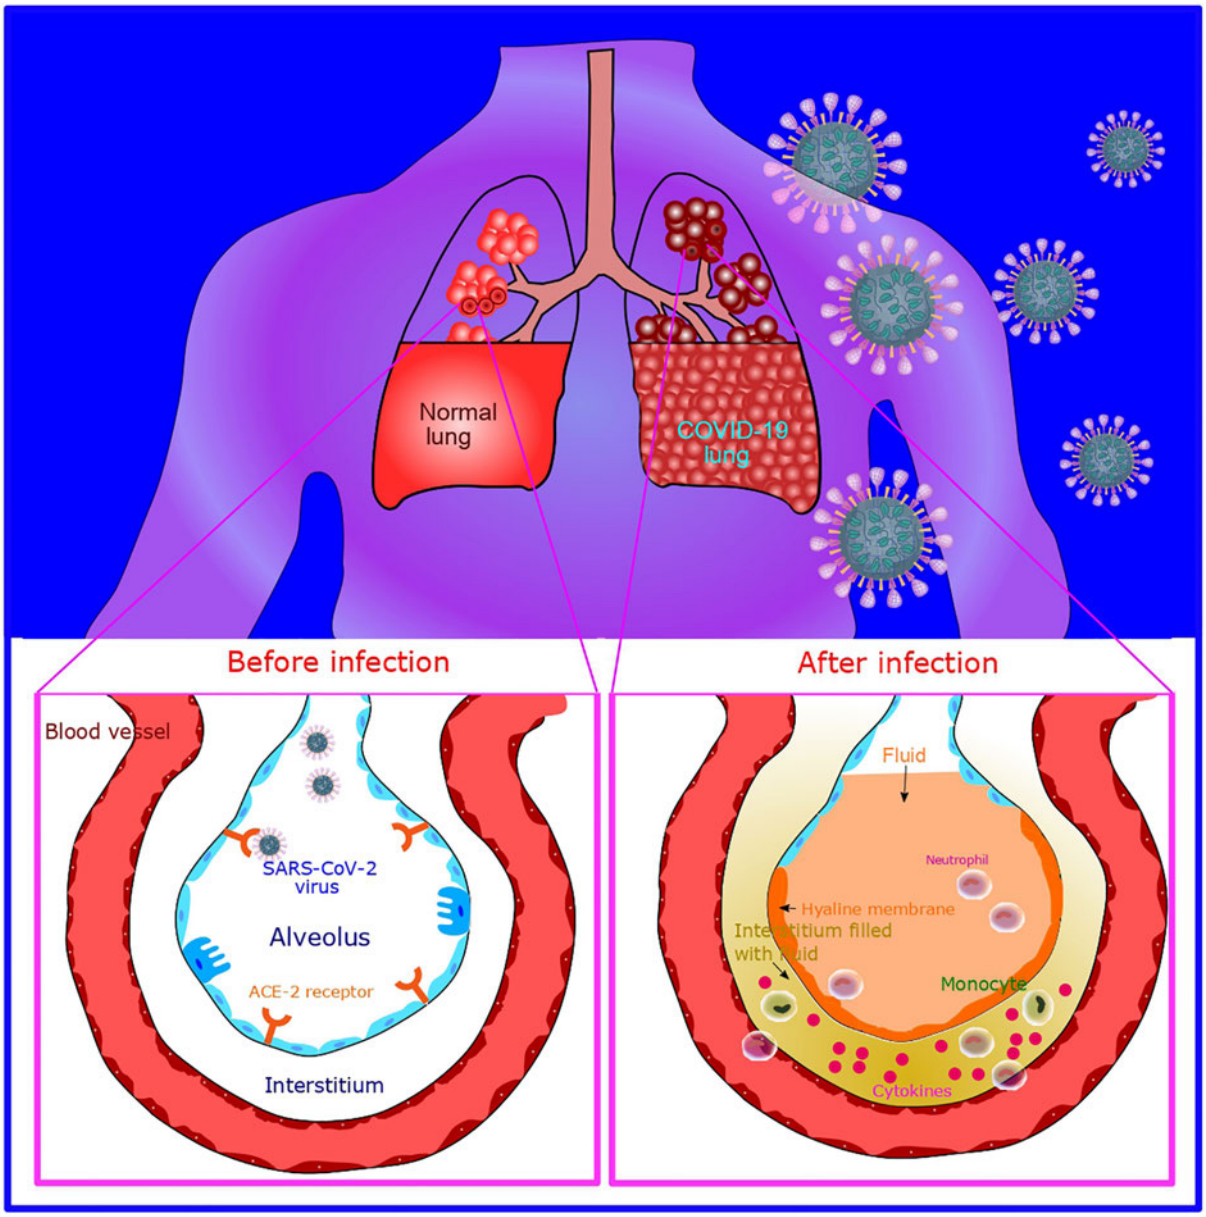

FIGURE 2 | Illustration of COVID-19 infection and its effect on the lungs. After SARS-CoV-2 infection, macrophages are released which subsequently causes cytokine release (cytokine storm). Further recruitment of neutrophills results in the release of reactive oxygen species (ROS) for destroying the infected cells. Further, fluid filling into the interstitial space and alveoli occurs.

nucleotide analog of RNA-dependent RNA polymerase (Gordon et al., 2020). An investigation in rhesus macaque model infection of MERS-CoV on preventive as well as the therapeutic potential of remdesivir revealed that the drug could reduce damage to the lungs and inhibit virus replication when administered either previous to or following infection (De Wit et al., 2020). The active metabolite of remdesivir can interact with both the active sites of enzyme and can produce delayed chain termination as well as distorted excision due to the ribose 1'-CN group, which is responsible for the enhanced antiviral action than other existing analogs (Shannon et al., 2020). Nine out of the ten ongoing clinical trials aim to evaluate the antiviral activity of remdesivir in SARS-Cov-2 infection. One of the studies is purely for the assessment of the adverse effects of the drug.

Umifenovir (Arbidol®)

Umifenovir is an antiviral agent that acts through multiple pathways and is effective against a variety of enveloped as well as non-enveloped DNA and RNA viruses. It is used for prophylaxis as well as treatment of influenza. It has been in use for more than 25 years in Russia and 14 years in China (Blaising et al., 2014). Since *in vitro* studies proved the efficacy

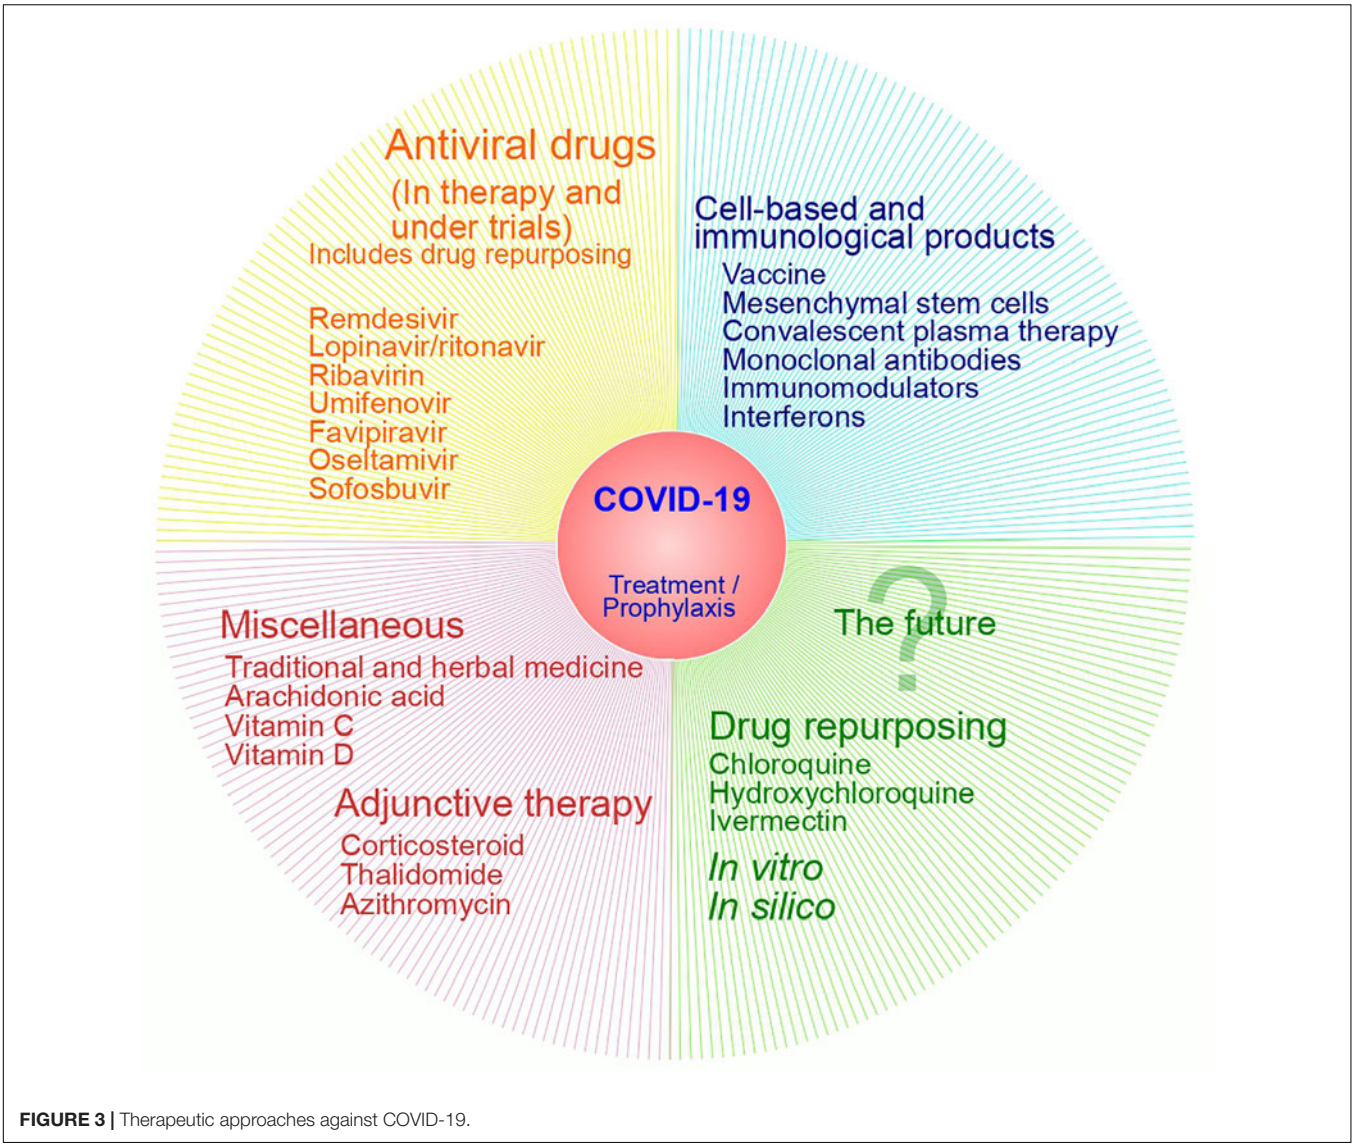

FIGURE 3 | Therapeutic approaches against COVID-19.

of this agent in SARS, it is being now used in the empirical therapy of COVID-19 in China (Song et al., 2020; Zhang J. et al., 2020). This drug is given orally for a maximum of 10 days at a dose of 200 mg, three times per day (Dong L. et al., 2020). In a study conducted in China, four patients administered with lopinavir/ritonavir, umifenovir, and one with traditional Chinese medicine along with essential support care. Three of them gained considerable relief from pneumonia, and two showed a negative viral test after the treatment period. The last patient with severe respiratory problems also showed significant improvement with this treatment procedure (Wang et al., 2020a). In a retrospective cohort study, 75% of the patients who took a combination of oral umifenovir and lopinavir/ritonavir recovered in 7 days as compared to 35% of patients who received lopinavir/ritonavir alone. And after 14 days, the viral clearance was achieved in 94% of the patients who received the drug combination, but it was only 69% in the other group (Deng et al., 2020). Also, umifenovir treatment could increase the discharging rate as well as a decline in the mortality rate(Wang et al., 2020b). Four trials are registered in ClinicalTrials.gov on umifenovir for COVID-19.

Lopinavir and Ritonavir

Both of these drugs are antiretroviral protease inhibitors and co-administration of these drugs improves the pharmacokinetics of both. Ritonavir is a potent inhibitor of microsomal enzyme cytochrome P-450 3A4, so co-administration of ritonavir leads to the increased bioavailability and half-life of the co-administered lopinavir (Cooper et al., 2003). Lopinavir/ritonavir is given two times per day in a dose of 400 mg/100 mg (Dong L. et al., 2020). After the lopinavir/ritonavir administration, coronavirus titers were null in a 54 years old male patient in Korea (Lim et al., 2020). In India, the Central Drugs Standard Control Organization agreed to use lopinavir/ritonavir therapy for 14 days with informed consent in high-risk categories who are symptomatic COVID-19 patients (Bhatnagar et al., 2020). Nevertheless, no benefit was observed in adult patients admitted

in the hospital due to severe COVID-19 with lopinavir/ritonavir therapy beyond standard care (Cao et al., 2020). More similar remarks were noticed and accordingly, the benefits of this combination are still doubtful (Kupferschmidt and Cohen, 2020). As a result, experts opined that the effectiveness of remdesivir and lopinavir/ritonavir should be confirmed by a randomized controlled trial. A retrospective data of pediatric patients with confirmed COVID-19 shows that all 36 children received interferon-alfa (INFα), 14 received lopinavir/ritonavir, and 6 needed oxygen inhalation resulted in full recovery irrespective of the drug within 14 ± 3 days. Treatment with INFα along with lopinavir/ritonavir plus ribavirin showed a beneficial action in COVID-19 therapy (Yuan et al., 2020). At the same time, some reports expressed that the use of lopinavir/ritonavir along with adjuvant drugs should be encouraged for the treatment of patients with COVID-19 (Ye et al., 2020). More than 20 clinical trials are registered for the evaluation of this combination in COVID-19.

Favipiravir

Favipiravir, a derivative of pyrazine carboxamide, is a purine nucleic acid analog that interferes with the replication of the virus and inhibits RNA dependent RNA polymerase of RNA viruses. It possesses broad-spectrum antiviral activity and is effective against the influenza virus, bunyavirus, arenavirus, and filovirus (Du and Chen, 2020; Singh et al., 2020). An early result of a clinical trial reveals that favipiravir has more strong anti-viral activity than lopinavir/ritonavir with significantly less adverse effects (Chavez et al., in press; Zhai et al., 2020). Due to its efficacy on virus clearance, the Turkish ministry of health approved favipiravir for treating critical patients with Covid-19 pneumonia (Kodaz, 2020). Eleven clinical trials are registered for this drug in COVID-19.

Oseltamivir

It is a neuraminidase inhibitor that hinders the neuraminidase enzyme expressed on the surface of the virus. This enzyme is needed for the release of the virus from the cells. It is approved for the prophylaxis as well as for the treatment of influenza (Li et al., 2012). Five trials are registered for this drug in COVID-19 treatment and details are given in **Table 1**.

In the study by Ding et al. about the clinical characteristics of COVID-19 patients, all the 115 subjects received oseltamivir along with antibiotics and oxygen inhalation and all recovered without the need for intensive care unit (ICU; Ding et al., 2020). A 71-year-old woman tested positive for COVID-19 with a childhood history of psoriasis pointed out exacerbation of psoriasis after oseltamivir and hydroxychloroquine treatment. Hydroxychloroquine inhibits epidermal transglutaminase, which leads to the collection of the epidermal cells, and to date, there were no reports that oseltamivir may affect psoriasis. Thus, it could be reasonably argued that hydroxychloroquine may lead to a global increase in the number of psoriasis (Kutlu and Metin, 2020).

In the study conducted by Huang et al. (2020), all the 41 patients were given empirical antibiotic treatment, and 93% received oseltamivir also, but the results are yet to be known. A 43-year-old female patient was recovered and discharged from the hospital after the use of oseltamivir along with traditional Chinese medicine. Unfortunately, this patient showed a positive SARS-CoV-2 test again after 22 days of hospital discharge, however, convalescent plasma therapy (CPT) along with other measures made her condition better (Chen D. et al., 2020; Luo, 2020).

Ribavirin

Ribavirin is a guanosine analog and nucleoside inhibitor to stop viral RNA synthesis. It was widely used to treat SARS in combination with or without steroids in severe cases. Virtual screening of some FDA approved medicines against SARS-CoV-2 main protease (M^{pro}) has been done and found that ribavirin, telbivudine, vitamin B12, and nicotinamide has an excellent docking score and can be made use in the treatment of COVID-19 (Kandeel and Al-Nazawi, 2020). In another molecular docking study, it was found that ribavirin, galidesivir, sofosbuvir, remdesivir, and tenofovir are effective agents in the treatment of COVID-19 since these drugs can tightly bind to the viral RNA dependent RNA polymerase (Elfiky, 2020). Since ribavirin shows the adverse effect of decreasing hemoglobin levels, it is not recommended for patients with respiratory distress (Jean et al., 2020). Out of the two clinical trials registered for this drug, one is completed, but results are not yet available.

Cell-Based and Immunological Products

Monoclonal Antibodies

In COVID-19 infection, activation of a huge number of mononuclear macrophages and T lymphocytes occur which results in the production of cytokines such as IL-6. This IL-6 will bind to the IL-6 receptor on the target cells, which leads to cytokine storm as well as dangerous inflammatory responses in the lungs and other organs (Xu et al., 2020).

Tocilizumab, a humanized monoclonal antibody that acts as a blocker of the IL-6 receptor, can bind to the IL-6 receptor with high affinity. It can prevent IL-6 itself from binding to its receptor, making it unable to injure the target cells, and lessen the inflammatory responses (Zhang C. et al., 2020). Its use is considered as one of the latest treatment strategies against COVID-19 (Bersanelli, 2020). The results of a retrospective study in fifteen COVID-19 patients, including moderate to critically ill, suggests that tocilizumab can be an efficient management option for patients with a risk of cytokine storms (Luo et al., 2020). Treatment with Tocilizumab, which blocks IL-6 receptors, results in notable outcomes like reduction in the elevated body temperature and improved respiratory function (Fu et al., 2020). Tocilizumab is also referred to as a promising choice for the treatment of the hyperinflammatory state associated with this infection in the second edition of "Vademecum for the Treatment of People With COVID-19" (Lombardy Section Italian Society Infectious And Tropical Diseases, 2020). In a COVID-19 patient with multiple myeloma, the treatment with tocilizumab was successful. The study recommends the need for randomized clinical trials for detailed evidence (Zhang X. et al., 2020). Further, several studies have been reported the use of tocilizumab as a promising treatment option for COVID-19 related respiratory

failure (Bachanova et al., 2020; Bennardo et al., 2020; Buonaguro et al., 2020; Cellina et al., 2020; Ceribelli et al., 2020; Liu B. et al., 2020; Michot et al., 2020; Mihai et al., 2020).

Coronavirus neutralizing antibodies mainly aim the spike proteins on the surface of the virus, which mediate the entry into host cells. Receptor binding can generate irreversible conformational alteration in the spike proteins and thus inhibits the viral fusion with host cells (Wang C. et al., 2020). It is now suggested that CR3022, a SARS-CoV-specific human monoclonal antibody, has the potential to emerge as an agent against SARS-CoV-2, along with other neutralizing antibodies (Tian et al., 2020). Sarilumab, gimsilumab, lenzilumab, etc. are the other monoclonal antibodies in the trial. More than 40 clinical trials on monoclonal antibodies are registered, including those on tocilizumab, sarilumab, gimsilumab, and lenzilumab. Details of selected clinical trials on biological agents against COVID-19 are provided in **Table 2**.

Interferons

Interferons are signaling proteins and have antiviral activity. Viruses trigger the release of interferons by the host cells. Type 1 interferons possess a wide range of antiviral effects *in vitro* and a recent clinical trial proved its efficacy in the treatment of MERS-CoV. With regard to this, interferon wastried in clinical trials as a treatment option for COVID-19. The β subtype is found more promising, and the treatment in the early stages of the infection is recommended (Sallard et al., 2020). The combination of ribavirin and INFα has been the most commonly used therapy to treat MERS outbreaks in South Korea (Kim et al., 2016). Due to the effectiveness of this therapy, this combination is recommended to treat COVID-19 infection in the fifth edition of the National Health Commission's Regimen of China (Du et al., 2020).

Mesenchymal Stem Cells

The human umbilical cord mesenchymal stem cell (MSC) possesses outstanding immunomodulatory and strong anti-inflammatory functions with proper safety (Metcalfe, 2020). Liang et al. (2020) reported that treatment with allogeneic human umbilical cord MSCs in a 65-year-old critically ill female patient with COVID-19 showed a significant and positive outcome with good tolerance. So this kind of therapy is an ideal choice for the management of seriously ill COVID-19 patients (Liang et al., 2020). In another study, seven patients who are dangerously ill with COVID-19, MSCs therapy significantly improved their condition without any adverse effects (Leng et al., 2020). Therefore, MSC therapy is a safe and effective option for critical cases of pneumonia associated with COVID-19. Even though the results are promising, proper clinical investigations are required for these kinds of cell-based therapies (Khoury et al., 2020). A total of 29 clinical trials are registered for the efficacy and safety evaluation of MSCs in COVID-19.

Convalescent Plasma Therapy

Convalescent plasma therapy is considered one of the advanced options sought for the treatment of COVID-19 (Zhao and He, 2020). Convalescent or immune plasma is the plasma collected from individuals who are cleared of infection with a sufficient amount of developed and antibodies. Convalescent plasma therapy will help to get immediate immunity for a short time in susceptible individuals (Bloch et al., 2020). Neutralizing antibodies are critical in virus clearance and vital in defense against various viral diseases. Passive immunity achieved due to convalescent plasma can provide neutralizing antibodies that can control the infection. In addition to antiviral action, convalescent plasma can also cause immunomodulation. Some antibodies can cause the inhibition of complement cascade and thus can control the formation of immune complexes. Convalescent plasma has anti-inflammatory effects also due to the action of a network of autoantibodies and can manage an overactive immune system. The effectiveness of this therapy is highly related to the concentration of neutralizing antibodies in the collected plasma (Rojas et al., 2020). A brief mechanism of CPT is depicted in **Figure 4**.

Despite this apparent advantage, several challenges are also associated with CPT such as anaphylactic reactions, transfusion transmitted infections, transfusion associated acute lung injury, circulatory overload, hemolysis, etc. Owing to the importance of this approach, the possibilities and challenges of CPT are now well discussed and described (Roback and Guarner, 2020).

From the previous studies related to SARS, it was reported that CPTresulted in a shorter hospital stay period as well as a lower death rate as compared to the control group (Soo et al., 2004; Cheng et al., 2005; Chen L. et al., 2020). Five seriously sick patients with COVID-19 showed promising results when received plasma transfusion. After the transfusion, body temperature and viral loads were declined and turned to negative within 12 days (Shen et al., 2020). In another study, a single dose of 200 mL of convalescent plasma antibody titers over 1:640 was transfused to 10 patients along with antiviral agents and supportive measures. The results confirmed that this therapy was well tolerated and could be able to neutralize viremia in critical COVID-19 cases (Duan et al., 2020).

In April 2020, the US FDA permitted CPT in dangerously sick patients with COVID-19 (Tanne, 2020). Two COVID-19 patients with severe pneumonia and ARDS showed a positive result by CPT along with corticosteroids (Ahn et al., 2020). A good number of clinical trials are registered for studying the safety and efficacy evaluation of CPT in COVID-19 patients (**Table 3**). Many clinical results showed that CPT produces remarkable improvement in clinical symptoms as well as radiological and biochemical parameters related with the SARS-CoV-2 infection (Bakhtawar et al., 2020).

Vaccines

Vaccine development needs many years to reach the market under normal circumstances. Fortunately, the data generated in the research on SARS-CoV as well as MERS-CoV helped in an express design and development of the COVID-19 vaccine. Thus, within three months of the emergence of COVID-19, a specific vaccine candidate entered Phase I clinical trials, and WHO announced the news of the availability of licensed vaccine for widespread use by the middle of 2021. Presently, different SARS-CoV and MERS-CoV vaccine candidate are in clinical trials against COVID-19. At the same time, thorough investigations

TABLE 2 | Details of clinical trials on biological agents against COVID-19.

No.	Intervention/treatment	Study type/Phase	Primary purpose	No. of participants	Sponsors and Collaborators (ClinicalTrials.gov Identifier)
1	Lopinavir/ritonavir Hydroxychloroquine sulfate Baricitinib (Janus kinase inhibitor) Sarilumab (anti-IL-6 receptor)	Interventional (Phase 2)	Treatment	1000	Lisa Barrett, Nova Scotia Health Authority (NCT04321993)
2	Xiyanping injection Lopinavir/ritonavir, alpha-interferon nebulization	Interventional (Phase 2,3)	Treatment	348	Jiangxi Qingfeng Pharmaceutical Co. Ltd. (NCT04275388)
3	Remdesivir Lopinavir/ritonavir, Interferon Beta-1A, Hydroxychloroquine	Interventional	Treatment	3100	Institut National de la Santé Et de la Recherche Médicale, France (NCT04315948)
4	lopinavir/ritonavir, remdesivir, interferon beta-1a, chloroquine and/or azithromycin	Observational	Adverse events	1000	Groupe Hospitalier Pitie-Salpetriere (NCT04314817)
5	Hydrocortisone, Ceftriaxone, Moxifloxacin, Levofloxacin, Piperacillin-tazobactam, Ceftaroline, Amoxicillin, clavulanate, Macrolide, oseltamivir, Lopinavir/ritonavir Hydroxychloroquine Interferon-β1a Anakinra	Interventional	Treatment (Phase 4)	6800	MJM Bonten (NCT02735707)
6	Lopinavir/ritonavir, Ribavirin, Interferon Beta-1B	Interventional (Phase 2)	Treatment	70	The University of Hong Kong (NCT04276688)
7	ASC09F Oseltamivir Ritonavir Oseltamivir	Interventional (Phase 3)	Treatment	60	Tongji Hospital (NCT04261270)
8	Hydroxychloroquine Lopinavir/Ritonavir Interferon Beta-1A Interferon Beta-1B	Interventional (Phase 4)	Treatment	60	Shahid Beheshti University of Medical Sciences
9	Abidol Hydrochloride Interferon	Interventional (Phase 4)	Treatment	100	Tongji Hospital (NCT04254874)
10	Recombinant human interferon Alpha-1b thymosin alpha 1	Interventional (Phase 3)	prevention	2944	Shanghai Jiao Tong University School of Medicine (NCT04320238)
11	Ganovo, ritonavir, Interferon	Interventional (Phase 4)	Treatment	11	The Ninth Hospital of Nanchang (NCT04291729)
12	Recombinant human interferon α1β	Interventional (early Phase 1)	Treatment	328	Tongji Hospital (NCT04293887)
13	Bromhexine Hydrochloride, Arbidol Hydrochloride Recombinant Human Interferon α2b	Interventional	Treatment	60	Second Affiliated Hospital of Wenzhou Medical University (NCT04273763)
14	Emapalumab(Anti-interferon Gamma) Anakinra (Interleukin-1Receptor Antagonist)	Interventional (Phase 2/3)	Treatment	54	Swedish Orphan Biovitrum (NCT04324021)
15	Tocilizumab	Observational	Treatment	30	University of L'Aquila (NCT04332913)
16	Favipiravir Tocilizumab	Interventional	Treatment	150	Peking University First Hospital (NCT04310228)
17	INO-4800, a Prophylactic Vaccine	Interventional (non-randomized)	Prevention	40	Inovio Pharmaceuticals (NCT04336410)
18	Biological: UC-MSCs	Interventional	Prevention	10	ZhiYong Peng (NCT0426952)
19	Biological: ChAdOx1 nCoV-19	Interventional (Phase 1/2)	Treatment	510	University of Oxford (NCT04324606)
20	Tocilizumab Sarilumab	Interventional (Phase 2)	Treatment	200	Marius Henriksen (NCT04322773)
21	Siltuximab Methylprednisolone	Interventional (Phase 2)	Treatment	100	Judit Pich Martínez (NCT04329650)
22	Tocilizumab Pembrolizumab (MK-3475)	Interventional (Phase 2)	Treatment	24	MedSIR (NCT04335305)

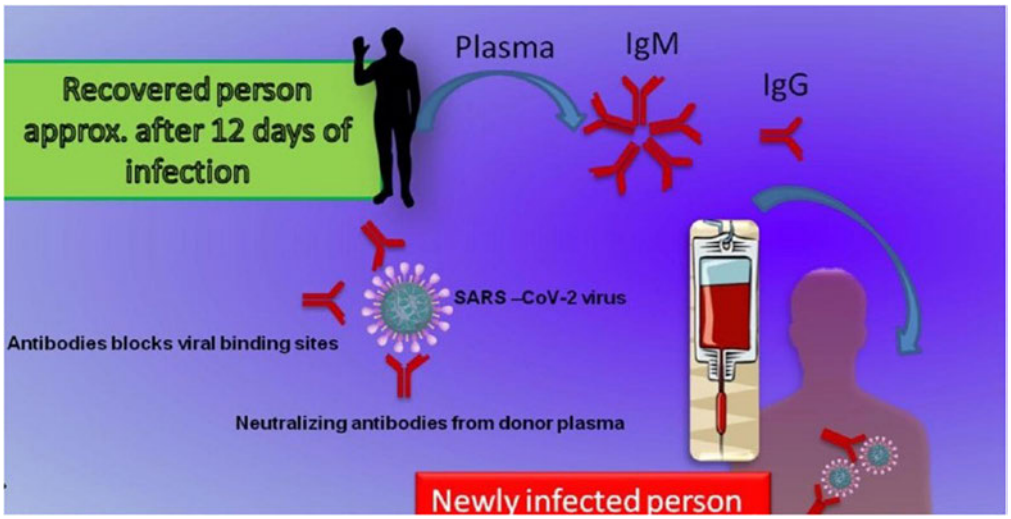

FIGURE 4 | Schematic representation of the convalescent plasma therapy along with its mechanisms of action. A person recovered from COVID-19 infection produces a sufficient amount of specific antibodies in 12–14 days. The plasma with neutralizing antibodies mainly IgM and IgG can be transferred to produce immediate immunity in suspected or infected persons. IgG and IgM anti-SARS-CoV-2 antibodies will bind to specific sites and neutralize the virus.

are required urgently to study the risk of immune enhancement. Therefore, along with early clinical trials, clinical evidence is also needed to support the possibility of immune enhancement (de Alwis et al., 2020). According to the latest WHO report there are more than 169 COVID-19 vaccine candidates currently under clinical trials. Among these clinical candidates, 26 are in the various phase of human trials and 10 reached up to phase 3 of the clinical trial. **Figure 5** shows some of the ongoing vaccine trials in lead which are specific to COVID-19.

Miscellaneous/Adjunctive Therapy

Traditional Chinese Medicine

Various Traditional Chinese Medicines like Shuanghuanglian oral liquid and Lianhuaqingwen capsule were also tried for treating SARS-CoV-2 infection and found satisfactory outcome. Some of them, like YinHu QingWen, Fuzheng Huayu, are in registered clinical trials (Wang L. et al., 2020). A total of 8 clinical trials are registered for the evaluation of the effectiveness of Traditional Chinese Medicine.

Vitamins

An adequate level of vitamin D is required to suppress the adhesion molecule (CD26), which helps in invasion to host cells. Since, vitamin D deficiency leads to increased risk of respiratory infections, supplementation with adequate dose is highly recommended in high-risk categories (McCartney and Byrne, 2020). Clinical studies show that a large dose of vitamin C can prevent viral infections. Thus, early use of antioxidants like vitamin C in large doses may be helpful to fight COVID-19 (Cheng, 2020).

Corticosteroids

Even though corticosteroids are used as adjuvant therapy in COVID-19 infection, WHO and the United States Centre for Disease Control and Prevention recommend that it should not be regularly used in COVID-19 patients, except indicated for other conditions. Low to moderate doses with close monitoring as a short course may be beneficial. More than ten trials are registered for the evaluation or comparison of the safety as well as efficacy of different corticosteroids in COVID-19 (Rosa and Santos, 2020).

Thalidomide

The severe lung injury in COVID 19 may be related to the extreme immune response as a result of cytokine storm. Thalidomide is an immunomodulatory agent, and it can stimulate T cells, decrease TNF-α production, and enhance the secretion of interleukins and natural killer cells. Its anti-inflammatory role is due to the capacity to reduce TNF-α by enhancing the degradation of mRNA in blood cells. Two trials are registered to test the safety and effectiveness of thalidomide in treating moderate or severe COVID-19 (Newfield, 2018).

Drug Repurposing Approach

Chloroquine or Hydroxychloroquine

Chloroquine is a popular drug used for the prophylaxis of malaria and amebiasis and also to treat autoimmune diseases like rheumatoid arthritis and lupus erythematosus. A wide range of mechanisms has been proposed for the action of chloroquine (Cortegiani et al., 2020). By altering the binding of the virus to the cell surface receptor, it can hold back the pre-entry step to the host cell (Vincent et al., 2005). Also, it can impair pH reliant endosome dependent entrance of enveloped viruses like chikungunya and dengue viruses (Gay et al., 2012; Wong and Chu, 2018). Post-translational variation of viral proteins can also be damaged by chloroquine. It can also spoil the viral protein maturation (Devaux et al., 2020). In addition, it acts as an immunomodulatory agent by the regulation of pro-inflammatory cytokines and cell signaling.

TABLE 3 | Details of convalescent plasma therapies at clinical trials.

No.	Intervention/treatment	Study type/Phase	Primary purpose	Number of participants	Sponsors and Collaborators (ClinicalTrials.gov Identifier)
1	Convalescent Plasma	Interventional (Phase 1)	Treatment	20	Hospital San Jose Tec de Monterrey (NCT04333355)
2	Anti-SARS-CoV-2 convalescent plasma	Interventional (Early Phase 1)	Treatment	20	Orthosera Kft. (NCT04345679)
3	Convalescent Plasma Transfusion	Interventional (Phase 2)	Treatment	20	Institute of Liver and Biliary Sciences, India (NCT04346446)
4	Convalescent Plasma	Interventional (Phase 2)	Treatment	15	Saint Francis Care (NCT04343261
5	COVID-19 convalescent plasma	Expanded Access	Treatment	Expanded Access	Mayo Clinic (NCT04338360)
6	Transfusion of COVID-19 convalescent plasma	Interventional (Phase 2)	Treatment	120	Assistance Publique - Hôpitaux de Paris (NCT04345991)
7	convalescent plasma from recovered COVID 19 donor	Interventional (Phase 2)	Treatment	40	King Fahad Specialist Hospital Dammam (NCT04347681)
8	Convalescent Plasma Standard Donor Plasma	Interventional (Phase 1/2)	Treatment	500	Stony Brook University (NCT04344535)
9	Convalescent Plasma	Interventional (Phase 2)	Treatment	55	Hackensack Meridian Health (NCT04343755)
10	Convalescent Plasma	Interventional (Phase 2)	Treatment	426	Erasmus Medical Center (NCT04342182)
11	Convalescent Plasma	Interventional (Phase 2)	Treatment	278	Cristina Avendaño Solá (NCT04345523)
12	Convalescent Plasma	Interventional (EarlyPhase1)	Treatment	10	University of Chicago (NCT04340050)
13	Plasma Hydroxychloroquine Azithromycin	Interventional (Phase 1/2)	Treatment	80	Universidad del Rosario (NCT04332835)
14	Convalescent Plasma	Interventional	Treatment	30	Mazandaran University of Medical Sciences (NCT04327349)
15	Convalescent Plasma	Observational		15	Shanghai Public Health Clinical Center (NCT04292340)
16	Anti- SARS-CoV-2 Plasma SARS-CoV-2 non-immune Plasma	Interventional (Phase 2)	Treatment	150	Johns Hopkins University (NCT04323800)
17	Convalescent anti-SARS-CoV-2 plasma Sarilumab, Baricitinib, Hydroxychloroquine	Interventional (Phase 3)	Treatment	1500	Thomas Benfield (NCT04345289)
18	high-titer anti-Sars-CoV-2 plasma, oxygen therapy	Interventional (Phase 1)	Treatment	115	Baylor Research Institute (NCT04333251)
19	Anti-coronavirus antibodies (immunoglobulins)obtained with DFPP from a convalescent patient	Interventional	Treatment	10	A.O. Ospedale Papa Giovanni XXIII (NCT04346589

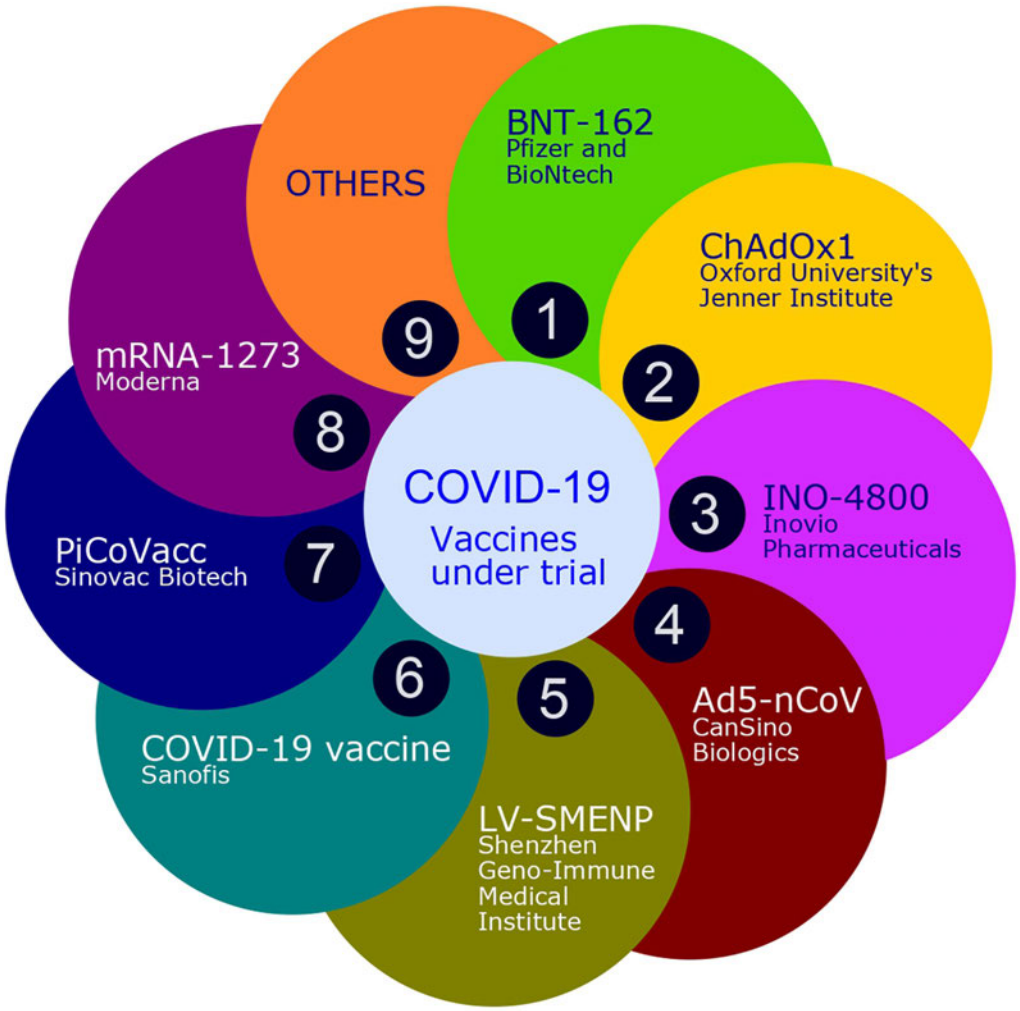

FIGURE 5 | Some of the ongoing vaccine trials in lead which are specific to COVID-19.

Several trials on the effectiveness of this agent have been found to be registered in the Chinese Clinical Trial Registry. Based on this, Liu and associates examined the antiviral action of hydroxychloroquine and chloroquine against COVID-19 *in vitro*. It was found that both the agents elevate the intracellular organelles' pH, which is critical in membrane fusion. Both the drugs were able to exert their actions to inhibit the viral entry as well as at some post-entry stages. It was found that the drugs could block the transport of the virus from the early endosomes to endolysosomes, which is essential for the release of the viral genome. The study concludes that hydroxychloroquine is as effective as chloroquine for the *in vitro* inhibition of SARS-CoV-2 infection with comparatively less toxicity (Liu J. et al., 2020). A survey in a University Hospital in Marseille reassured the disappearance or decrease of viral load in hydroxychloroquine treated patients, and the result is reinforced by concomitant use of azithromycin (Gautret et al., 2020).

Wang and associates demonstrated the effectiveness of chloroquine at entry as well as post-entry phases of COVID-19 infection *in vitro* cell lines. Further, the immune modulation property can induce synergism in its antiviral activity *in vivo* (Wang M. et al., 2020). Still, there is an opinion that the option of using chloroquine for the treatment of COVID-19 should be properly analyzed in light of the new hopeful declarations, by considering the possible side effects (Colson et al., 2020; Touret and de Lamballerie, 2020). Chloroquine causes under expression of phosphatidylinositol binding clathrin assembly protein and thereby affects endocytosis (Hu et al., 2020). Meanwhile, the assessment of safety and efficiency of chloroquine for treating COVID-19 demands the need for safety data from urgent high-quality trials from various geographical areas (Cortegiani et al., 2020). Interestingly, chloroquine phosphate shortened the course of the disease in clinical trials and thus seems to be better than the control, for the inhibition of pneumonia (Gao et al., 2020) Also, *in vitro* study revealed that hydroxychloroquine shows the more powerful effect as compared to chloroquine (Yao et al., 2020). As of now, more than 40 clinical trials are registered to assess and/or

compare the effectiveness and/or safety of chloroquine and hydroxychloroquine.

Metronidazole

Metronidazole is another nucleic acid synthesis inhibitor and a potential candidate which can counter most of the immunopathological symptoms of SARS-CoV-2 infection. *In vitro* as well as *in vivo* studies proved that this drug could reduce cytokine levels, which are generally increased during this disease. *In vitro* studies proved that metronidazole at high doses had a marked inhibitory effect on lymphoproliferative assay (Fararjeh et al., 2008; Rizzo et al., 2010). Also, it can reduce neutrophil-generated ROS in the event of inflammation. But studies with a big number of groups are needed to prove its effectiveness (Gharebaghi et al., 2020)

Sofosbuvir, an FDA approved nucleotide polymerase inhibitor mainly used for the management of hepatitis C is under test by a Chinese research foundation (Vellingiri et al., 2020). Previously sofosbuvir was used along with ribavirin and interferon. The use of sofosbuvir is reported in the management of the Zika virus also (Cheema et al., 2019).

Some Other Potential Agents

Baricitinib, carfilzomib, indinavir, baloxavir, ruxolitinib, fedratinib, and azvudine are some other potential agents to treat this respiratory disease (Peter et al., 2020). Among these, fedratinib, baricitinib, and ruxolitinib are potent anti-inflammatory agents and powerful Janus kinase inhibitors (Stebbing et al., 2020) which are approved for rheumatoid arthritis and myelofibrosis. It is reported that these drugs are effective to control the increased levels of cytokines usually observed in COVID-19 patients (Stebbing et al., 2020). Twelve clinical trials have been registered to evaluate the efficacy and safety of ruxolitinib in COVID-19 patients. Baricitinib is not considered an ideal choice for the treatment of COVID-19, since it may enhance the chance of co-infection and increase the incidence of anemia (Praveen et al., 2020). Eight clinical trials are registered for the evaluation of the efficacy of baricitinib in COVID-19 patients. The immune-modulating and anti-inflammatory agents are not usually recommended in pneumonia associated with COVID-19. Nevertheless, as per the pathology of pulmonary edema as well as the formation of hyaline membrane, it could be reasonably assumed that well-timed and appropriate therapy with immunomodulators along with other supportive measures may save the COVID-19 patients from ARDS. Based on these considerations, one clinical trial is going on for the evaluation of fingolimod, an immunology modulator generally used in multiple sclerosis (ClinicalTrails, 2020).

Nitazoxanide is an antiprotozoal drug with a broad-spectrum antiviral activity, which can also reduce the production of pro-inflammatory cytokines (Kelleni, 2020). With regard to this feature, it has been registered for studies in more than 6 clinical trials as monotherapy or as combination therapy for the management of COVID-19 (ClinicalTrails, 2020).

Severe acute respiratory syndrome coronavirus-2 infection depends on ACE2 and TMPRSS2 proteins on the host cell surface and these can be blocked by protease inhibitors (Nadeem et al., 2020). Camostat mesylate is a synthetic serine protease inhibitor that can inhibit TMPRSS2 protein in lung cells (Hoffmann et al., 2020; McKee et al., 2020). Nafamostat mesylate, another TMPRSS2 serine protease inhibitor, may also prevent the entry of virus into the host cell. Cell culture experiments proved that nafamostat mesylate inhibited SARS-CoV-2 infection in SARS-CoV-2 infected Vero E6 cells (EC_{50} = 22.5 μM) (Wang M. et al., 2020). There are numerous similarities in clinical, pathological, and laboratory findings of moderate to severe SARS-CoV-2 infection and haemophagocytic lymphohistiocytosis. The possibility of etoposide may be considered for treating haemophagocytic lymphohistiocytosis associated with moderately severe or severe forms of SARS-CoV-2 infection (Hamizi et al., 2020). The viroporine channel of COVID-19 can be effectively blocked by amantadine and thus can prevent viral genome release into the cytoplasm. Therefore, amantadine can be used to mitigate the effects of COVID-19 if used in an early stage of infection (Abreu et al., 2020). Niclosamide is another potential option since it can block endocytosis and autophagy of SARS-CoV-2 (Pindiprolu and Pindiprolu, 2020).

Drug repurposing approach by *in silico* studies will give potential clues about the agents which might be helpful to fight this deadly virus. It was found that lopinavir, galidesivir, asunaprevir, CGP42112A, remdesivir, indinavir, ABT450, ritonavir, and methisazone can interact with more than two protein structures of COVID-19. Among these, HIV protease inhibitors exhibited excellent outcomes in docking studies (Shah et al., 2020). Similarly, Wu and associates carried out an analysis by computational methods for discovering therapeutic targets of novel coronavirus as well as predicting potential medicines. The study reports more than 50 natural compounds and more than 50 drugs which may be considered for further studies for the treatment of COVID 19 (Wu et al., 2020). In a study using the drug-target interaction model, atazanavir, remdesivir, efavirenz, ritonavir, dolutegravir, lopinavir, darunavir showed good inhibitory potency, with atazanavir in the first position, followed by remdesivir (Beck et al., 2020). When docking was performed with solvent molecular dynamics on several natural compounds, compounds like 5,7,3',4'-Tetrahydroxy-2'-(3,3-dimethylallyl) isoflavone, myricitrin, and methyl rosmarinate were observed to be the most promising agents against COVID-19 (ul Qamar et al., 2020). Muralidharan et al. conducted computational studies to understand the synergism of lopinavir, ritonavir, and oseltamivir. They found that the combination of these three drugs resulted in superior binding energy as compared to the individual agents (Muralidharan et al., 2020).

Based on Feline Infectious Peritonitis Strategies, Olsen et al. (2020) suggested the use of nelfinavir and amodiaquine for the treatment of SARS-CoV-2 infection with a potential CNS invasion. *In vitro* study in Vero-E6 cells showed that remdesivir and lopinavir inhibit the replication of SARS-CoV-2 with EC50 at 23.15 and 26.63 μM concentrations, respectively. At the same time, homoharringtonine and emetine have EC50 values of 2.55 and 0.46 μM, respectively, for the inhibition of SARS-CoV-2 replication. In addition, a synergistic effect

for the combination of remdesivir and emetine has been also observed (Choy et al., 2020). It may be noted that a 60-year-old immunocompromised female cancer patient on darunavir/cobicistat along with hydroxychloroquine was able to leave the hospital within six days, which shows the potential of darunavir/cobicistat even in immunocompromised patients (Spezzani et al., 2020).

RAC/CDC42-activated kinases (PAK1) are required for the pathogenic process of different kinds of viruses including SARS-CoV-2. Therefore, PAK1 blockers like melatonin, propolis, cicloresonide, some anti-malaria drugs like ivermectin, and ketorolac could act as promising agents against COVID-19 (Maruta and He, 2020). Ivermectin is a broad-spectrum anti-parasitic agent approved by the FDA. An *in vitro* study demonstrated that it can cause a 5000 times decrease in SARS-CoV-2 viral RNA in 48 h and it needs further investigation and clinical trials as a promising therapeutic agent against COVID-19 (Caly et al., 2020). This study received wide attention which finally led USFDA to issue a letter clarifying that the study tested ivermectin neither in humans or animals. The letter also warned the use of ivermectin containing veterinary products in humans (FDA, 2020). The mechanism of action and dose of some potential drugs against COVID-19 are given in **Table 4**.

PERSPECTIVES

Hopefully, several perspectives and hypotheses are available related to the treatment and prophylaxis against COVID-19. Some of them appear interesting and promising for further consideration and studies. In such a perspective, it is mentioned that ATP has a crucial role in cellular function and cyclic ATP depletion can cause cellular dysfunction including immune cells. ATP-repletion can prevent the "cytokine storm" in COVID-19 and increase the cellular energy to fight against the virus (Taghizadeh-Hesary and Akbari, 2020). Other than the antiviral activity chloroquine/hydroxychloroquine cause the movement of extracellular zinc into intracellular lysosomes and thus hinders the enzyme RNA polymerase which is required for viral replication. Zinc deficiency is commonly seen in geriatrics and also in patients with diabetes, chronic pulmonary disease, cardiovascular diseases, etc. Therefore, zinc supplementation along with chloroquine therapy may reduce the mortality and morbidity rate in COVID-19 (Derwand and Scholz, 2020). Copper is a very important micronutrient required for the functioning of vital immune cells like B cells, helper T cells, natural killer cells, macrophages, etc. Therefore, enhancement of plasma level of copper may boost the immune system and may act as a preventive or therapeutic measure against COVID-19 (Raha et al., 2020). If COVID-19 results in long term cardiopulmonary damage, cardiopulmonary rehabilitation is required; exercise can be considered as a therapy of choice. Since physical movement of many people has become less in this pandemic situation, therefore exercise should be given prime importance. It is proposed that exercise may help in lowering the risk of SARS-CoV-2 infection by minimizing cardiopulmonary sequel in the recovery period (Heffernan and Young Jae, 2020). In a hypothesis, it is postulated that the

TABLE 4 | The mechanism of action and dose of potential drugs against COVID-19.

Drug	Mechanism of action	Dose
Remdesivir	Inhibition of RNA polymerase	200 mg initial dose after that 100 mg daily (IV) up to 9 days
Chloroquine/ Hydroxychloroquine	Modify the transcription process and signaling pathways	400 mg two times on the first day, then 200 mg two times up to 7 days
Umifenovir	Inhibition of membrane fusion	200 mg three times daily maximum up to10 days
Lopinavir/Ritonavir	Protease inhibitor	400/100 mg two times a day for 14 days
Favipiravir	Inhibits viral replication	1600 mg two times in the first day, then 600 mg two times per day up to 6 days
Oseltamivir	Reduce viral replication	75 mg two times daily up to 5 days
Ribavirin	Nucleoside inhibitor	500 mg two or three times daily along with interferon α or lopinavir/ritonavir maximum up to10 days
Metronidazole	Nucleic acid synthesis inhibitor	400 mg two times daily maximum up to 14 days
Baricitinib	Anti-Janus kinase inhibitor	4 mg/day for two weeks
Camostat Mesilate	Block cell entry (Serine protease inhibitor)	200 mg three times daily for 5 days
Darunavir/Cobicistat	Protease inhibitor/inhibitor of cytochrome P450 3A	800 mg/150 mg once daily for 5 days
Thalidomide	Anti-inflammatory, anti-angiogenesis, antifibrotic and immune regulation	100 mg for 14 days
Isotretinoin	Down regulator of ACE-2 receptors also PLpro inhibitor	0.5 mg per kg daily for one month
IFN α	Inhibition of viral replication	atomization: 45μg, two times daily for two weeks or 5 million units or equivalent dose, twice daily not more than 10 days
Fingolimod	Immunology modulator	0.5 mg per day orally for 3 days
Ruxolitinib	JAK1 and JAK2 inhibitor	10 mg two times a day for 14 days with dose reduction or escalation
Tocilizumab	IL-6 blocker	8 mg/kg

immunologic effect and enhancement of antibody production by diethylcarbamazine could confer its anti-COVID-19 effect. Diethylcarbamazine is expected to show the immunologic effects by the inhibition of lipoxygenase (LOX) and cyclooxygenase (COX) enzymes (Abeygunasekera and Jayasinghe, 2020). In a similar hypothesis, montelukast is suggested to be useful in restraining the progression of the disease. The anti-inflammatory effect, suppression of oxidative stress, and reduced cytokine production are supposed to facilitate the effect (Fidan and Aydoğdu, 2020). Clinical researches proved the benefit of surfactant treatment in patients with ARDS (Walmrath et al., 1996).Also it was found that early administration of natural lung surfactants can improve the pulmonary function in adult patients with severe respiratory distress syndrome (Mirastschijski et al., 2020). Surfactant based prophylactic management as well as therapy can be considered as another promising strategy (Pramod et al., 2020).

CONCLUSION

This review provides an overview of the current treatment strategies, ongoing clinical trials, and potential future options based on published research and registered clinical trials related to the COVID-19. The basics of SARS-CoV-2, the virus, and COVID-19, the disease, are provided. It was noted that none of the present therapies or strategies could be an absolute solution to end this pandemic. The drugs which have a repurposing option are selected based on its activity against RNA viruses like SARS-CoV, MERS-CoV, influenza virus, and Ebola virus. The hope of the successful vaccine, other immunological products, and cell-based therapeutics is still alive. Convalescent plasma therapy is successful in some cases. At present, it could be seen that none of the presently available approaches or drugs was able to stop this pandemic. The results of many clinical trials are yet to be announced. Further, the suggested future potential solutions seem to be promising to end this pandemic.

AUTHOR CONTRIBUTIONS

SK: conceptualization, writing – original draft, and funding acquisition. HA: supervision, writing – review and editing. SB-E: writing – review and editing. NA: supervision, writing – review and editing. SM: writing – review and editing. AN: writing – review and editing. PD: writing – review and editing. All authors contributed to the article and approved the submitted version.

FUNDING

This project was funded by the Deanship of Scientific Research (DSR) at King Abdulaziz University, Jeddah, under grant no. GCV19-25-1441.

ACKNOWLEDGMENTS

We therefore, acknowledge with thanks DSR for technical and financial support.

SHORT COMMUNICATION

The association between the use of ivermectin and mortality in patients with COVID-19: a meta-analysis

Chia Siang Kow[1] · Hamid A. Merchant[2] · Zia Ul Mustafa[3] · Syed Shahzad Hasan[2,4]

Received: 6 January 2021 / Revised: 27 February 2021 / Accepted: 6 March 2021 / Published online: 29 March 2021

Abstract

Objective The effect of ivermectin on mortality in patients with novel coronavirus disease 2019 (COVID-19) has been investigated in many studies. We aimed to perform a meta-analysis of randomized controlled trials to investigate the overall effect of ivermectin on the risk of mortality in patients with COVID-19.

Methods We systematically searched PubMed, Cochrane Central Register of Controlled Trials, Google Scholar, and preprint repository databases (up to February 28, 2021). Random-effects and inverse variance heterogeneity meta-analysis were used to pool the odds ratio of individual trials. The risk of bias was appraised using Version 2 of the Cochrane risk-of-bias tool for randomized trials.

Results Six randomized controlled trials were included in this analysis with a total of 658 patients who were randomized to receive ivermectin and 597 patients randomized in the control group who did not receive ivermectin. Of six trials, four had an overall high risk of bias. The estimated effect of ivermectin indicated mortality benefits (pooled odds ratio = 0.21; 95% confidence interval 0.11–0.42, $n = 1255$), with some evidence against the hypothesis of 'no significant difference' at the current sample size.

Conclusion We observed a preliminary beneficial effect on mortality associated with ivermectin use in patients with COVID-19 that warrants further clinical evidence in appropriately designed large-scale randomized controlled trials.

Keywords Bias · Clinical trial · COVID-19 · Ivermectin · Mortality

Introduction

Ivermectin is well known for its efficacy against a range of parasitic diseases, including onchocerciasis and strongyloidiasis. Recently, a systematic review [1] of in vivo and in vitro studies of ivermectin demonstrated its broad antiviral activity against a range of RNA and DNA viruses. Particularly, ivermectin demonstrated an in vitro antiviral effect towards the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) [2]. This has since attracted the interest of frontline clinicians to investigate the potential repurposing of ivermectin for the treatment of coronavirus disease 2019 (COVID-19). Therefore, we aimed to perform a meta-analysis of randomized clinical trials to investigate the mortality benefits of ivermectin in patients with COVID-19.

Methods

We performed a systematic literature search in electronic databases including PubMed, Google Scholar, Cochrane Central Register of Controlled Trials, and preprint servers (medRxiv, Research Square, SSRN) with no language restriction, for eligible studies published up to February 28, 2021. The search strategy was built based on the following keywords and MeSH terms: "COVID-19", "SARS-CoV-2", and "ivermectin". The clinical trial registries of the United States (clinicaltrials.gov), China (chictr.org.cn), and World Health Organization (who.int/

clinical-trials-registry-platform) were also searched for registered clinical trials of ivermectin for the treatment of COVID-19 to identify studies with reported findings. Two investigators (CSK and SSH) independently performed the literature screening to identify eligible studies. The reference lists of relevant articles were also reviewed to search for additional studies. Studies eligible for inclusion were randomized controlled trials comparing the mortality outcomes of ivermectin and its comparators in patients with COVID-19. We excluded studies with observational design, single-arm trials, non-randomized trials, and trials that did not report clinical outcomes. The systematic review followed the Preferred reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [3].

The outcome of interest was all-cause mortality. Each included trial was independently evaluated by two investigators (CSK and SSH) who also extracted the study characteristics. Data collected included author(s), trial design, country, patients' age, regimen of ivermectin, regimen of comparator treatment, and mortality outcomes. Two investigators (CSK and SSH) assessed the risk of bias of the trials included with Version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2) [4], which is a standardized method for assessing potential bias in reports of randomized interventions. RoB 2 is structured into a fixed set of domains of bias, focusing on different aspects of trial design, conduct, and reporting. We used both the random-effects model and inverse variance heterogeneity model for the meta-analysis to estimate the pooled odds ratio at 95% confidence intervals. We examined the heterogeneity between studies using the I^2 statistics and the $\chi 2$ test at 50% and $P < 0.10$, respectively. All analyses were performed using Meta XL, version 5.3 (EpiGear International, Queensland, Australia).

Results

Our systematic literature search retrieved 512 hits of which 401 were unique (titles retrieved after removing duplications) (Fig. 1). After screening, six randomized controlled trials [5–10] were included with a total of 658 patients who were randomized to receive ivermectin, and 597 patients were randomized to the control group who did not receive ivermectin. The six randomized trials that were included in the meta-analysis were respectively from Iraq [5], Iran [6], Bangladesh [7], Egypt [8], Turkey [9], and India [10]. Details of the included studies are shown in Table 1. A differing dosage regimen of ivermectin was noted across the six randomized controlled trials (Table 1).

The overall risk of bias assessed by RoB 2 is presented in Table 1. The trial by Niaee et al. [6] and Ravikirti et al. [10] had an overall low risk of bias. The other trials had an overall high risk of bias; the trial led by Mahmud et al. [7] had a high risk of bias in the domain of missing outcome data since a significant proportion (21%) of participants randomized was not included in the analysis; the trial by Elgazzar et al. [8] had a high risk of bias in the domain of randomization since the protocol for randomization was not reported; the trial by Hashim et al. [5] had a high risk of bias in the domain of randomization due to simple randomization method used with no information on allocation concealment and had also some concerns of bias in the domain of deviations from intervention due to unblinded participants; the trial led by Okumuş et al. [9] had a high risk of bias in the domain of randomization due to simple randomization method used and had also a high risk of bias in the domain of deviations from intended interventions due to open-label nature of the trial. The aforementioned four trials [5, 7–9] had a low risk of bias for other domains assessed.

The meta-analysis revealed a significantly reduced odds of mortality with the use of ivermectin among patients with COVID-19 relative to non-use of ivermectin; the estimated effect of ivermectin indicated mortality benefits (Fig. 2; pooled odds ratio = 0.21; 95% confidence interval 0.11 to 0.42, $n = 1255$) and with some evidence against the hypothesis 'no significant difference' at the current sample size.

Some may be concerned by the absence of real-time reverse transcription-polymerase chain reaction confirmatory test for COVID-19 diagnosis in a significant fraction of subjects in the trial by Niaee et al. [6], but exclusion of this trial in the meta-analysis still observed a significantly reduced risk of mortality with the use of ivermectin among patients with COVID-19 relative to non-use of ivermectin (pooled odds ratio = 0.23; 95% confidence interval 0.09–0.56).

Discussion

The mortality benefits demonstrated with the use of ivermectin in patients with COVID-19 from this meta-analysis is in agreement with the findings from the recent systematic review [1] and the largest observational study [11] on ivermectin thus far exhibiting a significantly reduced odds of mortality associated with the use of ivermectin (odds ratio = 0.27; 95% confidence interval 0.09–0.80). We, therefore, conclude a preliminary positive effect on mortality associated with ivermectin use in hospitalized patients with COVID-19 that warrants further clinical evidence in appropriately designed large-scale randomized controlled trials. Nevertheless, it should be noted that our meta-analysis was limited by a small number of patients included with a significant risk of biases in the majority of the included randomized controlled trials.

Mortality benefits elicited with the use of ivermectin in patients with COVID-19 likely stem from the ability of

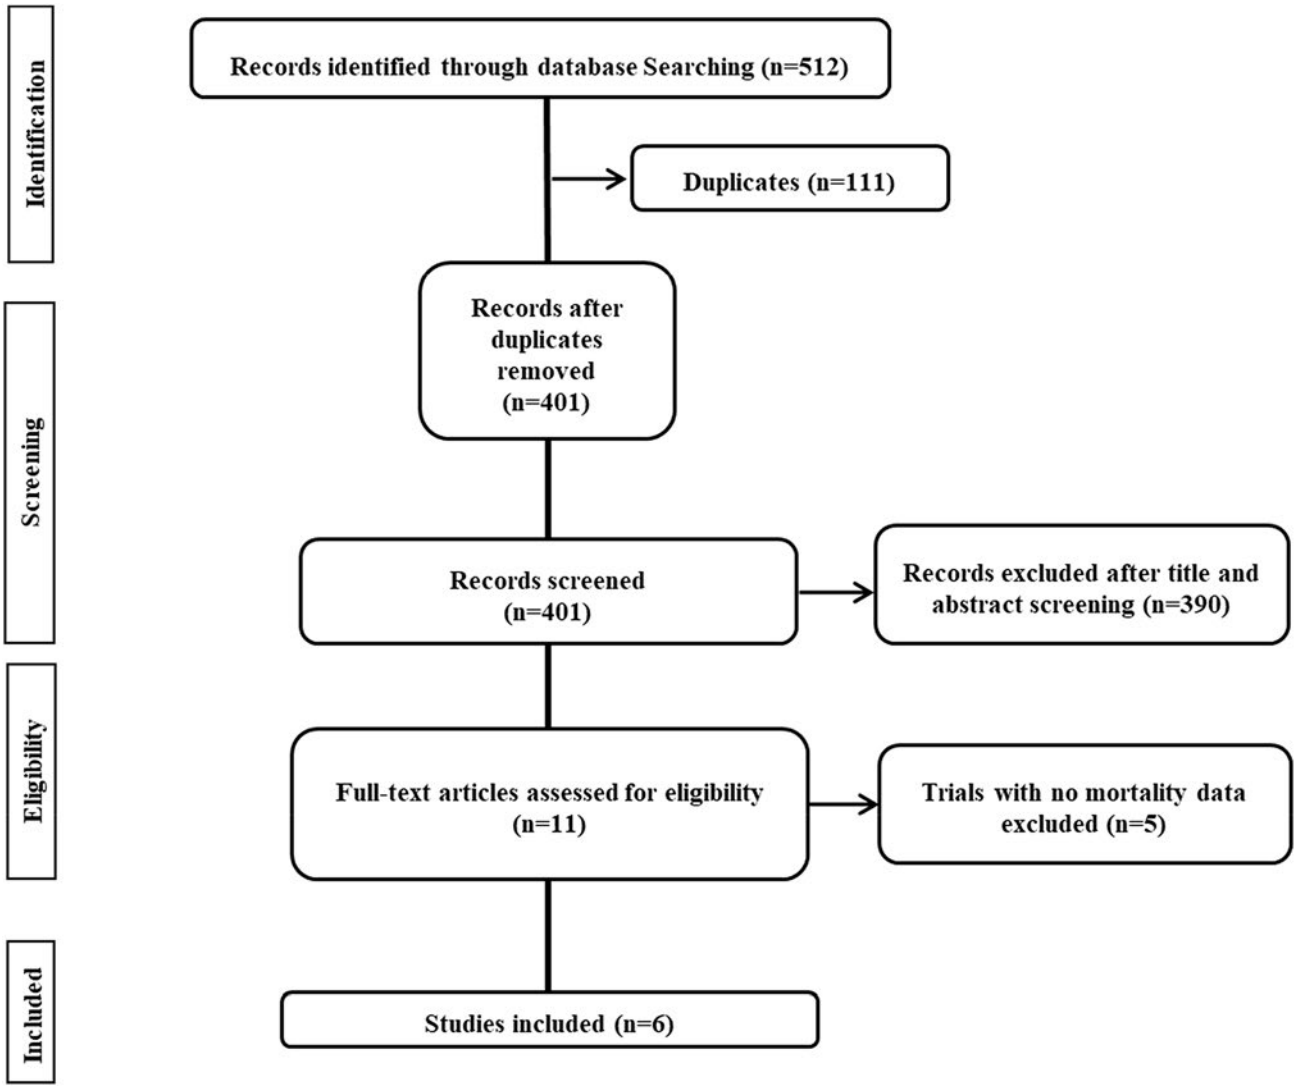

Fig. 1 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) flow diagram of process of study selection

ivermectin to hasten clinical recovery in which a higher proportion of patients achieved clinical improvement (inconsistently defined across the included trials) in the ivermectin group compared to the control group (60.7% versus 44.4% in the trial by Mahmud et al. [7]; 96.5% versus 62.0% in the trial by Elgazzar et al. [8]; and 46.7% versus 36.7% trial by Okumuş et al. [9]). Besides, ivermectin could also prevent clinical deterioration in patients with COVID-19 wherein a lower proportion of patients deteriorated clinically (inconsistently defined across the included trials) in the ivermectin group compared to the control group (4.3% versus 10.0% in the trial by Hashim et al. [5]; 8.7% versus 17.8% in the trial by Mahmud et al. [7]; and 2.5% versus 26.0% in the trial by Elgazzar et al. [8]).

Noteworthily, the use of hydroxychloroquine in the treatment arm in the trial by Niaee et al. [6] may have confounded study outcomes. The trial by Hashim et al. [5] also offered doxycycline along with ivermectin in the intervention arm along with the standard care that also included azithromycin and corticosteroids (dexamethasone or methylprednisolone if needed). Similarly, the study by Elgazzar et al. [8] also included a complex treatment regimen where trial subjects also received azithromycin, vitamin C, zinc, lactoferrin, acetylcysteine, and prophylactic or therapeutic anticoagulation in addition to ivermectin; this was compared with a controlled group that received hydroxychloroquine. There was a potentially higher risk of cardiac arrhythmia in the control group that may have confounded the higher mortality observed (2 deaths versus 24 deaths in treatment and control groups, respectively). Indeed, RECOVERY trial had previously demonstrated a greater risk of cardiac death in COVID-19 patients on

Table 1 Characteristics of included randomized trials

Study	Study design	Country	Age (median/mean)	Regimen of ivermectin in the intervention group	Regimen of comparative intervention in the controlled group	Mortality		Risk of bias[1]
						Ivermectin users (*n*/*N*; %)	Non-ivermectin users (*n*/*N*; %)	
Hashim et al. [5]	Randomized, single-blind, controlled trial	Iraq	Ivermectin users = 50.1 Non-ivermectin users = 47.2	Oral ivermectin 200 mcg/kg per day for two days, and in patients who needed more time to recover, a third dose of 200 mcg/kg per day was given 7 days after the first dose + oral doxycycline 100 mg every 12 h for 5–10 days + standard care	Standard care (acetaminophen 500 mg if needed, vitamin C 1000 mg twice daily, zinc 75–125 mg daily, vitamin D3 5000 IU daily, azithromycin 250 mg daily for 5 days, dexamethazone 6 mg daily or methylprednisolone 40 mg twice daily, if needed)	2/70; 2.9	6/70; 8.6	High
Niaee et al. [6]	Randomized, double-blind, placebo-controlled trial	Iran	Ivermectin users = 53–61 Non-ivermectin users = 55–58	First arm: single oral dose ivermectin 200 mcg/kg Second arm: three low interval oral doses of ivermectin (200 mcg/kg) in 1, 3, and 5 interval days Third arm: single oral dose ivermectin 400 mcg/kg Forth arm: three high interval oral doses of ivermectin (400, 200, 200 mcg/kg) in 1, 3, and 5 interval days	Placebo or oral hydroxychloroquine 200 mg/kg twice daily	4/120; 3.3	11/60; 18.3	Low

hydroxychloroquine [12]. On the other hand, the trial by Okumuş et al. [9] included hydroxychloroquine, favipiravir (a broad-spectrum antiviral drug), and azithromycin as part of the standard care in addition to ivermectin. It is worth mentioning that the randomized controlled trials by Niaaee et al. [6], Elgazzar et al. [8], and Okumuş et al. [9] contributed over 70% weight in this meta-analysis and therefore a more conclusive clinical evidence is still warranted to confirm the mortality benefits.

In addition, the reporting of adverse events in the included trials had been poor. Only two trials included the details on the safety of ivermectin in patients with COVID-19; the trial led by Mahmud et al. [7] reported erosive esophagitis in one patient in the treatment arm (ivermectin + doxycycline) but the use of doxycycline was likely the culprit, since doxycycline alone is one of the most common causes of drug-induced esophageal ulcers [13]; the trial led by Okumuş et al. [9] reported nausea and vomiting in two patients and increased serum levels of liver enzymes in one patient, but without serious adverse events or treatment-related adverse events with ivermectin.

We were aware of at least one treatment protocol of COVID-19 [14] at the time of writing this manuscript that recommended the use of ivermectin in patients with COVID-19. Given the reported mortality benefits with ivermectin are still preliminary, we suggest that ivermectin should preferably be administered under clinical trial settings until warranted by more conclusive large-scale randomized controlled trials.

Macrocyclic lactones

ABSTRACT

Melarsomine dihydrochloride (Immiticide®, Merial) is the only approved adulticidal drug for the treatment of canine heartworm disease (HWD). However, in cases where arsenical therapy is not possible or is contraindicated, a monthly heartworm preventive along with doxycycline for a 4-week period, which targets the bacterial endosymbiont *Wolbachia*, might be considered. There are published reports on the efficacy of ivermectin and doxycycline in both experimentally and naturally infected dogs, but no data on the use of other macrocyclic lactones (MLs) with a similar treatment regime. Preliminary results of studies in dogs show that a topical formulation of moxidectin, the only ML currently registered as a microfilaricide, is also adulticidal when combined with doxycycline. It is not yet known if the efficacy of these combination therapies is due to pharmacokinetic synergism. A recent study showed that serum levels of doxycycline in dogs treated with the combination protocol were not statistically different compared to dogs treated with doxycycline alone. However, lungs from dogs treated with the combination therapy showed a marked reduction in T regulatory cells, indicating that treatment efficacy may be due to a heightened immune response against the parasite. Further studies are necessary to evaluate the long-term clinical outcome of combination protocols and to establish the most efficient treatment for HWD in dogs.

1. Introduction

Canine heartworm disease (HWD) is caused by the filarial nematode *Dirofilaria immitis*, a vector-borne parasite transmitted by several mosquito species. The presence of adult worms in the pulmonary arteries of infected dogs causes changes in arterial structure and function that can lead to pulmonary hypertension and, eventually, to right-sided congestive heart failure (Bowman and Atkins, 2009).

The disease is endemic in many parts of the world and currently affected areas in Europe include Spain (including the Canary Islands), Portugal, the south of France, parts of southern Switzerland, Italy, Greece, Turkey, the Czech Republic, Slovenia, Romania and Bulgaria (Genchi et al., 2014). There are several factors that may explain the spread of the parasite from endemic areas to previously unaffected areas, including climate change, density of the vector population and the movement of microfilaraemic dogs that travel throughout Europe for holidays or as “rescue” adoptions.

Melarsomine dihydrochloride (Immiticide®, Merial) is the only approved adulticidal drug for treatment of HWD. However, treatment can often be followed by severe pulmonary thrombosis (Kramer et al., 2011) and the drug is not registered for use in many countries. In cases where treatment with melarsomine is not possible or is contraindicated, a monthly heartworm preventive along with doxycycline for a 4-week period, which targets the bacterial endosymbiont *Wolbachia*, might be considered. The following review will discuss the principles behind the combination protocols and the current application of this alternative adulticide strategy in dogs with HWD.

2. *Wolbachia* is an anti-filarial target

The endosymbiont *Wolbachia* was first described in *D. immitis* by Sironi et al. (1995). Since then, *Wolbachia* has been identified in a number of filarial worm species, including several that cause human diseases like elephantiasis (*Wuchereria bancrofti*) and river blindness (*Onchocerca volvulus*) Taylor et al. (2013). Endosymbiosis has been defined as the intimate association between two different organisms maintained through generations because host and symbiont equally benefit from the association. Studies have shown that *Wolbachia* is required for normal parasite development, fertility and long-term survival of different filarial species (Taylor et al., 2013; McCall et al., 2014).

Genetic and molecular studies in the last several years have been aimed at defining exactly what these bacteria do for heartworms and other filarial nematodes (Darby et al., 2012, Godel et al., 2012). Comparison of *Wolbachia* genomes with filarial genomes have revealed that these nematodes have become dependent on their endosymbionts for a wide range of biological processes, including the production of important metabolites like heme, nucleotides and riboflavin (Darby et al., 2012; Scott et al., 2012). This was confirmed by the recent sequencing of the *D. immitis*-derived *Wolbachia* genome. Indeed, heartworm *Wolbachia* encode enzymes for anabolic pathways that are missing in the worm such as biosynthesis of heme, purine, and pyrimidines (Godel et al., 2012). Thus, current research is aimed at the removal of *Wolbachia* through antibiotic treatment of infected hosts as an adulticide strategy.

3. Doxycycline and canine HWD

Elimination of *Wolbachia* is detrimental for the filarial worm and studies on different filarial species including *O. volvulus, W. bancrofti* and *Brugia pahangi* have shown that doxycycline treatment of infected hosts causes degeneration of oocytes and early embryonic stages, is microfilaricidal and has varying adulticide effects. Death of adult worms usually takes from 18 to 24 months (Taylor et al., 2013).

Several studies have also described the effects of doxycycline in dogs with experimentally acquired HWD. Bazzocchi et al. (2008) reported that following 2–6 weeks, intermittent cycles of doxycycline treatment (10 mg/kg/day) resulted in only 8.6% efficacy against adult worms in experimentally infected dogs. However, this study evaluated worm survival at 8 months post-treatment and, as mentioned above, it is likely that death of adult worms takes longer. In a more recent study (McCall et al., 2014), dogs with experimentally-acquired patent infection were treated with doxycycline for 1 month at 20 mg/kg/day. Worm survival was evaluated at 12 and 13 months post-infection (p.i.) and results suggested that treatment had a slow-kill, adulticidal effect, which was more evident at 13, than at 12 months after doxycycline treatment started. The most interesting result of the study, however, was the inability of microfilariae from doxycycline-treated dogs that developed into infective larvae in mosquitos to successfully develop into adults after subsequent infection in new dogs. This would suggest that *Wolbachia* plays an essential role in parasite development in the mammalian host.

Indeed, doxycycline treatment has also been evaluated for its effect on developing worms. McCall et al (2011) treated experimentally infected dogs with doxycycline for 1 month at 20 mg/kg/day at different time points p.i. with third stage larvae (L3) and then verified the presence of adult worms at 8 months p.i. When doxycycline was administered during the first month p.i., no live worms were observed at necropsy, indicating 100% efficacy against infective larvae. When antibiotic treatment was given starting at 40 days p.i., efficacy against developing worms was 98.4%. Finally, when treatment was initiated 65 days p.i., efficacy against juvenile worms was 69.6%. Interestingly, none of the dogs harboring live worms were microfilariemic.

4. Macrocyclic lactone (ML)/doxycycline combination protocols

As mentioned above, doxycycline has various detrimental effects on developing and adult heartworms, but adulticide efficacy is low and slow. Macrocyclic lactones (MLs) are highly efficacious against L3 and young fourth stage larvae (L4) and prevention of disease is based on this activity. However, preventive doses of MLs have been reported as also having a so-called “slow kill” effect against adult *D. immitis* (for review see McCall, 2005). The effects of MLs on adult worms include neuromuscular dysfunction and degeneration of late-stage embryos, thus also reducing the production of microfilariae. Venco et al. (2004) evaluated the use of monthly preventive doses of ivermectin in naturally infected dogs with HWD and showed that 100% of dogs were negative for circulating microfilariae by 4 months, while 71% became negative for circulating antigens after 24 monthly doses. The study also reported a significant decrease in parasite burden as evaluated by echocardiography. However, signs of pulmonary hypertension and interstitial inflammation increased in approximately 20% of dogs and the authors concluded that this adulticide protocol should be used with caution. Furthermore, the long-term use of ML preventives in dogs with HW infection has been implicated in the development of resistant *D. immitis* strains in the southern United States (Wolstenholme et al., 2015). Thus, any method utilizing only macrocyclic lactones as a slow-kill adulticide is not currently recommended.

The hypothesis that the combination of doxycycline and MLs may have greater activity against adult heartworms than either drug alone was first tested in experimentally-infected dogs (Bazzocchi et al., 2008). Treatment with 2–6 week, intermittent cycles of doxycycline (10 mg/kg/day) combined with weekly preventive doses of ivermectin resulted in 80% adulticide activity. The adulticide effect of ivermectin/doxycycline combination protocols has also been confirmed in naturally infected dogs (Grandi et al., 2010). Importantly, the combination of ivermectin and doxycycline was well tolerated and post-adulticide complications were minimal. Indeed, it has been reported that the elimination of *Wolbachia* results in a marked decrease in pro-inflammatory responses to dead and dying worms (Kramer et al., 2008; Kramer et al., 2011; Mavropoulou et al., 2014).

It is not clear why the two drugs work better together in eliminating a large population of heart-worms in a relatively short period of time (8 – 10 months). It is not yet known if this is due to a simple summation effect or if there exists a certain synergism between the two drugs. Menozzi et al. (2015) evaluated doxycycline levels by high-performance liquid chromatography (HPLC) in sera from *D. immitis*-experimentally infected dogs treated with a combination of ivermectin/doxycycline and compared them with sera from dogs treated with doxycycline alone. Results showed that doxycycline levels were not statistically different between the two groups, suggesting that the adulticide effect is not due to a higher drug concentration of doxycycline in the combination protocol. Passeri et al. (2014) reported there was a significantly lower number of T regulatory cells in the lungs of dogs treated with a combination of both drugs when compared either to the control group or to the other groups treated with either drug alone or with melarsomine. T regulatory cells play an important role in inducing hypo-responsiveness to helminth infections (Maizels et al., 2004; D’Elia et al., 2009), so these results would suggest that successful adulticide effects of doxycycline and ivermectin are associated with a decrease in immune tolerance towards the parasite.

5. The application of ML/doxycycline combination protocols in practice

5.1. Preparation for melarsomine treatment

There have been several reports on the clinical benefits of ML/doxycycline treatment before administration of melarsomine in HW-infected dogs. Indeed, the greatest risk of adulticide therapy is the subsequent rise in pulmonary pressure due to the formation of thrombi around dead and dying worms, together with an intense inflammatory reaction against the parasite. Pre-treatment with MLs/doxy can reduce worm mass and eliminate pro-inflammatory antigens (including *Wolbachia*), thus reducing post-adulticide complications. Kramer et al. (2011) reported that experimentally-infected dogs that received a combined doxycycline/ ivermectin protocol before treatment with melarsomine showed less severe arterial lesions and the virtual absence of thrombi when compared to dogs treated with melarsomine alone. Once HWD has been diagnosed, it is currently recommended to treat dogs with 1 month of doxycycline at 10 mg/kg/BID and with 3 months of monthly preventives; at days 60, 90 and 91, treat with melarsomine with a three-step protocol. Dogs are considered cleared of infection when antigen testing is negative at 6 months post-treatment.

5.2. As an alternative adulticide

As illustrated above, ML/doxycycline combinations have been shown to be adulticidal in both experimentally and naturally-infected dogs. All published studies have concentrated on preventive doses of ivermectin, either weekly or bi-weekly for 6 months, combined with doxycycline at 10 mg/kg either SID or BID (Bazzocchi et al., 2008; Grandi et al., 2010;Mavropoulou et al., 2014). Infected dogs usually begin to be negative for circulating antigens at about 12 months from the beginning of therapy. Treatment is well-tolerated with minimal radiological and clinical signs.

A recent report has evaluated the effects of another ML in combination with doxycycline. Topical moxidectin (Advantage Multi®, Bayer) is active against infective L3-L4 larvae and against circulating microfilariae. Savadelis et al. (2016) reported in *D. immitis*-experimentally infected dogs that 9 monthly doses of topical moxidectin combined with 30 days of 10 mg/kg doxycycline BID resulted in the elimination of microfilariae by 21 days post-treatment, thus breaking the transmission cycle of the parasite very quickly. Furthermore, heartworm antigen began declining 3 months post-treatment and treatment resulted in a 95.9% efficacy in eliminating mature adult heartworms by 10 months, indicating a more marked adulticidal effect compared to that of combinations with ivermectin. It is well documented that orally administered macrocyclic lactones have a typical specific pharmacokinetic (PK) pattern showing a high peak and a very short half live and thus a very short exposure to the worm. This is dose dependent of course, but even with higher doses the general PK pattern does not change (Daurio et al., 1992). In contrast, the moxidectin PK for the spot on formulation is much different with a peak establishing several days following application, a half-life of about 28 days, and the development of a steady state level after about 4 months, ensuring a constant and high exposure of the parasite to the drug (Bowman et al., 2016).

6. Conclusions

Doxycycline and ML combinations are adulticidal for *D. immitis*. Research should, however, continue for the identification of other anti-*Wolbachia* molecules and targets. It is also necessary to further study the interaction between MLs and doxycycline/others in order to determine the best combination protocol in terms of clinical and parasitological response. Finally, as is true for any treatment of any sick dog, it is always necessary to periodically monitor the patient's response to therapy.

Received 22 July 2008/Accepted 6 October 2008

We have discovered two metal ion binding compounds, pyrithione (PT) and hinokitiol (HK), that efficiently inhibit human rhinovirus, coxsackievirus, and mengovirus multiplication. Early stages of virus infection are unaffected by these compounds. However, the cleavage of the cellular eukaryotic translation initiation factor eIF4GI by the rhinoviral 2A protease was abolished in the presence of PT and HK. We further show that these compounds inhibit picornavirus replication by interfering with proper processing of the viral polyprotein. In addition, we provide evidence that these structurally unrelated compounds lead to a rapid import of extracellular zinc ions into cells. Imported Zn^{2+} was found to be localized in punctate structures, as well as in mitochondria. The observed elevated level of zinc ions was reversible when the compounds were removed. As the antiviral activity of these compounds requires the continuous presence of the zinc ionophore PT, HK, or pyrrolidine-dithiocarbamate, the requirement for zinc ions for the antiviral activity is further substantiated. Therefore, an increase in intracellular zinc levels provides the basis for a new antipicornavirus mechanism.

Curing virus infections harbors an enormous economic potential, and the search for new antiviral substances is of great interest for worldwide health. We have previously described the commonly used NF-κB inhibitor and metal ion chelator pyrrolidine-dithiocarbamate (PDTC) to significantly inhibit the replication of several picornaviruses such as human rhinovirus (HRV), poliovirus, coxsackievirus, and mengovirus (9, 22). These examples suggest that a common step in the life cycle of these picornaviruses is the target for the antiviral drug. In particular, we have demonstrated that PDTC has negative effects on picornavirus replication by influencing the processing of the viral polyprotein (21, 22).

The antiviral activity of PDTC is not restricted to the family *Picornaviridae*, since PDTC was shown to prevent the multiplication of human influenza virus, a member of the *Orthomyxoviridae* (33, 34). However, due to strong differences in the life cycle and host-cell interaction between human influenza virus and picornaviruses, it is likely that entirely different mechanisms might be relevant for the antiviral action of PDTC against these viruses.

Currently, the precise mode of the antiviral action of PDTC is unknown, although several theories have been substantiated with experimental evidence. Antioxidative properties of PDTC are postulated to be the reason for antiviral effects against influenza virus infections (33), which is not the case for human rhinovirus multiplication (9).

We have demonstrated that the antiviral effects of PDTC are metal ion dependent, and, in particular, Zn^{2+} ions play a pivotal role. To underline the hypothesis that influx of zinc into the cells has antiviral capacity, pyrithione (PT) and hinokitiol (HK) were examined. PT is known to be a zinc ionophore that leads to a rapid increase in intracellular zinc levels (27), and HK is a chelator of divalent metal ions (2).

We provide evidence that both PT and HK inhibit replication of picornaviruses by impairing viral polyprotein processing. The basis of the antiviral activity is dependent upon the availability of zinc ions. We show that the import of extracellular zinc ions is a key feature of the common antiviral property of these compounds.

MATERIALS AND METHODS

Cell, media, and reagents. HeLa cells (strain Ohio; European Collection of Cell Cultures, Salisbury, United Kingdom) were cultured in RPMI 1640 supplemented with 10% heat-inactivated fetal calf serum, 2 mM L-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin (all obtained from Gibco, Invitrogen, Austria). PDTC (pyrrolidine-dithiocarbamate ammonium salt), pyrithione (2-mercaptopyridine *N*-oxide sodium salt), Zn-EDTA, Ca-EDTA, Mg-EDTA, and *N*,*N*,*N*′,*N*′-tetrakis (2-pyridylmethyl) ethylenediamine (TPEN) were purchased from Sigma-Aldrich, Austria. HK (β-thujaplicin) from Calbiochem was dissolved in dimethyl sulfoxide and stored at −20°C.

Virus preparation and titration. Strain HRV2 was obtained from the American Type Culture Collection and routinely grown in suspension cultures of HeLa cells (strain Ohio; Flow Laboratories, McLean, VA) as described previously (31). CVB3 (Nancy strain) was derived from transcription of the p53CVB3/T7 plasmid (36). The mengovirus strain EMCV was obtained upon transfection of in vitro-transcribed RNA from cDNA clone pM16.1 (5).

Virus titers in 50% tissue culture infectious doses ($TCID_{50}$) were determined according to Reed and Muench (26). From our experience, typical interassay variation is less than ±0.5 log $TCID_{50}$/ml.

Infection of cells. HeLa cells were grown in six-well plates and infected at 70% confluence with HRV2 with indicated multiplicity of infection (MOI) in RPMI medium supplemented with 2% fetal calf serum, 2 mM L-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin. After 2 h of infection, input virus was removed, and cells were washed three times with acidic HEPES buffer and once with phosphate-buffered saline (PBS). For further incubation, infection medium was applied for the indicated amounts of times. If indicated, chemicals were present during parts or the whole period of infection. Whenever HK was used,

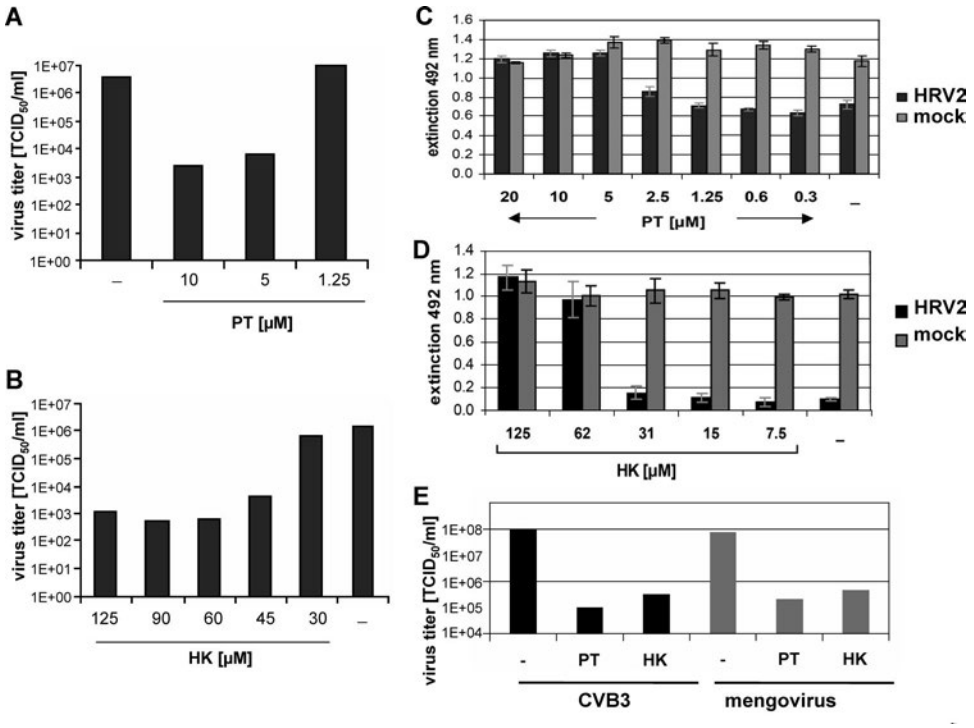

FIG. 1. PT and HK dramatically reduce picornavirus multiplication and increase cell viability. Viral titers of HRV2-infected HeLa cells (MOI = 20) in the presence or absence of indicated concentrations of PT (A) or HK plus 30 mM $MgCl_2$ (B) were determined 24 h p.i. Results for one representative experiment of three experiments are shown. HeLa cells were infected with HRV2 (MOI = 50) or mock infected, and different concentrations of PT (C) or HK-$MgCl_2$ (D) were added. At 24 h p.i., a CellTiter 96 AQ_{ueous} nonradioactive cell proliferation assay was performed according to the manufacturer's protocol. Extinction at 492 nm reflects cell viability. The means ± standard deviations of quintuples obtained in one representative experiment of three performed are shown. (E) HeLa cells were infected with CVB3 or mengovirus (MOI = 10) and incubated with 10 μM PT or 75 μM HK-30 mM $MgCl_2$, respectively. Virus production of infected cells was determined by $TCID_{50}$ assay at 24 h p.i. The results for one of two representative experiments are shown. −, control.

application of 30 mM $MgCl_2$ was essential to avoid cytotoxicity. Virus production was determined in the supernatants of infected cells by $TCID_{50}$ determination.

Confluent monolayers of HeLa cells were infected with CVB3 or mengovirus for 30 min. Cells were then washed twice with PBS and cultured in medium at 37°C in the presence or absence of indicated chemicals. At indicated time points, the cells were disrupted by three cycles of freezing and thawing, and virus titers were determined by end point titration.

Cell viability assay. HeLa cells were infected with HRV2 (MOI = 50) or mock infected in the presence or absence of different concentrations of PT or HK-$MgCl_2$. At 24 h postinfection (p.i.), a CellTiter 96 AQ_{ueous} nonradioactive cell proliferation assay (Promega, WI) was performed according to the manufacturer's protocol. Extinction at 492 nm reflecting cell viability was measured in a Labsystems Multiscan RC plate reader.

Western blot analysis. HeLa cells were infected with HRV2 as described for virus infection. At 0, 2, 4, 6, 8, and 24 h p.i., the medium was removed, and the cells were lysed by the addition of protein sample buffer. Protein extracts were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), electroblotted onto polyvinylidene difluoride membranes, and analyzed using a rabbit polyclonal antibody against eIF4GI (37), as described previously (9).

Pulse-labeling and immunoprecipitation. HeLa cells were preincubated with 10 μM PT or 125 μM HK-30 mM $MgCl_2$ for 30 min and infected with HRV2 (MOI = 50) in the presence of the substances. At 6 h p.i., newly synthesized proteins were labeled with [^{32}S]Met/Cys (Hartmann Analytic, Germany) for 1 hour. At 7, 8, and 9 h p.i., VP2 or VP2-comprising precursor proteins were isolated by immunoprecipitation using the monoclonal VP2-specific 8F5 antibodies (30) and analyzed by SDS-PAGE and autoradiography as described previously (21).

HeLa cells infected with CVB3 (MOI = 50) were incubated with 125 μM PDTC, 75 μM HK-30 mM $MgCl_2$, or 10 μM PT in the presence or absence of 10 μM TPEN. Five hours p.i., cells were starved half an hour prior to 1 h of labeling with [^{35}S]Met/Cys. After labeling, cells were lysed, and cellular extracts were subjected to immunoprecipitation using either antibodies specific for 3D or 3C (kindly provided by C. Cameron, Pennsylvania State University) as described previously (22). Then, the protein pattern was analyzed by SDS-PAGE and autoradiography.

Radioactive zinc uptake studies. HeLa cells in serum-free culture medium (zinc concentration of 0.6 μM as measured by atomic absorption analysis) were incubated with 5 μM $^{65}Zn^{2+}$ (0.82 mCi/mg Zn^{2+}; Hartmann Analytic, Germany) in the presence of indicated concentrations of PDTC, PT, or HK-$MgCl_2$. At the indicated time points, the cells were harvested by filtration on GF/C glass fiber filters (Whatman, Maidstone, United Kingdom). To remove extracellular $^{65}Zn^{2+}$, filters were washed with a buffer containing EDTA (15 mM HEPES, 100 mM glucose, 150 mM KCl, 1 mM EDTA [pH 7]), and the amount of intracellular $^{65}Zn^{2+}$ was determined in a Packard Cobra II γ-counter.

Fluorescence microscopy. HeLa cells grown in μ-slide VI slides (Ibidi, Germany) were loaded with 5 μM FluoZin-3 acetoxymethyl ester (Invitrogen) or 1 μM RhodZin-3 acetoxymethyl ester (Invitrogen) in PBS for 15 min at 37°C. Subsequently, cells were incubated for 1 h in growth medium to allow deesterification. Then, PDTC, PT, or HK was added to the medium for the indicated incubation times. In some experiments, chemicals were removed after 30 min, and fresh medium was applied for 1 h. Fluorescence was monitored in a live-cell microscope system (Olympus cellR) using fluorescein isothiocyanate settings for FluoZin-3 and Cy3 settings for RhodZin-3. A Hamamatsu Photonics Orca-ER camera was used.

RESULTS AND DISCUSSION

PT and HK inhibit picornavirus multiplication and increase cell viability of infected cells. We have previously discovered that the drug PDTC substantially interferes with the multiplication of several picornaviruses (9, 22). These antiviral

FOI 26-3132 - Document 5

effects of PDTC are dependent on metal ions, in particular zinc ions. To further substantiate the hypothesis that zinc ions play a major role in virus inhibition, two structurally different metal ion binding compounds, PT (4, 12, 17, 35) and HK (2, 23, 32), were analyzed regarding their effects on HRV production (Fig. 1). HeLa cells were infected with HRV serotype 2 with an MOI of 20 in the presence or absence of PT or HK. At 24 h p.i., supernatants were collected, and virus titers were determined. The presence of 5 μM and 10 μM PT decreased viral titers by around 3 orders of magnitude (Fig. 1A). Likewise, HK significantly diminished viral multiplication in a dose-dependent manner (Fig. 1B). Similar results were obtained using a different HRV serotype (HRV14) or an alveolar carcinoma cell line (A549) (data not shown).

To quantify cell viability a colorimetric viability assay was performed. HeLa cells infected with HRV2 showed a significant loss of viability 24 h p.i. (Fig. 1C and D). In contrast, PT (Fig. 1C) and HK (Fig. 1D) retained viability to normal levels at concentrations between 5 μM and 20 μM PT and 62 μM and 125 μM HK, respectively. Based on additional experiments, 50% inhibitory concentrations of 3 μM for PT and 42 μM for HK were determined. Importantly, no cytotoxicity of PT and HK was found in mock-infected HeLa cells (Fig. 1C and D, gray bars) and A549 cells (data not shown) under these conditions. The absence of cytotoxicity is in contrast to reports about proapoptotic activities of PT and HK in other cell lines such as HL-60 cells (15, 19, 20).

It is of great interest to investigate whether PT and HK act specifically for HRV or whether these drugs target a common step in the picornavirus life cycle. Thus, the role of PT and HK during infection with coxsackievirus strain B3 (CVB3) and the mengovirus strain EMCV (which will hereafter be referred to as mengovirus) was examined (Fig. 1E). In a single-round infection experiment with CVB3 or mengovirus, viral titers of around 10^8 $TCID_{50}$/ml were obtained. In the presence of PT or HK, the titers were significantly reduced by around 3 and 2 orders of magnitude, respectively. These data are in agreement with the antiviral activities of PDTC against these viruses that were reported previously (22).

PT and HK abolish eIF4GI cleavage and affect viral polyprotein processing. Different steps of the HRV infection in the presence of PT or HK were studied to analyze whether PT and HK act mechanistically similar to PDTC. Early events in the viral life cycle, such as virus entry and uncoating, were not affected by PT and HK (data not shown). A hallmark of rhinovirus infection is the cleavage of the eukaryotic translation initiation factors eIF4GI and eIF4GII by the viral $2A^{pro}$ (7, 11), leading to the shutoff of host-cell protein synthesis (8). To test whether PT and HK affect eIF4GI cleavage, protein extracts of HRV2-infected cells were analyzed by Western blotting (Fig. 2A). In the absence of PT or HK, around 50% cleavage of eIF4GI was obtained at 4 h p.i. At 6 h and 8 h p.i., eIF4GI was nearly completely processed into its typical cleavage products. In the presence of PT or HK, no significant amounts of eIF4GI cleavage products were found within 24 h of infection. This is in agreement with data obtained with PDTC (9).

As PDTC shows a clear inhibition of viral polyprotein processing (21), P1 processing was also examined in the

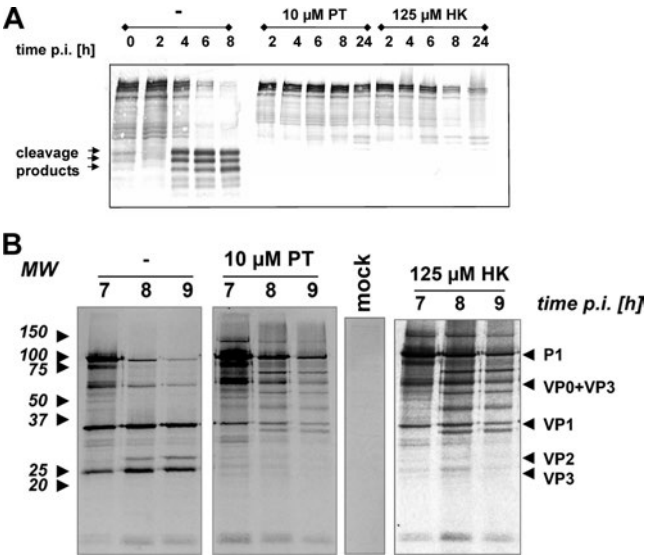

FIG. 2. PT and HK abolish HRV2-triggered eIF4GI cleavage and affect viral polyprotein processing. (A) HRV2-infected HeLa cells (MOI = 20) were either mock treated or treated with 10 μM PT or 125 μM HK-30 mM $MgCl_2$. After the indicated time points, protein extracts were collected and analyzed by Western blotting using an antibody specific for eIF4GI and its cleavage products. (B) HeLa cells were preincubated with 10 μM PT or 125 μM HK-30 mM $MgCl_2$ for 30 min and infected with HRV2 (MOI = 50) in the presence of the substances. At 6 h p.i., newly synthesized proteins were labeled with [^{32}S]Met/Cys for 1 hour. At the indicated time points, VP2 or VP2-containing precursor proteins were isolated by immunoprecipitation and analyzed by SDS-PAGE and autoradiography. Immunoprecipitation of mock-infected labeled cells did not show any signal. MW, molecular weight in thousands.

presence of PT or HK (Fig. 2B) by a pulse-chase labeling experiment, followed by immunoprecipitation with a VP2-specific antibody, 8F5, which pulls down VP2, VP2-containing precursors, and viral proteins bound to VP2 (30). Labeling of viral proteins started at 6 h p.i. for 60 min, and subsequently, cell lysates were prepared every hour. In untreated cells, the processing of the P1 precursor protein was clearly visible between 7 h and 9 h p.i. as a reduction of the amount of the corresponding polyprotein band. At the same time, smaller bands comprising VP2 and VP3 appeared. In the presence of either PT or HK, the processing of the P1 protein was blocked, and no mature VP2 or VP3 products could be detected. Moreover, various intermediate processing products were obtained in the presence of PT or HK, giving an identical picture to the processing defects observed using PDTC (21).

To specifically monitor the activity of $3CD^{pro}$, which is responsible for the processing of the P1 region and which autocleaves itself into $3C^{pro}$ and $3D^{pol}$, the polyprotein-processing pattern of coxsackievirus infection in the presence of PDTC, PT, and HK was investigated (Fig. 3). CVB3-infected HeLa cells incubated with PDTC, HK, or PT were starved half an hour prior to 1 h of labeling at 5.5 h p.i. Subsequently, immunoprecipitation experiments using polyclonal antibodies raised against CVB3 $3C^{pro}$ and $3D^{pol}$ were performed and analyzed as described above. PDTC, PT, and HK abolished coxsackievirus polyprotein processing into the

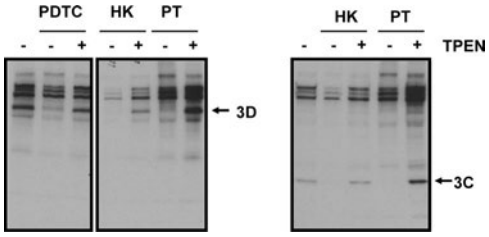

FIG. 3. PT and HK abrogate 3D and 3C processing of CVB3. HeLa cells infected with coxsackievirus B3 (MOI = 50) were incubated with 125 μM PDTC, 75 μM HK-30 mM $MgCl_2$, or 10 μM PT in the presence or absence of 10 μM TPEN. At 5 h p.i., cells were starved half an hour prior to 1 h of labeling with [^{35}S]Met/Cys. Harvested cell lysates were subjected to immunoprecipitation using either antibodies specific for 3D (left panel) or 3C (right panel) and then analyzed by SDS-PAGE and autoradiography. Results for a representative experiment are shown. −, TPEN absent; +, TPEN present.

mature viral proteins 3D and 3C in a similar manner indicating a common antiviral mechanism of all three compounds. The presence of 10 μM of the strong metal ion chelator TPEN restored viral polyprotein processing, suggesting that the observed inhibition is based on the availability of metal ions.

These data indicate that polyprotein processing of picornaviruses is a sensitive step for treatment with zinc ionophores. We have evidence that viruses such as respiratory syncytial virus (belonging to the family of *Paramyxoviridae*) which do not depend on polyprotein processing during their life cycle are not inhibited by PDTC treatment (data not shown). An unspecific adverse effect of PDTC on general cellular functions that lead to virus inhibition is therefore unlikely.

EDTA abolishes the antipicornavirus effects of PT and HK. We and others have shown that treatment with PDTC or PT leads to a rapid elevation of the concentration of free cytoplasmic Zn^{2+} ions (6, 22, 16–18). The importance of metal ions was further substantiated by experiments using EDTA as a general extracellular metal ion chelator (Fig. 4). In the presence of 10 μM EDTA, the antiviral properties of PT and HK against HRV2 (Fig. 4A), CVB3 (Fig. 4B), and mengovirus (Fig. 4C) are lost, indicating the involvement of metal ions. By using Zn^{2+}-, Ca^{2+}-, or Mg^{2+}-saturated EDTA (25), we demonstrate that only Zn-EDTA retains the antiviral property of PT or HK. This indicates that the availability of Zn^{2+} ions is a prerequisite for the antiviral activity of these compounds. None of the EDTA-metal ion complexes alone had any antiviral effect at the concentrations tested.

PDTC, PT, and HK treatments cause a rapid and efficient influx of $^{65}Zn^{2+}$ into cells. It is unclear whether PDTC, PT, and HK mobilize zinc ions localized in intracellular storage vesicles or allow extracellular ions to enter the cytoplasm. To directly monitor import of extracellular zinc ions into HeLa cells, we employed radioactive $^{65}Zn^{2+}$ to determine the effects of PT, HK, and PDTC on zinc import (Fig. 5A). HeLa cells were incubated for different time periods with 5 μM $^{65}Zn^{2+}$ and PDTC, PT, or HK and then harvested by filtration on GF/C glass fiber filters. The amount of intracellular $^{65}Zn^{2+}$ was measured by γ-counting of the filter membranes. In the presence of $^{65}Zn^{2+}$ alone, no significant increase in radioac-

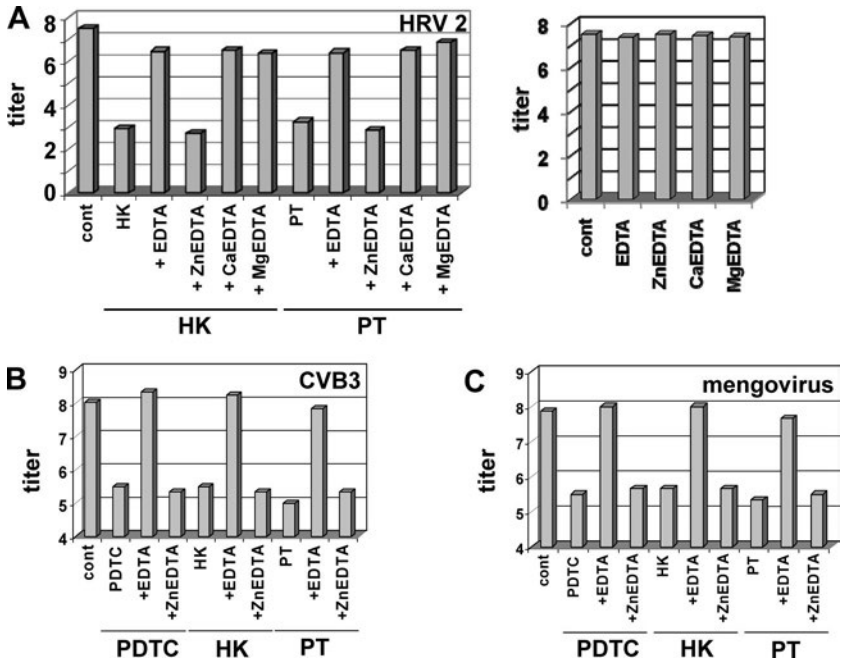

FIG. 4. Zinc ions are responsible for the antiviral property of PT and HK. HeLa cells were infected with HRV2 (MOI = 20) (A), CVB3 (MOI = 10) (B), or mengovirus (MOI = 10) (C) and incubated with 10 μM EDTA or 10 μM of Zn-EDTA, Ca-EDTA, and Mg-EDTA, respectively. If indicated, 10 μM PT (A, B, and C), 125 μM HK-30 mM $MgCl_2$ (A), or 75 μM HK-$MgCl_2$ (B and C) was added at the time of infection. The virus titers in the supernatants of the infected cells were determined by a $TCID_{50}$ assay at 24 h p.i. and shown as log $TCID_{50}$/ml. Viral infection without addition of compounds is labeled as "cont." The results for one representative experiment of three are shown.

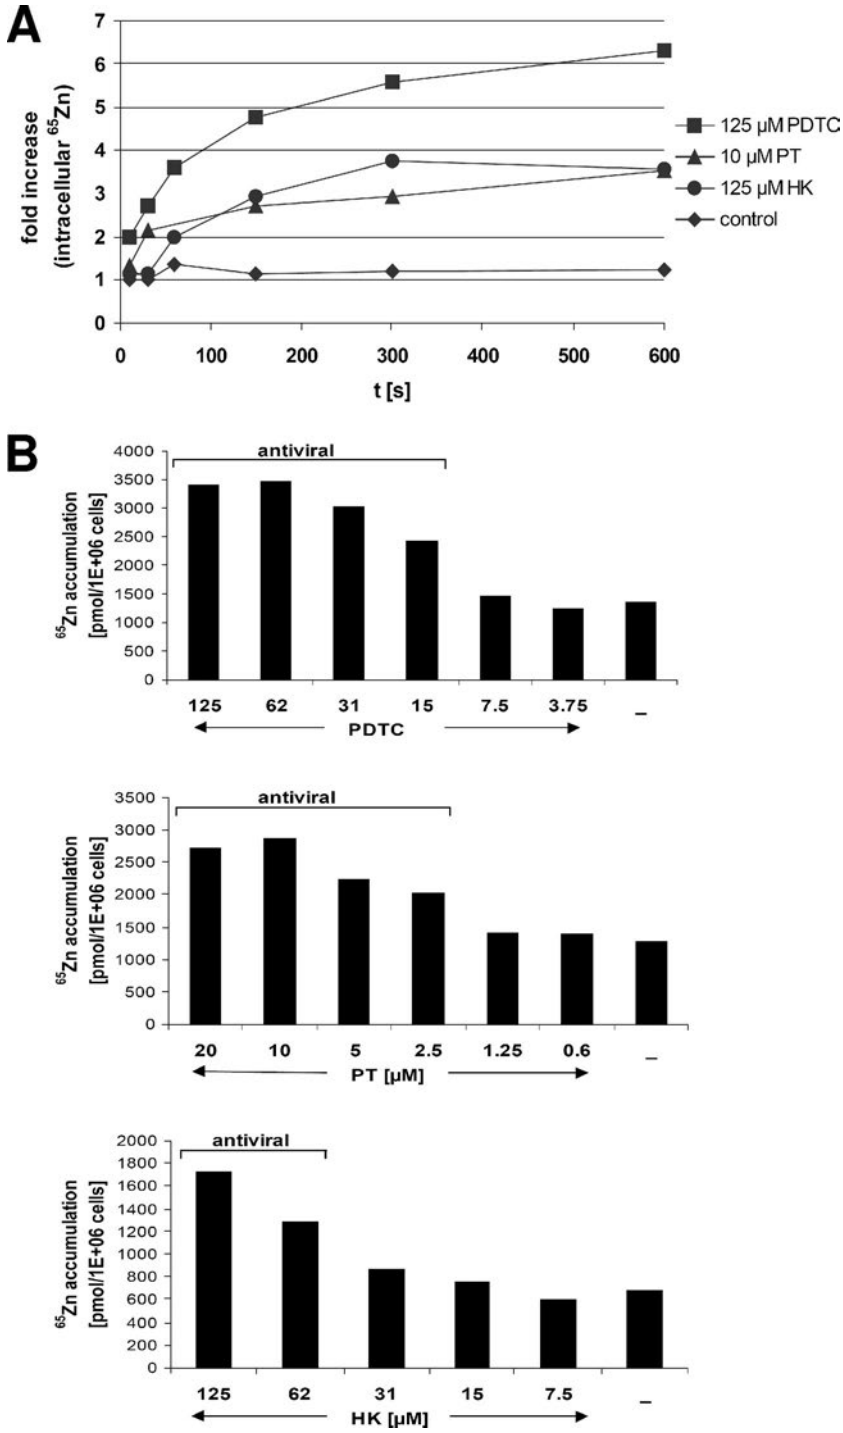

FIG. 5. PDTC, PT, and HK cause import of extracellular $^{65}Zn^{2+}$ levels in a dose-dependent manner. (A) HeLa cells in serum-free culture medium were incubated with 5 μM $^{65}Zn^{2+}$ and 125 μM PDTC, 10 μM PT, or 125 μM HK-30 mM $MgCl_2$. At the indicated time points, the cells were harvested and washed with a buffer containing EDTA, and the amount of intracellular $^{65}Zn^{2+}$ was determined in a Packard Cobra II γ-counter. Statistical variations between different samples are determined to be a maximal ±10% (data not shown). The results for one of three experiments are shown. (B) HeLa cells in serum-free culture medium were incubated with 5 μM $^{65}Zn^{2+}$ and various concentrations of PDTC (top panel), PT (middle panel), or HK-$MgCl_2$ (lower panel) for 15 min. Then, the cells were collected and washed, and the amount of intracellular $^{65}Zn^{2+}$ was determined as described above. The results for one of five experiments are shown.

tivity of the collected cells was measured, whereas the presence of either PT or HK facilitated a threefold increase of intracellular $^{65}Zn^{2+}$ within a few minutes. PDTC elevated the intracellular $^{65}Zn^{2+}$ level sixfold. These results demonstrate that all three substances facilitate import of extracellular zinc ions via a rapid uptake mechanism.

As shown in Fig. 5B, this zinc uptake is dose dependent. The presence of more than 15 μM PDTC, 2.5 μM PT, or 62 μM HK

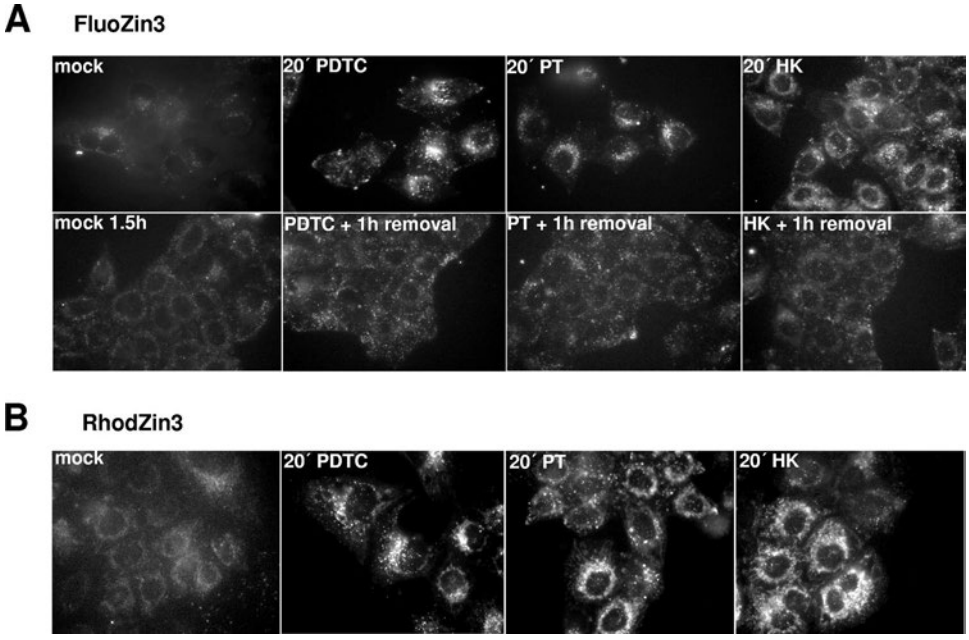

FIG. 6. Zinc ionophores influence the labile Zn^{2+} pool. HeLa cells were loaded with 5 μM FluoZin-3 (A) or 1 μM RhodZin-3 (B) in PBS for 15 min at 37°C. After extensive washing and 1 h of de-esterification in medium, zinc uptake was induced by treatment with 125 μM PDTC, 10 μM PT, and 125 μM HK-30 mM $MgCl_2$ in growth medium. If indicated, after 30 min of chemical treatment, ionophores were removed for 1 hour (PDTC + 1 h removal, PT + 1 h removal, HK + 1 h removal). Pictures were taken at the indicated time points by live fluorescence microscopy with 60× optics. Examples of images of three independent experiments were chosen.

caused significant $^{65}Zn^{2+}$ uptake after 15 min. It is noteworthy that this concentration range was found to be antiviral (Fig. 1) (9), suggesting that the influx of zinc ions is essential for mediating the common antiviral property of these compounds.

Intracellular localization of zinc ions imported via PT, HK, and PDTC. To directly visualize the ability of PDTC, PT, and HK to increase the intracellular pool of labile Zn^{2+}, specific zinc indicators were used (Fig. 6). FluoZin-3 is a Zn^{2+}-sensitive and -specific fluorescent probe that has no specific cellular localization (14). In cells loaded with FluoZin-3, intracellular fluorescence was minimal (Fig. 6A, top panel) due to a very low level of free zinc ions (24). After induction with 10 μM PT, 125 μM PDTC, or 125 μM HK, a rapid and significant increase in fluorescence was found reflecting an elevation of the intracellular labile "chelatable" zinc level. Noteworthy, these experiments were carried out in normal growth medium and apparently the Zn^{2+} concentration present in the medium is sufficient to lead to ionophore-mediated zinc ion transport.

The observed punctate pattern of FluoZin-3 fluorescence is in agreement with recent data from rainbow trout cells incubated with high levels of extracellular zinc (24). In a large variety of mammalian cell types, vesicular storage sites for zinc which have been designated "zincosomes" can be detected (1). Zincosomes play a role in detoxifying excess zinc and are suggested to colocalize with endosomal compartments and lysosomes (13).

The uptake of zinc ions is reversible. When the zinc ionophores PDTC, PT, and HK were removed, the fluorescence declined close to background within 1 h (Fig. 6A, bottom panel).

To specifically monitor the free mitochondrial zinc pool, RhodZin-3 was used (28). HeLa cells loaded with RhodZin-3 exhibited a very weak fluorescence, indicating low levels of labile Zn^{2+} inside the mitochondrial compartment (Fig. 6B). In contrast, upon 20 min of treatment with PDTC, PT, or HK, the signal of RhodZin-3 fluorescence was strongly enhanced. This mitochondrial localized signal was found to be constant over at least 80 min of PT incubation (data not shown). The role of a labile Zn^{2+} fraction in mitochondria during viral infection is currently unclear and has to be the subject of further studies.

Concluding remarks. Conclusively, all three antiviral substances are potent zinc ionophores increasing the intracellular pool of labile zinc. This strong elevation is constant as long as the zinc ionophores are present but is reversible after removal of PDTC, PT, or HK.

The reversibility of the elevation of free-zinc concentrations is in agreement with data that we had obtained when virus multiplication was monitored in a setup when PT, HK, and PDTC were present for short intervals only. In contrast to the significant viral titer reduction evoked by permanently present PDTC, PT, or HK, a short (1 h) pulse of zinc ionophore treatment between 2 h and 5 h p.i. was not sufficient to significantly reduce viral titers (data not shown). These data indicate that a prolonged presence of ionophores during viral replication is needed to exert antiviral effects. In previous data, we have shown that a clear reduction of virus titer was obtained when PDTC treatment started up to 4 h after infection, continuing to 24 h (9).

In conclusion, we have identified a set of three antiviral compounds against HRV, coxsackievirus, and mengovirus infections, which differ in their chemical structures but appear to use import of zinc ions as a common trigger for exerting their antiviral effect. It was reported that PDTC reduces coxsackie-

virus B3 replication through inhibition of the ubiquitin-proteasome pathway (29). We tested the proteasome inhibitor MG-132 at nontoxic concentrations for antiviral properties against HRV2 and HRV14. However, functional MG-132 concentrations that cause a massive accumulation of ubiquitinylated proteins within 8 h of incubation were not antiviral (data not shown). Thus, proteasomal inhibition is not likely to be the major cause of the antiviral activity of PDTC, PT, or HK.

Importantly, PDTC, PT, and HK lead to efficient import of zinc ions that are naturally present in the cell culture medium. Uptake of Zn^{2+} into cells interferes with the viral life cycle. Already in 1974, Butterworth and colleagues have shown that adding high concentrations of zinc ions to cells impairs picornavirus polyprotein processing (3); however, the mechanistic basis still remains incompletely understood. On the one hand, viral proteases might be affected in their functions directly; on the other hand, zinc ions could contribute to folding problems of the viral polyprotein that lead to inseparable precursors. Folding inhibition was recently suggested as a target for antiviral strategies (10).

Several attempts have been employed to create mutants resistant against PDTC during human rhinovirus or influenza virus infections. However, no resistant viruses were obtained, hinting at a cellular mechanism of action which is expected to be similar for HK and PT. On account of these findings, PDTC, PT, and HK may provide an interesting basis for the development of new classes of antipicornaviral therapeutics.

Summary

Background

There are limited antiviral options for the treatment of patients with coronavirus disease 2019 (COVID-19) that have demonstrated clinical efficacy and none of them is an oral drug. Ivermectin (IVM), a macrocytic lactone with a wide anti-parasitary spectrum, has shown potent in vitro activity against SARS-CoV-2 in cell cultures.

Methods

We completed a pilot, randomized, controlled, outcome-assessor blinded clinical trial with the goal of evaluating the antiviral activity of high dose IVM in COVID-19 patients. Eligible patients were adults (aged 18 to 69 years) with mild or moderate RT-PCR confirmed SARS-CoV-2 infection within 5 days of symptoms onset. 45 patients were randomized in a 2:1 ratio to standard of care plus oral IVM at 0·6 mg/kg/day for 5 days versus standard of care. The primary endpoint was viral load reduction in respiratory secretions at day-5. Viral load in respiratory secretions was measured through quantitative RT-PCR. Concentrations of IVM in plasma were measured on multiple treatment days. This trial is registered with ClinicalTrials.gov, NCT004381884.

Findings

The trial run between May 18 and September 29, 2020 with 45 randomized patients (30 in the IVM group and 15 controls). There was no difference in viral load reduction between groups but a significant difference in reduction was found in patients with higher median plasma IVM levels (72% IQR 59 – 77) versus untreated controls (42% IQR 31 – 73) (p=0·004). The mean ivermectin plasma concentration levels also showed a positive correlation with viral decay rate (r:0·47, p=0·02). Adverse events were reported in 5 (33%) patients in the controls and 13 (43%) in the IVM treated group, without a relationship between IVM plasma levels and adverse events.

Interpretation

A concentration dependent antiviral activity of oral high dose IVM was identified in this pilot trial at a dosing regimen that was well tolerated. Large trials with clinical endpoints are necessary to determine the clinical utility of IVM in COVID-19.

Research in context

Evidence before this study

The potential role of ivermectin against SARS-CoV-2 was first reported in April 2020 when an Australian group published in-vitro results. Since then, multiple opinion papers and uncontrolled studies tried to understand the meaning of those results and utility of ivermectin in COVID-19. We searched clinicaltrials.gov on October 16 and identified 39 registered trials. A Pubmed search on the same date identified 72 published articles on ("COVID" or "SARS") AND "ivermectin", none of them a clinical trial o randomized controlled trial.

Added value of this study

Our study is the first contribution that provides evidence of the antiviral activity of ivermectin against SARS-CoV-2 in patients with COVID-19 through a randomised, controlled, outcome-assessor blinded clinical trial. The incorporation of quantitative viral load determinations and measurements of ivermectin plasma levels allows an in-depth interpretation of the data and the identification of ivermectin systemic concentrations needed for a significant antiviral effect. The use of an untreated control group highlights the need for controlled trials and on the viral load dynamics in the natural history of COVID-19. Finally, we also add further information on the safety of high dose ivermectin.

Implications of all the available evidence

A concentration dependent antiviral effect of ivermectin in COVID-19 was identified, with significant reductions in SARS-CoV-2 viral load in respiratory secretions among patients achieving high systemic ivermectin concentration compared to untreated controls. These results, that did not show toxicity related to the use of high dose ivermectin, provide evidence of the antiviral effect and support the design of trials to investigate the clinical implications of our findings. Further exploration of the factors involved in the oral bioavailability of ivermectin are also warranted.

Introduction

The emergence of a novel coronavirus, Severe Acute Respiratory Syndrome coronavirus 2 (SARS-CoV-2) in Wuhan in December 2019 and its pandemic spread causing (COVID-19) at a global scale, with over 33 million reported cases and 1 million deaths by the end of September 2020 has prompted the search of pharmacologic interventions to treat, prevent and mitigate the consequences of this potentially devastating acute respiratory infection. Several therapeutic agents have been evaluated at different disease stages as potential antiviral therapies; most of them as part of a drug repurposing strategy for active principles already used in other therapeutic indications. Although different molecules such as hydroxychloroquine, lopinavir and remdesivir have demonstrated antiviral activity against SARS-CoV-2 *in vitro*, evidence from randomized controlled clinical trials has only demonstrated clinical benefits for intravenous remdesivir in sub-groups of hospitalized patients. [1]

Ivermectin (IVM) is a widely used antiparasitic drug against several filarial diseases, scabies, and strongyloidiasis, with over 900 million tablets distributed in 2019 through the World Health Organization (WHO) for the treatment of onchocerciasis and lymphatic filariasis as part of WHO`s Essential Medicines List. [2,3] After decades of intensive, safe, and effective use, IVM has more recently been evaluated for potential new indications including malaria and several viral infections that were shown to be susceptible to IVM in vitro like Dengue, Zika, and Influenza. [4] A potent activity against SARS-CoV-2 was reported in Vero-hSLAM cells cultures using high concentrations of IVM.[5] Different pharmacokinetic (PK) and pharmacodynamic (PD) models suggested that the extremely high plasma concentrations necessary for the antiviral effect observed *in vitro* would require doses far from those safely used in humans, in order to reach concentrations close to 2 μM, the half-maximal inhibitory concentration (IC50) required against SARS-CoV-2 *in vitro.* [6] IVM is prescribed in weight-based regimens, most frequently at 0·2 mg/kg, although 0·4 mg/kg is approved for *Wuchereria bancrofti* infections.[7] Based on its safety profile, higher dosing regimens are under evaluation due to their potential utility for new indications and dosing strategies. [7,8]

To evaluate the antiviral activity and safety profile of high dose IVM in COVID-19 patients and to advance the knowledge on the role of this drug, we completed a proof of concept randomized controlled clinical trial in hospitalized patients with mild and moderate disease. To achieve further insights into the potential clinical utility of IVM in COVID-19, the relationship between drug PK (systemic exposure) and PD (dynamic of the viral load) aspects was investigated. Here we present the results of the trial with descriptions on the impact of IVM on SARS-CoV-2 viral load in respiratory secretions.

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

Methods

Study design and participants

A multicenter, individually randomized, open label, outcome assessor blinded, controlled clinical trial to assess the antiviral activity and safety of a 5-day regimen of high dose IVM versus no treatment in a 2:1 allocation ratio, in adult hospitalized patients with mild to moderate COVID-19. All patients in both groups received standard of care. The trial was done at 4 hospitals in the metropolitan area of Buenos Aires, Argentina.

Ethical approval was obtained from the Institutional Independent Ethics Committees and from district and national regulatory agencies. All participating individuals provided written informed consent. The trial was done in accordance with the principles of the Declaration of Helsinki. This study is registered with ClinicalTrials.gov, NCT004381884.

Eligible participants were COVID-19 patients aged 18 to 69 years-old with RT-PCR confirmed infection, hospitalized with disease stages 3 to 5 from the WHO 8-Category ordinal scale of clinical status and no requiring intensive care unit admission. Eligibility criteria included COVID-19 symptoms onset $\leq$ 5 days at recruitment, absence of use of drugs with potential activity against SARS-CoV-2 and available in Argentina during the trial (hydroxychloroquine, chloroquine, lopinavir and azithromycin); and those drugs were not permitted during the first week of the trial. Exclusion criteria included the use of immunomodulators within 30 days of recruitment, pregnancy, breast feeding, poorly controlled comorbidities and known allergies to IVM. Patients of child-bearing age (men and women) were eligible if agreed to take effective contraceptive measures (including hormonal contraception, barrier methods, or abstinence) during the study period and for at least 30 days after the last study drug administration.

Randomization and masking

Enrolled participants were randomly assigned (2:1) to either IVM group or untreated control group. Randomization was stratified for each Center. Randomization sequence was prepared by a centralized, web-based system in blocks of variable size (3, 6 or 9 cases per block) and communicated to the trial physicians that recruited the patients upon entry to the web system information on availability of the signed Informed Consent Form and verification of all eligibility criteria. Patients, nurses, and physicians were not blinded to the treatment arm. Outcome assessors (virology staff) were blinded to the treatment group by receiving the samples labeled with randomization code and visit number.

Procedures

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

All participating patients were evaluated at study entry when a full history and physical exam were performed, including weight and height. Patients in the IVM group received oral treatment for 5 consecutive days with either breakfast or lunch at approximately 24 hours intervals. IVM 6 mg ranurated tablets (IVER P, Laboratorios Elea/Phoenix, Argentina) were used in all cases at a dose of 0·6mg/kg/day based on baseline weight rounding to the lower full (6mg) and half (3mg) dose. Patients were assessed daily by hospital nurses and physicians from the research teams in each hospital during the 7-day initial period and at day 21 to 30 from study entry. All clinical findings, including adverse events and concomitant medication, were entered in paper based clinical records and then entered into an electronic case report form that was monitored and validated by trial staff. Nasopharyngeal swabs were collected at baseline and 24, 48 and 72 hours and on day 5 for SARS-CoV-2 viral load quantification. Blood samples were obtained by venipuncture for plasma IVM concentrations, 4 hours after drug intake on treatment days 1, 2, 3, and 5 (aiming at measuring peak plasma levels) and on day 7 (aiming to estimate drug elimination) in the IVM group. Blood samples were obtained from participants in both groups for hematologic and chemical parameters.

Outcomes

The primary outcome measure was the reduction in SARS-CoV-2 viral load between baseline and day-5 in both groups. Secondary outcomes included clinical evolution at day-7, relationship between IVM plasma concentrations and the primary outcome, and frequency and severity of adverse events in each group.

SARS-CoV-2 viral load measurements

Viral load of SARS-CoV-2 from nasopharyngeal swabs was quantified from samples stored in viral transport medium at -80ºC until use. For the viral load assay, viral RNA was extracted using QIAamp Viral RNA Mini Kit (Qiagen, Hilden, Germany) from 140 µL of stored samples. Then, an in-house reverse transcriptase quantitative PCR (RT-qPCR) targeting N gene of SARS-CoV-2 was performed. The standard curve consisted of an in vitro transcribed viral RNA serially diluted in a cellular RNA matrix from negative nasopharyngeal samples. This assay included the measure of a housekeeping gene as an internal control and normalizer. The housekeeping gene cycle threshold (Ct) was used to correct the specific-SARS-CoV-2 Ct according to the number of cells in the sample. Therefore, viral load measurements were expressed as $\log_{10}$ copies per reaction instead of $\log_{10}$ copies per mL as discussed by Han and colleagues. [9] The performance of the assay includes: i) efficiency = 99%, ii) reproducibility with a coefficient of variation (CV) between 1·01 to 2·31, iii) repeatability with a CV between 0·27 to 1·89%, iv) dynamic range from 10 to 1 x 10^8 copy per reaction, v) specificity = 100% tested against SARS-CoV-2 negative samples and a panel of respiratory viruses. All these parameters were determined according to the guidelines for in vitro quantitative diagnostic assays as were reported previously. [10,11]

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

Measurement of IVM plasma concentration profiles

Concentrations of IVM in plasma samples collected from treated patients were determined by High-Performance Liquid Chromatography (HPLC) with fluorescence detection. The chromatography technique was adapted as previously described. [12] An aliquot of plasma was combined with moxidectin (used as internal standard). After an acetonitrile-mediated chemical extraction, IVM was converted into a fluorescent molecule using N-methylimidazole and trifluoroacetic anhydride (Sigma Chemical, St Louis, MO, USA). An aliquot (100 µL) of this solution was injected directly into the HPLC system (Shimadzu Corporation, Kyoto, Japan). HPLC analysis was undertaken using a reverse phase C18 column (Kromasil, Eka Chemicals, Bohus, Sweden, 5 µm, 4.6 mm × 250 mm) and an acetic acid 0·2% in water/methanol/acetonitrile (1·6/60/38·4) mobile phase at a flow rate of 1·5 mL/min at 30 °C. Fluorescent detector was set at 365 nm (excitation) and 475 nm (emission wavelength). Full validation of the analytical procedures used to measure IVM plasma concentrations was performed. The determination coefficient (r^2) of the calibration curve was 0·995. The mean absolute drug recovery percentage was 94%. The precision of the method showed a coefficient of variation below 8·1%. The limit of drug quantitation was 0·3 ng/mL. Drug concentrations in experimental plasma samples were obtained by peak area integration using the Solution Software (Shimadzu Corporation, Kyoto, Japan).

Pharmacokinetic and pharmacodynamic analysis of the data

The drug plasma concentrations measured in each patient at the different post-treatment times were plotted. The pharmacokinetic parameters were determined using PK Solutions 2·0 (Ashland, Ohio, US) computer software. The area under the IVM concentration-time curves for (AUCivm) (named as systemic drug exposure) were calculated by the trapezoidal rule.[13] The estimation of the area under the viral load-time curves (AUCvl) was estimated as a pharmacodynamic indicator of drug activity. The viral decay rate was calculated from the viral load curve-time using 4 points as 2·303 x slope.[13] The data analysis included the estimation of the drug PK/PD relationship. The ratio between drug exposure (PK) (expressed as AUCivm) and the dynamic of the viral load (PD) (expressed as AUCvl) was estimated as an indicator of the relationship between drug exposure and antiviral activity.

Statistical analysis

Trial design included a sample size calculation that was determined on current recommendations for pilot trials, indicating at least 10 cases per group [14]or based on the sample size calculation for

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

the full-scale clinical trial and include at least 9% of that size for a confidence interval of 80% (Cocks).[15] Based on these grounds and low effect size (0·3) the sample size for a full-scale trial would be 342 and a pilot of at least 31 based on Cocks *et al*. In view of the presumed effect of IVM on the replication of SARS-CoV-2 and the limited available information of viral dynamics at the time of study design (April 2020), the sample size of the pilot trial with an α error of 0·05 a power of 0·80 and a low effect size according to standardized size effects,[16] was calculated for a 2:1 randomization in 30 patients in the IVM group and 15 in the control group, to detect differences between 2 independent groups in the decrease in mean viral load in nasopharyngeal swabs between baseline and day-5.

Groups were compared and the continuous variables were analyzed for statistical significance with the Mann-Whitney and the Kruskal-Wallis non-parametric test. Correlations were analyzed using the Spearman rank test. Data analysis was performed with GraphPad Prism version 5·00 for Windows (La Jolla California USA (www.graphpad.com)). The statistical analysis for PK parameters and percentages of viral load reduction at day 5 post-treatment was performed using the Instat 3·0 software (GraphPad Software, CA, US). Parametric (ANOVA, Bonferroni multiple comparisons) and non-parametric (Kruskal–Wallis) tests were used for the statistical comparison. When difference across three groups was significant, pairwise comparisons were made with Dunn`s multiple comparisons test. Non-parametric correlation was used for the relationship between viral load reduction and IVM systemic concentration. In all cases, p-values <0·05 were considered statistically significant. Two missed values of viral load were estimated by regression analysis using the existing data.

Role of the funding source

The sponsors of the study participated in study design, but had no role in primary data collection, data analysis, data interpretation, writing of the report, or the decision to submit for publication. All authors had full access to all the data in the study and had final responsibility for the decision to submit for publication.

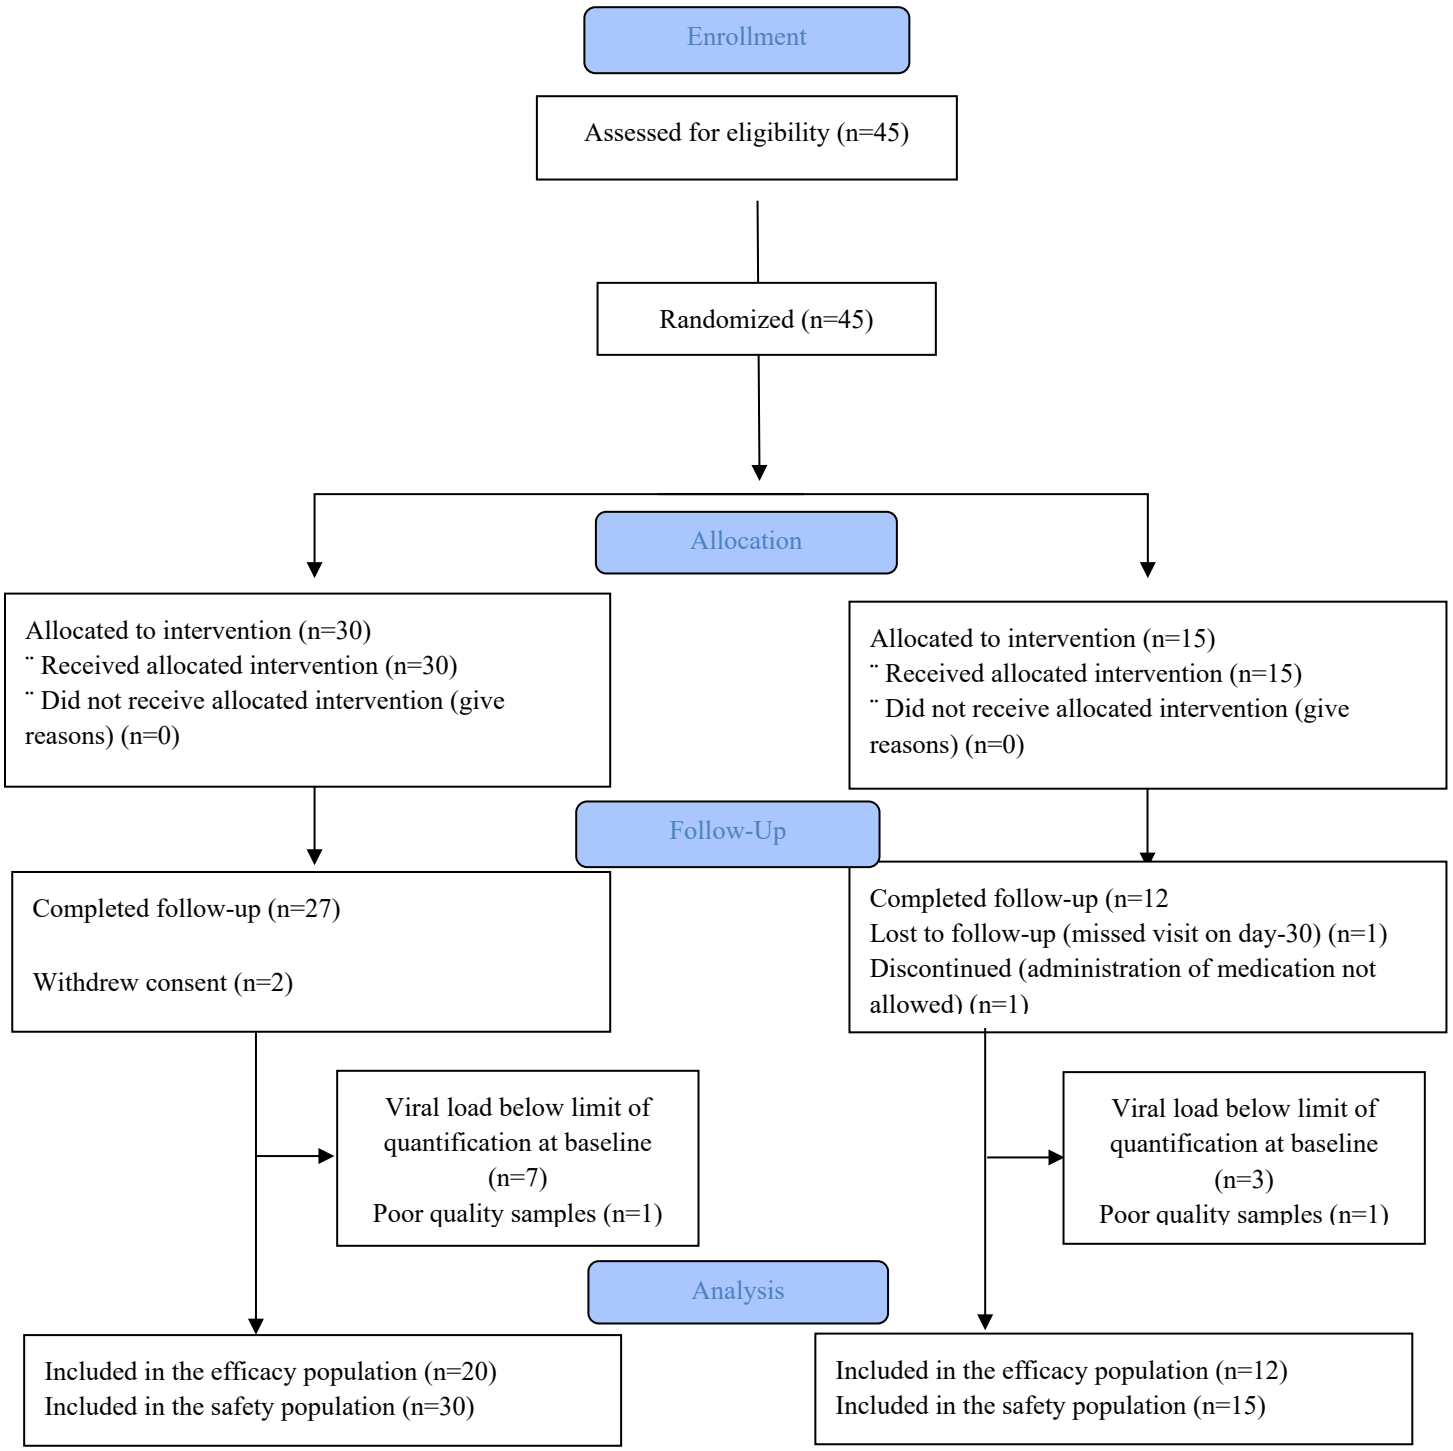
Results

Enrolment started on May 18 and finished on September 9, 2020, with 45 participants recruited among the 4 participating hospitals. On September 29, the last scheduled visits were completed. As planned, 30 were randomized to the IVM group and 15 to the untreated control group. Two subjects withdrew consent in the IVM group; in 1 case due to a mild rash and nausea after 1 dose of IVM and the other due anxiety; in both cases, the adverse events were judged as possibly related to IVM and resolved spontaneously; the remaining 28 subjects in the IVM group completed treatment. All doses of IVM were completed during hospitalization. One case in the control group was withdrawn from the study due to the initiation of lopinavir on day-5 due to disease progression. All patients assigned to the treatment group started treatment, therefore all subjects were included in the safety analysis (figure 1). One patient in the control group was lost to follow-up after the visit on day-7.

Baseline characteristics showed a mean age of 40·89 (SD 12·48) among study participants, without differences between groups; sex distribution was 20 (44%) females and 25 (56%) males (table 1). Comorbidities and disease stages were similar between groups; with the most frequent comorbidity being obesity in both groups, followed by hypertension, diabetes and chronic obstructive pulmonary disease (table 1). The number of days between symptoms onset and enrolment had a mean (SD) of 3·6 days (1·4) in the control group and 3·5 (1) in the treated group, without significant differences between groups nor cases enrolled beyond the eligibility criteria of up to 5 days since symptoms onset. No major differences in clinical symptoms, signs, or laboratory parameters were observed between groups at baseline (table 1). Disease progression was registered in 3 (7%) of the study population; 2 in the treated group and 1 in among the controls, with 1 case in the IVM group requiring invasive mechanical ventilation and no significant differences in clinical evolution at day-7 between groups.



Quantitative viral load at baseline of the whole study population had a median (IQR) of 3·69 log_{10} copies/reaction (1·97-5·74), including 5 (11%) undetectable cases and another 5 (11%) detectable although with <15 copies/reaction (<1·18 log_{10} copies/reaction) at baseline, all these cases remaining undetectable in most samples through the follow-up and excluded from the efficacy analysis. No differences in viral load were detected between males and females. Another 4 cases including 2 with poor quality samples and 2 with early withdrawal were also excluded. The remaining 32 cases (20 treated and 12 control) constitute the efficacy analysis population (fig 1). Baseline viral load in this population had a median (IQR) of 5·59 log_{10} copies/reaction (4·75 - 6·12) in the control group and 3·74 log_{10} copies/reaction (2·8 - 5·79) in the treatment group (p=0·08) (table 1). Viral load dynamics changed similarly in both groups over the study period without significant differences and decreasing over time (figure 2).

The estimation of IVM systemic exposure in treated patients was based on the collection of blood samples at 4-hours after each of the first 3 doses, after the 5th, and at 48 hours after the last

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

administered dose. This time-sampling design aimed at measuring the predicted IVM plasma peak plasma concentration (Cmax) and estimating the pattern of drug elimination from the body.

Viral load reduction between baseline and day-5 was also similar between groups (figure 2). When mean plasma IVM concentration levels were analyzed in relation to reduction in viral load, a significant positive correlation was identified, with those patients achieving higher mean plasma concentrations of IVM reaching higher reductions in viral load in nasopharyngeal secretions (r: 0·44; p<0·04). This correlation was stronger when the reduction in viral load was related to the IVM exposure corrected by viral load at baseline (r: 0·60; p<0·004). The mean IVM plasma concentration levels also showed a positive correlation with the viral decay rate (r:0·47, p=0·02).

Figure 2. Viral load by quantitative RT-PCR on upper respiratory tract secretions since treatment initiation in patients receiving IVM 0·6 mg/kg/day for 5 days versus untreated controls. Data are mean (SD). Day-1 indicates

.

baseline measurements.

Based on the observed antiviral response, treated patients were divided in two subgroups where 160ng/ml was the threshold plasma concentration. Median Cmax in this subgroup was 202 ng/ml (IQR: 167-268 ng/ml) in the >160ng/ml subgroup and 109 ng/ml (IQR: 91-141 ng/ml) in the <160 ng/ml subgroup (p<0·0001). To further explore this PK/PD relationship, viral load dynamics and reductions between baseline and day-5 were analyzed in the 2 subgroups of IVM treated patients (figure 3a), with median (IQR) reductions in viral load of 42% (31-73) in the control group, 40% (21-46) in treated patients with <160ng/mL median plasma concentrations,

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

and 72% (59-77) in the higher concentration group (Kruskal-Wallis p=0·0096), with a statistically significant differences between the latter and the other groups (figure 3b).

Drug-induced effects on viral clearance were also assessed using viral decay rates as an endpoint parameter and its relationship with drug exposure. The viral load decay rate in treated patients with IVM plasma levels >160ng/mL was significantly greater (median 0·64 d^{-1}) compared to that calculated in the untreated control group (median 0·13 d^{-1}) and also to the subgroup with <160ng/mL median plasma concentrations (median 0·14 d^{-1}) (p=0·041) (figure 4a). Similar differences in decay rate were observed comparing controls and subgroups of patients with ratio AUCivm/AUCvl >50, and ratio AUCivm/AUCvl < 50 (p=0·0006) (figure 4b). No significant differences in baseline viral load were observed between IVM concentration subgroups. The relationship between IVM concentration did not correlate with body weight (r^2=0·1) or body mass index (r^2=0·07) among the 28 patients that completed treatment with IVM.

Adverse events were reported in 18 (40%) of the 45 patients included in the safety analysis, which by the design of the study was unblinded; 13 (43%) in the IVM group and 5 (33%) in the control group (table 2). The most frequent adverse event and the only experienced by more than 1 case in the IVM group was rash in 3 (10%) cases (all mild, self-limited and lasting approximately24 h); in the control group, single events of abdominal pain, dizziness, anxiety, anguish, and hyperglycemia (all mild) were reported. A single serious adverse event (SAE) was reported in the trial in a patient in the IVM group with hyponatremia, which has been recently recognized in case series of COVID-19 cases and has not been reported in association to IVM use.[17] A relationship between IVM systemic concentration and adverse events failed to reveal a link between these variables.

Discussion

The results of this pilot clinical trial indicate a concentration-dependent antiviral activity of IVM over SARS-CoV-2 infected patients with mild and moderate disease stages treated within 5 days of symptoms onset. This is the first clinical trial that confirms previous in vitro activity shown in Vero-hSLAM cell cultures.[5] The relevance of IVM plasma concentrations as a surrogate indicator of drug exposure in the sites of viral replication such as nasopharyngeal mucosa and lung tissues, confirms theoretical models stating the need for higher doses than usual to achieve *in vivo* antiviral activity; however, contradict those concerns stating that those drug concentrations would not be achievable at doses with an adequate safety profile.[6,18] A large IVM distribution into different tissues has been demonstrated in different animal species. The extensive pattern of IVM distribution to lung tissue has been well characterized in cattle with a lung tissue to plasma ratio of 2·67.[12] Considering that similar volumes of distribution have been reported for IVM in both cattle and humans and the systemic availability observed in treated patients in this clinical trial, it is reasonable to estimate median IVM levels >395 ng/g in lung tissue. A similar pattern of IVM distribution to lung tissue has been recently simulated using a minimal physiologically based PK model.[19]

The beneficial antiviral effect was seen in the viral load reduction between baseline and day-5 and in viral decay rates only after IVM plasma concentration measurements allowed discrimination between patients achieving higher levels and identifying a strong direct relationship between drug systemic exposure and parameters of viral elimination. Using the threshold of 160 ng/mL for IVM plasma concentrations as an indicator of adequate systemic exposure, statistically significant differences compared to untreated controls were demonstrated even after adjusting for baseline viral load, with those falling below 160 ng/mL reaching viral elimination parameters similar to the control group. Additionally, relevant conclusions on the natural history of the illness can be derived from the behavior of the control group in this trial, which demonstrates the self-limited nature of viral load in SARS-CoV-2 infections, that in 22% of the cases was already extremely low or undetectable at baseline; a finding similar to what has been observed in another trials [20], highlighting the relevance of adequate timing of implementation of antiviral treatment, a critical issue in the design of clinical trials of potential antiviral therapies.

IVM plasma concentrations >160ng/mL were measured in 9 (45%) patients included in the efficacy analysis population. In another trial using a 3-day regimen of 0·6mg/kg for mosquitocidal activity and malaria control among adults, median Cmax (CI95%) was 119ng/mL (45-455).[8] Diet is a key variable affecting the oral bioavailability of IVM, with increased plasma concentrations achieved with fed state, mostly related to the fat content of the meal; still other variables probably play significant roles since IVM is characterized by a high intra and interindividual variability in key PK parameters .[21,22] The interaction of IVM with ABC transporters as P-glycoprotein [23] and the modulation of P-glycoprotein activity after oral

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

administration is well known.[24] Thus, variable constitutive and/or induced level of expression and activity of intestinal P-glycoprotein in treated patients, may have contributed to the observed large variability in the pattern of IVM absorption and systemic exposure.

Safety and efficacy of high dose IVM are a subject of research in view of its potential role in increasing clinical usefulness in new indications as is the case of malaria and also aiming for simplified fix-dose rather than weight-based strategies as in Mass Drug Administration campaigns against different Neglected Tropical Diseases. Although further information is needed, this trial adds evidence on the safety of multiple-day high-dose regimens of IVM, without unexpected findings.

Limitations of this trial include a small sample size to detect clinical outcomes beyond antiviral activity, being the latter the critical question this trial was designed to answer. The finding of 2 distinct populations regarding mean IVM systemic concentrations was identified despite the body weight-based dosing and the indication of administering the drug tablets with meals. The lack of a proper registry of the actual content of the meals ingested around the intake of each treatment may add a source of variation to the observed IVM plasma profiles among treated patients.

The assessment of the effect of drug candidates against viruses causing acute respiratory infections is hampered by several aspects of these host-pathogen relationships including short incubation periods, relatively rapid immune control of viral replication, and the high variability in symptom scores among patients.[25] For that reason, key components for adequate endpoints in these trials are sensitive quantifiable measurements of the underlying cause of disease as the quantitative RT-PCR with a wide dynamic range, to control high inter-individual variability in natural infection. [26] Still in this trial, the addition of an integrated assessment taking into consideration drug PK parameters was necessary to identify the potential clinical utility of IVM in SARS-CoV-2 infections. In IVM treated patients, AUCivm/AUCvl ratios >50 were associated with significantly higher viral decay rates. As it has been proposed in an influenza model of antiviral candidate drugs evaluation [25], viral decay rates proved to be a critical parameter of antiviral activity. Additionally, as it has been clearly demonstrated for acute viral infections, early treatment initiation plays a critical role in antiviral activity.[26,27] The potential clinical relevance of these findings remains to be confirmed in trials with clinical endpoints. Beyond clinical aspects of the illness, lowering viral burden might influence infectivity, although there is conflicting data regarding the relationship between burden of viral shedding and infectivity. [28]

Drug repurposing has focused great attention on the search for viable treatments in the context of COVID-19 pandemic, allowing reduced development time and cost. In addition, the use of host-based antiviral compounds has been proposed as an alternative strategy over direct antivirals, that could overcome limitations derived from drug resistance or viral mutations. [29] The proposed antiviral mechanism of IVM is through its ability to inhibit the nuclear import of viral proteins

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714649

mediated by IMPα/β1 heterodimer [5], and it has also been suggested that IVM could promote defense mechanisms such as pyroptosis in infected epithelial cells.[30]

In summary, our findings support the hypothesis that IVM has a concentration dependent antiviral activity against SARS-CoV-2 and provides insights into the type of evaluations to be considered in the assessment of antiviral drugs for the control of COVID-19. Follow-up trials to confirm our findings and to identify the clinical utility of IVM as either sole intervention or in combination with other tools for the control of the ongoing pandemic outbreak are warranted.

The recent outbreak of the COVID-2019 (coronavirus disease 2019) due to the infectious severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has realized the requirement of alternative therapeutics to mitigate and alleviate this lethal infection. These alternative therapies are effective when they are started at the initial stage of the infection. Some drugs that were used in previous other related infections SARS-CoV-2003 and Middle East respiratory syndrome coronavirus (MERS-CoV)-2012 could be potentially active against currently emerging SARS-CoV-2. This fact imparts some rationale of current interventions, in the absence of any specific therapeutics for SARS-CoV-2. It is imperative to focus on the available antimicrobial and adjunct therapies during the current emergency state and overcome the challenges associated with the absence of robust controlled studies. There is no established set of drugs to manage SARS-CoV-2 infected patients. However, closely following patients' conditions and responding with the dosage guidelines of available drugs may significantly impact our ability to slow down the infection. Of note, it depends upon the condition of the patients and associated comorbid; therefore, the health workers need to choose the drug combinations judiciously until COVID-19 specific drug or vaccine is developed with the collective scientific rigor. In this article, we reviewed the available antimicrobial drug, supportive therapies, and probable high importance vaccines for the COVID-19 treatment.

Keywords: antimicrobial therapy, coronavirus disease 2019, drug, severe acute respiratory syndrome coronavirus 2, supportive therapy, vaccine

INTRODUCTION

Coronavirus is named after the crown-like structures projected from the envelope of its surface. Coronavirus belongs to the family Coronaviridae, which comprises of four genera: α-coronavirus, β-coronavirus, δ-coronavirus, and γ-coronavirus. α and β-coronaviruses infect mammals; however, γ and δ-coronaviruses mostly infect birds. The highly contagious coronavirus disease 2019 (COVID-19) belongs to the genus β-coronavirus (Loeffelholz and Tang, 2020; Zhu et al., 2020). It is caused by a novel β-coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) outbreak that has by far affected almost all the countries amounting to the death of about 850,000 individuals till date internationally.

The SARS-CoV-2 contains four structural proteins, namely, spike, membrane, envelope, and nucleocapsid (Bosch et al., 2003). The transmembrane spike proteins are trimeric glycoproteins present on the surface of the virus. These proteins are responsible for diversity and host-tropism of the virus. The virus attaches to the angiotensin-converting enzyme 2 (ACE2) (functional host-receptors for SARS-CoV-2), and through membrane fusion or endocytosis enters the host cell (Li et al., 2003; Chen Z. et al., 2020). In the alveolar space, ACE2 has highly expressed an upper side of lung epithelium cells, and therefore, SARS-CoV-2 can easily enter and abolishes these cells (Hamming et al., 2004; Jia et al., 2005; Zou et al., 2020). The released viral genetic material (single-stranded positive-sense ribonucleic acid) reaches the nucleus and starts the self-replication, transcription, and translation. The biosynthesis of viral proteins in the host-cells enables it to assemble, mature, and get released as new copies of viral particles.

The SARS-CoV-2 primarily infects respiratory system but other organs like kidney, heart, ileum, and spleen can also be infected (Kabir et al., 2020). The common symptoms of this virus infection include dyspnoea, dry cough and fever (Huang et al., 2020). However, generalized weakness, diarrhoea, vomiting, headache, and dizziness may also be observed (Shi et al., 2020). There is currently no specific therapeutics available for the prevention or cure for SARS-CoV-2 as per the Food and Drug Administration (FDA), the World Health Organization (WHO), and the Centers for Disease Control and Prevention (CDC). The WHO guidelines emphasized the role of supportive care on the basis of illness severity, i.e., symptomatic treatment for mild infections and evidence-based ventilatory management for acute respiratory distress syndrome and early recognition and treatment of bacterial infections and sepsis in severe COVID-19 cases (World Health Organization, 2020). So far, agents under clinical trials are also being used based on their *in vitro* activity against SARS-CoV-2. However, there are minimal clinical evidence could be collected so far, and the efficacy of such drug therapies in the treatment of SARS-CoV-2 has not been established. The vaccines against COVID-19 will probably take at least a year to become available, and the use of available drugs to prevent disease (chemoprophylaxis) is the main option in hand for the management of infected patients.

Therefore, for the management of the SARS-CoV-2, the current treatments are entirely supportive by nature. In general, pharmacological treatment is not suggested for young patients with mild indications and without other underlying chronic conditions (Gao et al., 2020). **Figure 1** shows the life cycle of SARS-CoV-2 along with its possible inhibitors at various stages of its attachment, multiplication, and growth in the host cell. Available antimicrobials, adjunctive, supportive therapies, and probable vaccines are discussed in the following sections. Dugs and support therapies that are currently under clinical are listed in the **Supplementary Material**.

ANTIMICROBIAL THERAPIES AGAINST COVID-19

Chloroquine

Chloroquine (**Figure 2**) has been used for years against malaria. This cost-effective and widely available therapeutic agent is also a robust antiviral, as it blocks a virus from invading the human cells. A large number of research groups are currently reviewing whether it effectively decreases the viral load in patients with SARS-CoV-2 (Savarino et al., 2006; Marmor et al., 2011; Cortegiani et al., 2020). However, *in vitro* and limited clinical data indicate therapeutic advantages against SARS-CoV-2 infection. SARS-CoV-2 is an enveloped virus, and it enters the cell by endocytosis. Endocytosis is a cellular process in which elements are taken into the cell by making a tiny vesicle. Once inside, a dip in pH promotes the fusion of the virus envelope with the membrane of the vesicle that encompasses it, to be released into the cytoplasm (McChesney, 1983). Till date, chloroquine is verified effective against COVID-19 *in vitro* through influencing bis (monoacylglycero) phosphate entry by controlling the endocytic pathway (Carrière et al., 2020). The use of chloroquine against COVID-19 might be a risk and require continuous monitoring until confirmed clinical evidence are available.

Hydroxychloroquine

Hydroxychloroquine is also classified under the antimalarial agent. It is a comparatively less toxic analog of chloroquine, which has already been found to stop the replication of SARS-CoV-2 *in vitro* in cell culture studies (Colson et al., 2020; Yao X. et al., 2020). It exhibits the mechanism of action, similar to the chloroquine for COVID-19 patients. It primarily increases the pH in the endosomes, thereby, stops their acidification and maturation and interferes with the entry of the virus in the cell (Hacker et al., 1998; Macfarlane et al., 1998; Vincent et al., 2005; Christophe et al., 2006). Also, it inhibits the toll like receptors (TLRs) and thereby reduces the pro-inflammatory cytokines Interleukin-6 production (Fox, 1993; Fox, 1996; Ben-Zvi et al., 2012; Jorge et al., 2018; Sahraei et al., 2020; Wu et al., 2020a).

Hydroxychloroquine is being used as a potential therapeutic agent for the treatment of SARS-CoV-2 infected patients under the FDA-Emergency Use Authorization (EUA) by following the same guidelines as recommended for chloroquine. However, it is not an FDA-approved drug for the treatment of SARS-CoV-2 infection. Hydroxychloroquine shows better *in vitro* efficacy

FQI-26-3132 Document 5

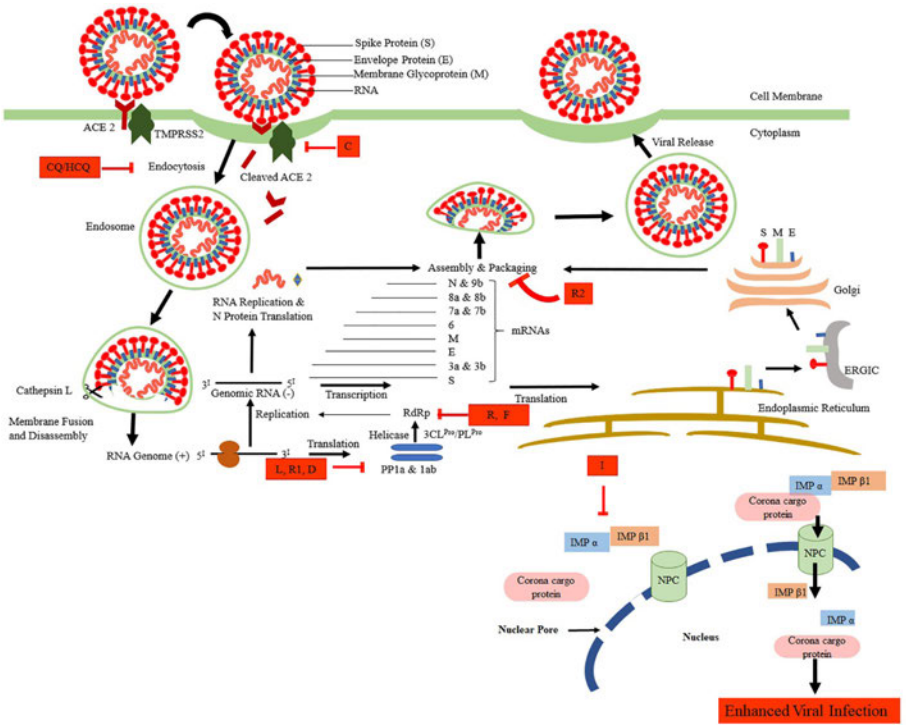

FIGURE 1 | The life cycle of SARS-CoV-2 and its possible inhibitors. SARS-CoV-2 enters the target cells *via* an endosomal pathway. The S protein binds with the angiotensin-converting enzyme 2 (ACE2) of the cell primed by serine protease TMPRSS2. Viral RNA is unveiled in the cytoplasm to produce PP1a and PP1ab polyproteins, which are cleaved to form non-structural proteins. These non-structural proteins facilitate the formation of negative RNA by the process of replication and transcription. This, in turn, translates to N protein, another set of translation takes in the endoplasmic reticulum-ERGIC-Golgi to produce structural proteins (S, M, and E). Finally, the packing of viral RNA with N proteins and further assembly of S, M, and E proteins take place to form SARS-CoV-2 buds, which are released from the infected cell by exocytosis. Various drugs that are shown to inhibit the SARS-CoV-2 at various stages are CQ/HCQ, Chloroquine/Hydroxychloroquine; L, Lopinavir; R1, Ritonavir; I, Ivermectin; R, Remdesivir, R2, Resveratrol; D, Darunavir; C, Camostat.

against SARS-CoV-2 as compared to the chloroquine. Effective concentration-50 (EC50) values of the hydroxychloroquine were reported to be 6.25 μM at 24 h and 5.85 μM at 48 h as compared to chloroquine, which is about 100 μM at 24 h and 18.01 μM at 48 h. Moreover, hydroxychloroquine has comparatively better compatibility with other antiviral agents e.g., lopinavir, ritonavir, ribavirin, oseltamivir, remdesivir, etc., which could be used concomitantly during COVID-19 treatment (Wang et al., 2020). In addition, it does not interfere with intravenous immunoglobulins and interferons. Although there are some common adverse drug reactions of hydroxychloroquine such as nausea, stomach pain, vomiting, headache, and in some cases, itching, they do not require discontinuation of the drug.

Prolonged use of the drug may lead to some significant side effects irregular heartbeats, yellowing of the eyes, convulsions or seizures, retinopathy, blurred vision, muscle weakness, difficulty hearing, bruising, or bleeding of the skin, etc. (Ling Ngan Wong et al., 2008; Marmor et al., 2011). Therefore, risk and benefit balance assessment must be done while recommending the hydroxychloroquine in such cases. There are *in vitro* and clinical results in support (Gautret et al., 2020; Yu et al., 2020) and against (Cavalcanti et al., 2020; Chen J. et al., 2020; Geleris et al., 2020; Molina et al., 2020; Rosenberg et al., 2020) the use of hydroxychloroquine for COVID-19 patients. Of note, the data available so far suggest that therapeutic efficacy of HCQ in COVID-19 is well overshadowed by its ineffectiveness and detrimental effects as shown by some of the above-referred studies. Therefore, it is suggested to avoid use of HCQ for COVID-19 patients (unless necessary) until clear, sufficient, well-conducted, randomized, and controlled clinical data is available to reach the right conclusions.

Lopinavir and Ritonavir

Lopinavir and Ritonavir (**Figure 3**) are HIV Protease inhibitors. Animal model and in- vitro studies suggest that lopinavir and ritonavir have therapeutic activity for SARS-CoV and Middle East respiratory syndrome coronavirus (MERS-CoV), but their role in the treatment of SARS-CoV-2 is not clear (Chen et al., 2004; Yao T. T. et al., 2020). These drugs may bind to the Mpro, which is a vital enzyme for the SARS-CoV-2 replication. Mpro facilitates proteolytic processing, which is released by auto-cleavage of pp1a and pp1ab. Then Mpro, in turn, cleaves pp1a and pp1ab to release functional proteins necessary for viral replication (Adedeji et al., 2014; Liu et al., 2020). A retrospective cohort study was done to review the clinical course, and risk factors for mortality during lopinavir-ritonavir

FQI-26-3132 | Document 5

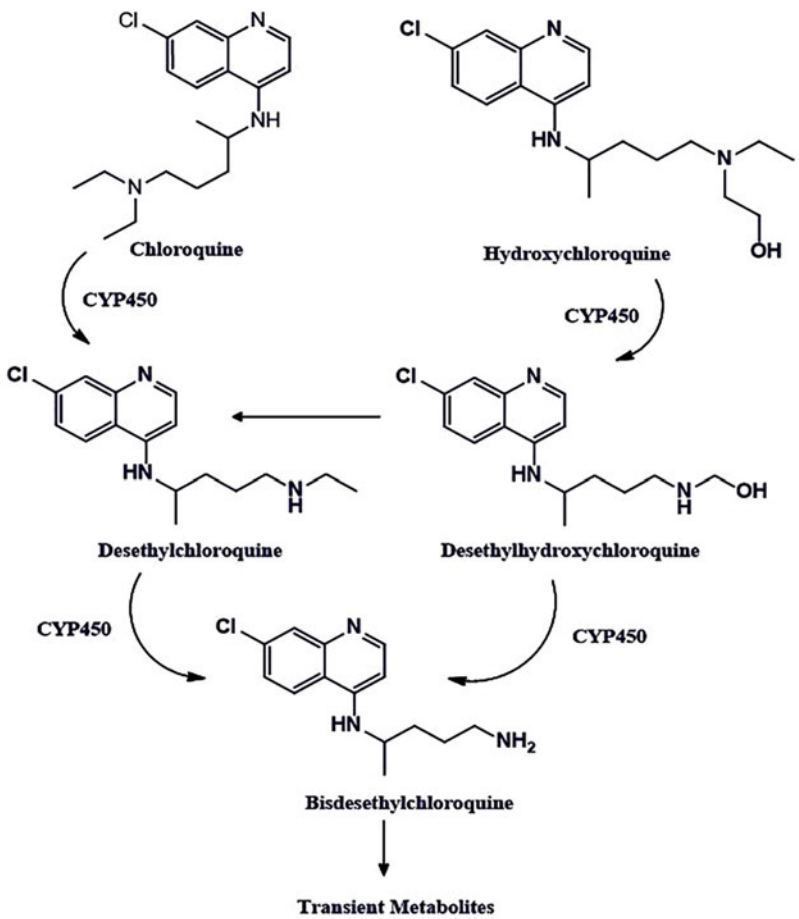

FIGURE 2 | The chemical structures of chloroquine and hydroxychloroquine. The chloroquine contains the N-diethyl group, whereas hydroxychloroquine has an N-hydroxyethyl group at the same position, which is the only structural difference these two drugs have. Both drugs share bis-desethylchloroquine as a common metabolite.

therapy of the SARS-CoV-2 infected hospitalized patients (n=29). There was no difference found in the virus shedding duration with lopinavir-ritonavir (Zhou F. et al., 2020).

As per another recent randomized, open-label, controlled trial (n=199) studies, lopinavir-ritonavir treatment applied to standard supportive care did not result in clinical improvement or mortality in severely infected patients with SARS-CoV-2 as compared to the patients on standard supportive care only. However, the median time to the clinical improvement was found to be reduced by one day with lopinavir-ritonavir treatment (Cao et al., 2020). This modest improvement still seems to be significant because the study was carried out on the severely infected patients with a mortality rate of 22.1% as compared to the 11%–14.5% as reported in preliminary descriptive studies of hospitalized SARS-CoV-2 infected patients (Chaolin et al., 2020; Chen N. et al., 2020; Osborne et al., 2020). After analyzing the recently published clinical outcomes, it was found that the clinical improvement time was not significantly reduced for SARS-CoV-2 infected patients upon the use of lopinavir-ritonavir as compared to standard care. The study by Cao et al. (2020) demonstrating lower acute respiratory distress syndrome (ARDS) with lopinavir-ritonavir and less adverse drug reactions as compared to the standard care. Overall, the effectiveness of lopinavir-ritonavir in severe SARS-CoV-2 could not be considered very encouraging until more conclusive clinical data is available.

Further, trials with the optimal sampling methods and specimen from the lower respiratory tract from the mild to severe SARS-CoV-2 infected patients may lead to better conclusions for lopinavir-ritonavir treatment. More clinical trials (NCT04261907, NCT04321174, NCT04330690, ChiCTR2000030187) data for evaluating the therapeutic efficacy of lopinavir-ritonavir in COVID-19 are awaited.

Ivermectin

Ivermectin (**Figure 4**) is a broad-spectrum antiparasitic drug but shown promises of antiviral activity in recent *in vitro* studies (Canga et al., 2008; Wagstaff et al., 2012; Lundberg et al., 2013; Tay et al., 2013; Götz et al., 2016). Importin (IMP) α/β1 is a heterodimer which facilitates the nuclear import of coronavirus

FOI-26-3132 - Document 5

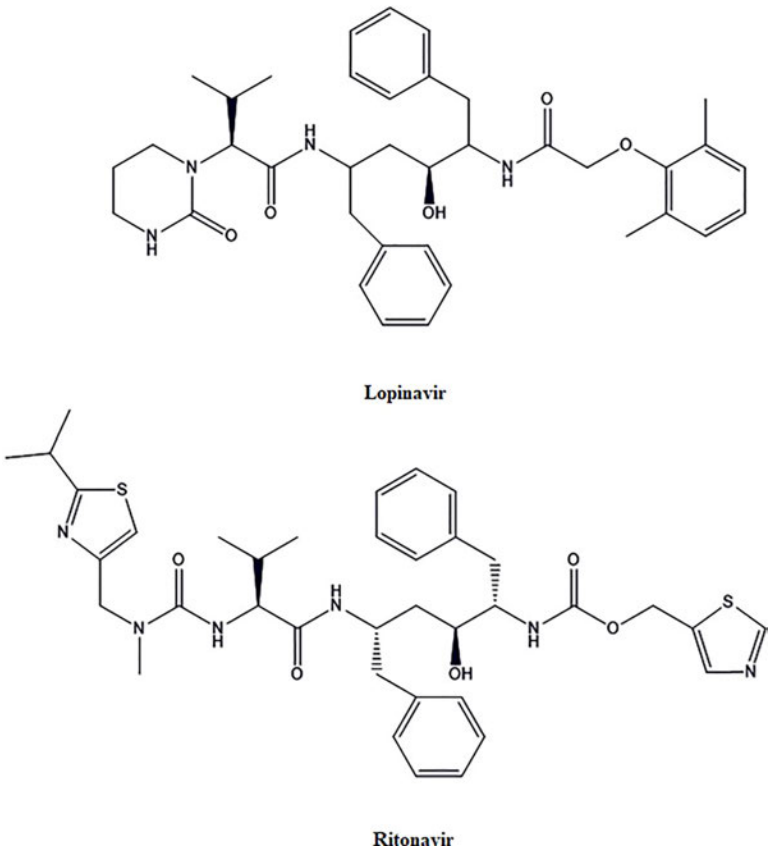

FIGURE 3 | The chemical structures of lopinavir structure of ritonavir.

cargo protein, present in the cytoplasm of the infected cell. It translocates coronavirus protein through the nuclear pore complex (NPC) inside the nucleus where the complex gets separated. The cargo could diminish the antiviral response of the infected cell, leading to increased infection. Ivermectin binds to Impα/β1 heterodimer, thereby destabilize and prevents Impα/β1 from interacting with viral protein. It leads to the stoppage of the translocation of the viral protein into the nucleus. This mechanism is further substantiated by various studies to demonstrate the effect of ivermectin on RNA-virus infections, e.g., human immunodeficiency virus-1 (HIV-1) (Wagstaff et al., 2011), Venezuelan equine encephalitis virus (VEEV), influenza, West Nile Virus (Yang et al., 2020), and Dengue virus (DENV) 1-4. This is due to the dependence of these RNA viruses on IMPα/β1 during infection (Caly et al., 2012; Jans et al., 2019).

Of note, the FDA has only approved this drug for the treatment of parasitic worms such as onchocerciasis and intestinal strongyloidiasis along with some topical formulations for the human to be used upon prescription only for external parasite treatment such as rosacea and head lice. One of the recent *in vitro* studies conducted by Clay et al. (2020) confirmed the antiviral activity of ivermectin against SARS-CoV-2. The SARS-CoV-2 infected Vero/hSLAM cells were subjected to 5 μM ivermectin for 48 h. The study indicates about 5,000-fold decrease in viral RNA as compared to the control. This was the first study to assess and demonstrate the effectiveness of ivermectin in COVID-19. The authors reported that the ivermectin may have antiviral effects by inhibition of IMP α/β receptor, which is responsible for transmission of the viral proteins into the nucleus of host cell. Based on the findings in the study authors proposed clinical studies to further confirm the potential benefits of this drug in the treatment of COVID-19 (Heidary and Gharebaghi, 2020). It is worth mentioning here that ivermectin activity in cell has not been reproduced in the mouse infection models for many viruses. Also, its activity has been not yet proven clinically. The concentration of drug required to be effective in SARS-CoV-2 infected cell culture is in the microgram range but its safe blood levels for imparting therapeutic activity is 20–80 ng/ml. Still, the ivermectin is being available worldwide which may be due to its favorable pharmacokinetics and therapeutic window. Therefore, treatment with ivermectin for COVID-19 patients should be strictly by licensed health workers after a careful review of the patient's health condition until robust and conclusive clinical data (NCT04360356, NCT04343092, NCT04351347) are available.

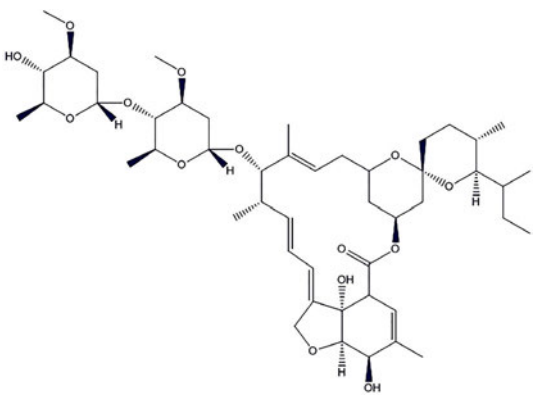

FIGURE 4 | The chemical structure of ivermectin.

Remdesivir

Remdesivir is an investigational nucleoside analog and available only through compassionate use and study protocols. The *in vitro* studies suggest that it exhibits antiviral activity including SARS-CoV-2 (Agostini et al., 2018; Brown et al., 2019; de Wit et al., 2020; Ko et al., 2020; Gordon et al., 2020). Mono-phosphoramidate remdesivir is a prodrug of remdesivir-triphosphate (Warren et al., 2016). Remdesivir (**Figure 5**) is a 1′-cyano-substituted adenosine nucleotide analog that undergoes a metabolic mechanism, activating nucleoside triphosphate metabolite, which inhibits the RNA dependent RNA polymerase (RdRp).

Remdesivir-triphosphate competes with adenosine-triphosphate (ATP) and gets incorporated in the viral RNA. The RNA synthesis terminates after three nucleotides are further added from the position of remdesivir-triphosphate incorporation (Sheahan et al., 2017). The *in vitro* studies suggest that remdesivir exhibits potential therapeutic activity against clinical isolate [Half-cytotoxic concentration (CC50) > 100 mcgM; EC50 = 0.77 mcgM; Selective index (SI) > 129.87] of SARS-CoV-2. One of the recent studies reported that the clinical improvements were observed in 68% (36 out of 53 patients) of the hospitalized COVID-19 patients when treated with remdesivir on a companionate use basis (Grein et al., 2020). However, currently reported studies have some vital limitations such as the small sample size, the relatively less duration of follow-up, potential missing data, the insufficient of information on some patients that were initially involved in the study, and the absence of a randomized control group. Currently, several clinical trials for the evaluation of the efficacy of remdesivir in COVID-19 patients is being conducted (NCT04302766, NCT04323761). More significant and conclusive clinical evidence is expected in the coming months.

Favipiravir

Favipiravir (**Figure 6**) inhibits RNA-dependent RNA polymerase (RdRp). It structurally resembles the endogenous guanine and shows broad-spectrum antiviral activity through competitive inhibition (Furuta et al., 2013). The *in vitro* studies suggest its therapeutic activity against RNA viruses (respiratory syncytial virus, rhinovirus, and, poliovirus) (Furuta et al., 2002; Dong et al., 2020; Shiraki and Daikouku, 2020; Yanai, 2020). Recently, Wang et al. (2020) conducted *in vitro* and demonstrated the effectiveness of favipiravir against SARS-CoV-2. In another open-label control study was done by Cai et al. (2020) to assess therapeutic potentials of favipiravir against SARS-CoV-2. Total of 35 patients were given oral favipiravir with interferon-α aerosol inhalation and a significant reduction in viral clearance time was observed. The multivariable Cox regression analysis further confirmed that the favipiravir was individually associated with faster clearance of the virus. The favipiravir also demonstrated noteworthy improvement in chest imaging and significantly smaller adverse reactions (e.g., nausea, vomiting, etc.) as compared to the lopinavir/ritonavir treated patients. Further, case reports for effectiveness of favipiravir are also reported by the Japanese association for infectious diseases on their web symposium as it was able to improve the clinical symptoms by 90%, 85%, and 61%, in mild, moderate, and severe COVID-19 cases, respectively after 14 days from the start of the treatment (Japanese Association for Infectious Diseases, 2020) Based on the evidence, favipiravir may be a relatively safe and effective drug for COVID-19 at present and expected to emerge as a broad-spectrum antiviral drug against SARS-CoV-2. Its efficacy (NCT04349241, NCT04358549, NCT04346628, NCT04351295, ChiCTR 2000030113) and different combinations with other drugs (favipiravir + hydroxychloroquine: NCT04359615; favipiravir + tocilizumab: NCT04310228; favipiravir + imatinib + telmisartan + hydroxychloroquine: NCT04356495) are being clinically evaluated for effectiveness against COVID-19.

Apart from the above-mentioned antimicrobial agents, there are some drugs such as darunavir, oseltamivir, nitazoxanide, and ribavirin, that are being discussed in the scientific community to have efficacy against SARS-CoV-2. However, due to the absence of clinical evidence or higher risk factors in comparison to the benefits, such drugs are not recommended to be used in COVID-19. Darunavir is an HIV protease inhibitor that is being considered for its therapeutic activity against COVID-19;

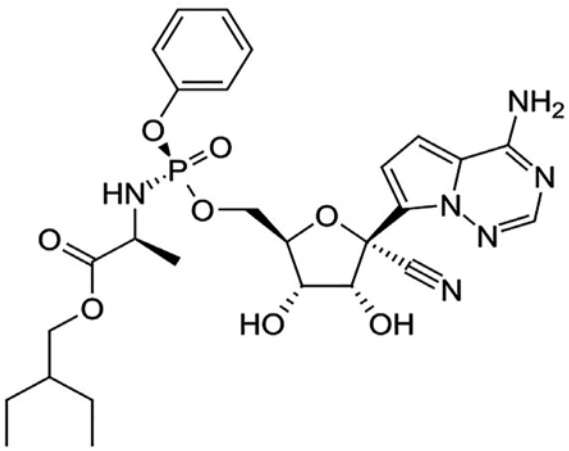

FIGURE 5 | The chemical structure of remdesivir.

FOI 26-3132 Document 5

however, there are no *in vivo* or clinical data available so far, to support the pharmacological efficacy and safety of the drug for COVID-19 patients. The oseltamivir is a neuraminidase inhibitor SARS-CoV-2 does not utilize the neuraminidase enzyme for their budding and multiplication (McKimm-Breschkin, 2012). Therefore, no therapeutic activity is expected by oseltamivir for COVID-19. Nitazoxanide shows some activity against SARS-CoV-2. However, it does not demonstrate any benefit when tested clinically (Gamino-Arroyo et al., 2019).

Moreover, its safety profile and tolerance are also some of the major concerns. Another antiviral agent ribavirin is a guanosine analog that inhibits the replication of DNA and RNA virus. It has shown mixed pharmacological efficacy toward other novel viruses, e.g., SARS-CoV and MERS-CoV (Graci et al., 2006). However, there is no conclusive clinical demonstration of its efficiency toward SARS-CoV-2. Also, the dosage used for its testing for MERS-CoV (800-3600mg/Day) poses a significant adverse reaction profile (Gross and Bryson, 2015; Mo et al., 2016; Arabi et al., 2019). Though, outcomes of some clinical trials for ribavirin in combination with other drugs (ribavirin + lopinavir/ritonavir + interferon-β1b are: NCT04276688, ribavirin+ interferon (IFN)-α/lopinavir-ritonavir/chloroquine phosphate/ arbido: NCT04306497) are still awaited.

ADJUNCTIVE/SUPPORTIVE CARE AGAINST COVID-19

Monoclonal Antibodies

Tocilizumab

It is widely reported that the SARS-CoV-2 activates the innate immunity and the levels of numerous cytokines, such as interleukin (IL)-1β, IL-6, IL-8, TNF, granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF), along with chemokines, such as monocyte chemoattractant protein (MCP)1, macrophage inflammatory protein (MIP)1α, and interferon gamma-induced protein (IP10) get increased with higher levels in those who are severely infected (Schett et al., 2020; Zhang C. et al., 2020; Zhang W. et al., 2020). Tocilizumab competitively inhibits the soluble as well as membrane-bound IL-6 receptor and thereby interferes with its diverse mediated signaling process. IL-6 is formed by T-cells, B-cells, monocytes, lymphocytes, and fibroblasts. This pro-inflammatory cytokine, which is associated with various physiological processes, e.g., activation of T-cell and immunoglobulin secretion, acute-phase protein synthesis initiation in the liver, and activation of hematopoietic precursor cell differentiation and proliferation. Tocilizumab is given intravenously in the treatment of COVID-19 in some countries such as China, and Italy resulted in encouraging outcomes (Harrison, 2020). In one of the retrospective reviews, 21 SARS-CoV-2 infected patients were analyzed, when tocilizumab was added to the standard therapy. Clinical symptoms, lymphocyte percentage, computed tomography (CT) opacity changes, and C-reactive protein (CRP) levels were reported to be improved in these patients, which suggests that tocilizumab has clinical benefits (Xu et al., 2020). However, there were no comparators reported in this study.

In another retrospective study, laboratory descriptors of IL-6 and CRP were assessed for prior and after tocilizumab treatment of 15 COVID-19 patients (7 critically ill; 6 seriously ill; 2 moderately ill). The CRP levels rapidly ameliorated in all the patients, and the IL-6 level in serum was found to further increased initially and then reduced [decreased from 126.9 (10.7–257.9) to 11.2 (0.02–113.7) mg/L ($P < .01$)] after tocilizumab therapy in 10 patients. However, 3 patients who received only one dose of the tocilizumab failed to recover (died), and 2 showed disease aggravation (Luo et al., 2020). Although the above-mentioned studies reported a better response of tocilizumab in COVID-19 patients, one should be cautious while evaluating the outcomes as the reported cases and the duration of treatment (ranging from 2–7 days) still seems to be insufficient. Furthermore, the use of laboratory parameters to express disease activity is a difficult task and may influence the outcome of the study. More significant clinical data for the efficacy of tocilizumab in the management of COVID-19 is awaited from ongoing trials (NCT04335071, NCT04356937, NCT04363853, NCT0 4317092, etc.).

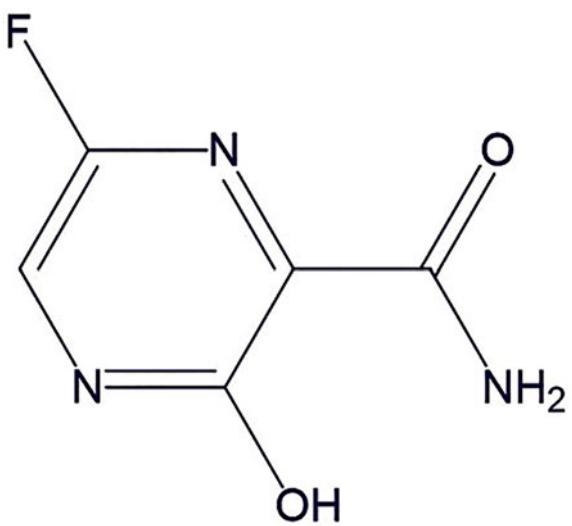

FIGURE 6 | The chemical structure of favipiravir.

Sarilumab

Sarilumab is also an IL-6 receptor inhibitor that interferes with the IL-6 driven through binding with both membrane-bound and soluble IL-6 (sIL-6R and mIL-6R) receptors. The clinical efficacy of sarilumab for COVID-19 patients is under the process of evaluation (NCT04324073; NCT04315298; NCT04327388; NCT04322773; NCT04321993), and the pharmacological potential of it could only be concluded once the robust data evidence are available (Menzella et al., 2020).

Leronlimab

Leronlimab is an investigational humanoid monoclonal antibody and may be used for mitigation of the cytokine storm, which

FOL-26-3132 Document 5

could be a major component in severely diseased COVID-19 patients. It binds with chemokine receptor-5 (CCR5) to alleviate the cytokine release syndrome. The evaluation of leronlimab is now being done in a limited number of severely SARS-CoV-2 infected patients with the emergency investigational new drug application, FDA (CytoDyn, 2020). Data from ongoing clinical trials (NCT04343651, NCT04347239) for the evaluation of therapeutic efficacy and safety of leronlimab will yield a better understanding of its role in the management of COVID-19.

Baricitinib

Baricitinib is a Janus kinase (JAK) inhibitor. Cytokine receptor interactions with cell-membrane produce signals which are further transmitted by the intracellular JAK enzymes to impact the process of immune cell function and hematopoiesis. JAKs phosphorylate and trigger signal transducers and activators of transcription proteins (STATs) during this signal transmission pathway, which affects the intracellular activity. Baricitinib modulates the signaling pathway by preventing phosphorylation of JAKs and thereby inhibiting the STATs activation. The cytokine signal transduction takes place by the pairing of JAKs. Baricitinib has a higher binding affinity for JAK1, JAK2, and tyrosine-protein kinase-2 (TYK2), as compared to JAK3. It inhibits the cytokine activated STAT phosphorylation facilitated by JAKs (JAK1-JAK2, JAK1-JAK3, JAK1-TYK2, or JAK2-TYK2) in the human leukocytes. Baricitinib is an approved drug for rheumatoid arthritis therapy, and if it could pose an antiviral activity by inhibiting JAK-STAT signaling with the same approved dose, that would be a great advantage. However, at the time of early viral infection JAK-STAT signaling pathway (primarily JAK1 and JAK2) activated by interferon gives rise to the increase in the regulation of several interferon-controlled genes that rapidly kill viruses in infected cells (Favalli et al., 2020). To crack this mechanism, many viruses, have developed viral encoded factors to counteract and antagonize the JAK-STAT pathway, which is a crucial descriptor of their viral effect (Fleming, 2016). Therefore, inhibiting the JAK-STAT signaling by baricitinib seems to be substantial facilitation for viral evolution in the host cell.

This argument poses an interesting question upon the general use of baricitinib as an adjunct therapy for COVID-19 patients. However, it is also speculated that patients with the early asymptomatic infection do not need hospitalization, and about 80% of patients can get cured, mostly by endogenous antiviral mechanisms, which certainly includes the interferons (Richardson et al., 2020; Stebbing et al., 2020). Such patients do not require JAK-STAT signaling inhibition. Only the hospitalized patients with after the peak SARS-CoV-2 load (after about 7–10 days of indication onset) show the hyper inflammation due to the so-called cytokine storm resulted from a severe infection, may require the baricitinib therapy. Of note, this clinically critical stage is supported by high level signaling through JAK-STAT pathway, and thereby, enhanced interferons $\alpha+\beta$ and IL-6 levels are reported in the patients. In one of the recent pilot study, 12 moderately SARS-CoV-2 infected patients were found to show improvements in clinical and laboratory parameters with baritinicib (Cantini et al., 2020). In another non-controlled, retrospective cohort study with 15 moderate to severe COVID-19 patients, it was reported that baritinicib with HCQ leads to recovery and clinical improvements (Titanji et al., 2020). However, the efficacy of baritinicib could not be confirmed with scant and insufficient clinical results until enough data about the clinical efficiency and safety profile of baricitinib (NCT04321993, NCT04320277) is available.

COVID-19 Convalescent Plasma

The rationale behind this therapy is that the patient recovered from the COVID-19 may contain antibodies against SARS-CoV-2 in their plasma. Though convalescent plasma (CP) is not intended to prevent COVID-19, it may be used for the severely ill patients at the life-threatening stages as the last resort to improve the survival rate. Of course, the clinical evaluation data for its efficacy must be substantial to prove its effectiveness against the virus. There is evidence that CP works well in reducing the mortality rate of severely infected patients without the occurrence of severe adverse events (Soo et al., 2004; Cheng et al., 2005; Lai, 2005; Chen L. et al., 2020). Moreover, such treatment has worked well with MERS (Arabi et al., 2015) influenza A H1N1 pandemic 2009 virus (Hung et al., 2013), and HIV 1 (Lu et al., 2016). In a timely descriptive study, the effects of ABO-compatible CP therapy were evaluated on 6 COVID-19 positive patients. The evaluation was done based on symptoms improvement, radiologic changes, and laboratory testing. The therapy resulted in the resolution of GGOs and the consolidation of 5 out of 6 patients. There was an instant rise in the anti-SARS-CoV-2 antibody titers in 2 patients, but not all (Ye et al., 2020). These findings suggest that PC therapy is not only effective but also specific in COVID-19. In another CP evaluation study, 6 COVID-19 positive patients (tested by IgM ELISA) were given the therapy. After 11 days of CP transfusion, these patients did not need ventilator support (Zhang L. et al., 2020), which is indicative of the positive response of CP in COVID-19 treatment.

In another study, 5 severely ill patients with ARDS were given CP (two successive dosages of 200–250 ml) along with SARS-CoV-2-specific immunoglobulin G (IgG) titer. Four out of five patients showed body temperature reduction just after 3 days and an increase in the partial pressure of arterial oxygen and percentage of inspired oxygen ratio (PAO_2/FIO_2) after 12 days of treatment (Shen et al., 2020). Their sequential organ failure assessment score also reported being decreased along with the viral load, which became normal after 12 days of CP transfusion. After 14 days of the treatment, mechanical ventilation was not required, which is further indicative of the recovery of the COVID-19 patients. The investigational new drug (IND) regulatory steps led down by FDA to be followed by the investigators/licensed physicians to participate in the study who may have collected the CP from the COVID-19 recovered patients. CP seems to be an effective and safe therapy for critically ill patients infected with SARS-CoV-2. However, some clinical outcomes from multicentered randomized controlled trials are required to substantiate therapeutic promises of CP. A large number of clinical trials are going on

FOI-26-3132 Document 5

for assessment of therapeutic potency and safety of CP in COVID-19, and most of them are currently in phase 2 (NCT04359810, NCT04347681, NCT04345991, NCT04343261).

Conditional Support Therapy

Bronchodilators

Bronchodilators have the potential to enhance the risk of viral transmission with nebulized therapy. Therefore, there is not much role of bronchodilators in the supportive therapy and management of COVID-19 patients except there are chronic obstructive pulmonary disease or asthma (Institute for Safe Medication Practices, 2020). Even with such underlaying diseases, just the metered dose of inhalers is recommended.

NSAIDs

The role of nonsteroidal anti-inflammatory drugs (NSAIDs) in the management of COVID-19 patients is still under investigation (FDA, 2020). Drugs such as ibuprofen may increase angiotensin-converting enzyme 2 (ACE2) expression in the diabatic that could lead to detrimental results in COVID-19 patients. Ibuprofen may also increase the ACE2 expression in case of angiotensin II type-I receptor blockers treated patients (Loutfy et al., 2003; Fang et al., 2020). As a result, it is also suggested that the enhanced expression of ACE2 in the comorbid patients may facilitate the COVID-19 infection. Though, acetaminophen may be carefully used for fever control in the critically ill COVID-19 patients with high temperatures.

Corticosteroids

Corticosteroids (prednisone, methylprednisolone, dexamethasone, and budesonide) may be considered for patients with ARDS or refractory shock (Lian et al., 2020; Wu et al., 2020b; Zhou Y. H. et al., 2020). After exploring the published literature for corticosteroids against coronaviruses, we found that more studies are exploring the therapeutic promises of corticosteroids rather than NSAIDs (Lam et al., 2004; Wong et al., 2004; Chihrin et al., 2005). Overall, corticosteroids were found to have a positive response with respect to SARS-CoV due to their known capability to modulate the inflammations and reduce the immunopathological injury. One of the studies with porcine respiratory coronavirus infected pigs suggests that dexamethasone treatment with one or two doses of corticosteroids lessen early proinflammatory response. However, the prolonged use of corticosteroids may enhance the replication of virus (Zhang et al., 2008). On the contrary, a separate study with SARS-CoV patients indicated that early high dose of steroids with a quinolone gives the most favorable patient outcomes (Zhao et al., 2003). The studies on SARS-CoV infected mice model when treated with dexamethasone showed the alleviation of pulmonary inflammation (Hao et al., 2005).

Recent preliminary clinical trial results suggest that dexamethasone is effective in the life-saving of critically ill COVID-19 patients. This randomized, open-label controlled, adaptive, platform trial showed that dexamethasone reduced the mortality by one third and one fifth in patients getting invasive mechanical ventilation and oxygen support without mechanical ventilation, respectively. However, dexamethasone dose was not effective in reducing the mortality rate in patients not receiving any respiratory support (RECOVERY Collaborative Group, 2020). Results of the clinical trials for various corticosteroids, e.g., prednisone: NCT04344288, NCT04359511; methylprednisolone: NCT04343729; dexamethasone: NCT04360876; inhaled budesonide: NCT04355637 are waited for more clear evidence for the efficacy of corticosteroids in COVID-19.

Inhaled Pulmonary Vasodilators

The data about the use of pulmonary vasodilators are under investigation and aerosolized vasodilators to be avoided in the management of COVID-19 patients. There is no evidence to date about the efficacy of inhaled pulmonary vasodilators such as prostacyclins, nitric oxide, phosphodiesterase inhibitors, endothelin receptor antagonists, etc. in acute respiratory failures in SARS-CoV-2 infection (American Association for Respiratory Care, 2020; Department of Defense, 2020). Data regarding the clinical efficiency of nitric oxide are under investigation (NCT04305457, NCT04306393).

Anticoagulation

Low molecular weight heparin may be recommended to the COVID-19 patents, in the absence of contraindications such as platelet count < 25 x 109/L or active bleeding for venous thromboembolism prophylaxis. Therapeutic intensity anticoagulants may not be recommended for COVID-19 if venous thromboembolism is not present. During the heparin treatment with 449 COVID-19 patients, an increased D-dimer has been reported in the infected hospitalized patients. Mortality of the heparin treated patients was reported to be lower than non-treated patients after 28 days with SIC score ≥ 4 (Tang et al., 2020; Thachil et al., 2020). Ongoing clinical trials (NCT04345848, NCT04362085, NCT04359277, NCT04367831) data for therapeutic and prophylactic efficacy of anticoagulation in COVID-19 will establish better conclusions.

PROBABLE VACCINES

A total of 31 possible vaccines against COVID-19 have already reached to the clinical trials with 142 in the pre-clinical trials (**Table 1**). One such probable vaccine in the clinical trial stage is the recombinant adenovirus vector type 5-based vaccine, developed from the SARS-CoV-2 S gene using a non-replicating viral vector platform (Phase 1- ChiCTR2000030906; Phase 2- ChiCTR2000031781, NCT04313127). This study is sponsored by CanSino Biologics Inc. in Hubei, China and to be manufactured by Beijing Institute of Biotechnology, China. Phase 1 (n=108 healthy individuals) of the vaccine trial is an open, dose-escalating, and single-center study to assess the adverse reactions after 7 days of vaccine administration. Phase 2 (n= 500 healthy individuals) is randomized, placebo-controlled, and double-blind to assess the immunogenicity and safety by finding out the adverse reaction within 0-14 days, anti-SARS-CoV-2 antibody and SARS-CoV-2 neutralizing response after 28 days of the vaccine administration using intramuscular route.

FQI-26-3132 | Document 5

TABLE 1 | Probable vaccines under clinical trials for COVID-19 (as of August 28, 2020).

Vaccine Platform	Candidate Vaccine	Manufacturer/Developer	Route of Administration	
			Intramuscular	Intradermal
RNA	LNP-encapsulated mRNA	NIAID/Moderna	•	
	3 LNP-mRNAs	Pfizer/Fosun Pharma/BioNTech	•	
	mRNA	Curevac	•	
		Duke-NUS/Arcturus	•	
		Walvax Biotech/Academy of Military Sciences (PLA)	•	
	LNP-nCoVsaRNA	Imperial College, London	•	
Protein subunit	Adjuvanted recombinant protein (RBD-Dimer)	Chinese Academy of Sciences (Microbiology Institute)/Anhui Zhifei Longcom Biopharmaceutical	•	
	RBD-based	Kentucky Bioprocessing, Inc	•	
	Adjuvanted recombinant SARS CoV2 glycoprotein nanoparticle vaccine	Novavax	•	
	Trimeric subunit Spike protein (Native) vaccine	GSK/Dynavax/Clover Biopharmaceuticals	•	
	Advax™ adjuvant + Recombinant spike protein	Vaxine Pty Ltd/Medytox	•	
	Molecular clamp stabilized spike protein with MF59 adjuvant	CSL/Seqirus/University of Queensland	•	
	S-2P protein + CpG 1018	NIAID/Dynavax/Medigen Vaccine Biologics Corporation	•	
	RBD + Adjuvant	Instituto Finlay de Vacunas, Cuba	•	
	Peptide	FBRI SRC VB VECTOR, Rospotrebnadzor, Koltsovo	•	
Non-replicatingviral vector	Adenovirus type 5 vector	CanSino Biological Inc./Beijing Institute of Biotechnology	•	
	Ad26COVS1	Janssen Pharmaceuticals	•	
	Adeno-based	Gamaleya Research Institute	•	
	Replication defective Simian adenovirus (GRAd) encoding S	Univercells/ReiThera/LEUKOCARE	•	
	ChAdOx1-S	AstraZeneca/Oxford University	•	
Inactivated	Inactivated	Chinese Academy of Medical Sciences	•	
		Sinovac	•	
		Sinopharm/Wuhan Institute of Biological Products	•	
	Whole-Virion Inactivated	Bharat Biotech	•	
DNA	Plasmid vaccine with electroporation	International Vaccine Institute/Inovio Pharmaceuticals		•
	Plasmid vaccine + Adjuvant	AnGes/Takara Bio/Osaka University	•	
	Plasmid vaccine	Cadila Healthcare Limited		•
	Vaccine (GX-19)	Genexine Consortium	•	
Virus-like particles	Plant-derived VLP adjuvanted with GSK or Dynavax adjs.	GSK	•	
Replicating viral vector	Measles-vector based	Pittsburg University CVR/Merck Sharp & Dohme/Institute Pasteur/Themis	•	
		Sinopharm/Beijing Institute of Biological Products	•	

Here, • = Yes; Blank = No

Another vaccine at the clinical trial level is S gene-based synthetic vaccine, INO-4800 (NCT04336410). It is a DNA plasmid vaccine with electroporation for intradermal route of administration. This open-label study to evaluate the immunogenicity, tolerability, and safety profile of INO-4800 vaccine by testing two different dosages using CELLECTRA® 2000. It is currently in phase 1 (n=120) of the clinical trial with a time frame of 28 weeks, developed by Inovio Pharmaceuticals in Missouri and Pennsylvania, and manufactured by International Vaccine Institute, United States.

Two inactivated vaccine types are being evaluated for the safety and immunogenicity for SARS-CoV-2. Both are randomized, placebo-controlled, and double-blind evaluation studies. One sponsored by Sinovac Biotech Co., Ltd, at Jiangsu, China (NCT04352608) (n=744 estimated) is to evaluate the safety indices of adverse reactions (0–28 days), immunogenicity indexes of neutralizing-antibody (emergency vaccination schedule; 0–14 days, nonemergency vaccination schedule; 0–28 days) for 2 doses. The second is Vero cells based inactivated vaccine (ChiCTR2000031809), sponsored by Henan provincial center for disease control and prevention, China to be conducted in Beijing Institute of Biological Sciences/Wuhan Institute of Biological Sciences for immunogenicity and safety.

The fifth probable vaccine is mRNA-1273 (NCT04283461), which is under open-label dose-ranging trial (n=45 estimated) to evaluate its immunogenicity, reactogenicity, and safety upon twice 0.5 ml IM dose administration to deltoid muscle on 1st and 29th day. mRNA-1273 encodes for a full-length, prefusion stabilized S protein of SARS-CoV-2 and is a novel lipid nanoparticle (LNP)-encapsulated mRNA-based vaccine sponsored by ModernaTX, Inc, United States.

ChAdOx1 (NCT04324606) is another probable vaccine being developed using nonreplicating vector technology to be tested with IM administration. It is based on the adenovirus vaccine vector with SARS-CoV-2 spike protein. Developed by the University of Oxford, United Kingdom, and to be manufactured by AstraZeneca, aimed to conduct a randomized, single-blinded, multi-center phase 1 and 2 study (n= 1112 estimated) to assess

FOI 26-3132 Document 5

the immunogenicity, safety, and efficacy of the ChAdOx. It is single-dose probable vaccine.

There are some other notable probable vaccines are Anhui Zhifei Longcom Biopharmaceutical along and Institute of Microbiology, Chinese Academy of Sciences sponsored adjuvanted recombinant protein (RBD-Dimer), Osaka University, AnGes and Takara Bio sponsored DNA plasmid vaccine and adjuvant, Bharat Biotech's whole virion inactivated vaccine, Cadila's DNA plasmid vaccine, Arcturus/Duke-NUS sponsored mRNA vaccine, Genexine Consortium's GX-19 DNA vaccine, etc.

Apart from above mentioned probable vaccines, Codagenix and Serum Institute of India are investing in viral deoptimization to synthesize rationally designed live attenuated vaccine. It is in the pre-clinical stage and technical details of the proposed vaccine are awaited. To date, all these vaccine proposals are in the trial phase, and there is no approved vaccine specific for SARS-CoV-2 antiviral activity. In the pandemic paradigm, the development of a vaccine needs a quick start with many parallel steps without a pause as compared to the traditional vaccine development where linear steps with multiple analysis pauses are taken to reduce the attrition rate and financial losses. Therefore, it is imperative that some of these may fail; however, chances of getting a vaccine specific to SARS-CoV-2 seems to be higher due to the vast understanding of the viral genome at an unprecedented speed.

CONCLUSION

In the current outbreak, it is imperative to understand which patients might benefit from which set of therapy, especially when more than one disease progression pattern exists. The clinical data available so far is scant and inconsistent; therefore, a set of drugs or combinations or support therapy with complete therapeutic confidence is difficult to derive. Nevertheless, understanding of the treatment and management of COVID-19 patients is evolving very fast. The continuous emergence of clinical trial outcomes, pharmacologic therapy, and efficacy of available drugs for SARS-CoV-2 as clinical data is eagerly awaited. Investigation to assess the therapeutic promises of these drugs require a large number of controlled clinical trials and comparative evaluation for a better understanding of their effectiveness in COVID-19.

ABSTRACT

Background

Pneumonia is a leading cause of morbidity and mortality in children younger than five years of age. Most deaths occur during infancy and in low-income countries. Daily zinc supplements have been reported to prevent acute lower respiratory tract infection (LRTI) and reduce child mortality. This is an update of a review first published in 2010.

Objectives

To evaluate the effectiveness of zinc supplementation in the prevention of pneumonia in children aged two to 59 months.

Search methods

We searched CENTRAL (Issue 21 October 2016), MEDLINE (1966 to October 2016), Embase (1974 to October 2016), LILACS (1982 to October 2016), CINAHL (1981 to October 2016), Web of Science (1985 to October 2016) and IMSEAR (1980 to October 2016).

Selection criteria

Randomised controlled trials (RCTs) evaluating zinc supplementation for the prevention of pneumonia in children aged from 2 months to 59 months.

Data collection and analysis

Two review authors independently assessed trial quality and extracted data.

Main results

We did not identify any new studies for inclusion in this update. We included six studies that involved 5193 participants.

Analysis showed that zinc supplementation reduced the incidence of pneumonia by 13% (fixed-effect risk ratio (RR) 0.87; 95% confidence interval (CI) 0.81 to 0.94, six studies, low-quality evidence) and prevalence of pneumonia by 41% (random-effects RR 0.59; 95% CI 0.35 to 0.99, one study, n = 609, low-quality evidence). On subgroup analysis, we found that zinc reduced the incidence of pneumonia defined by specific clinical criteria by 21% (i.e. confirmation by chest examination or chest radiograph) (fixed-effect RR 0.79; 95% CI 0.71 to 0.88, four studies, n = 3261), but had no effect on lower specificity pneumonia case definition (i.e. age-specific fast breathing with or without lower chest indrawing) (fixed-effect RR 0.95; 95% CI 0.86 to 1.06, four studies, n = 1932).

Authors' conclusions

Zinc supplementation in children is associated with a reduction in the incidence and prevalence of pneumonia.

PLAIN LANGUAGE SUMMARY

Zinc supplementation for the prevention of pneumonia in children aged two to 59 months

Review question

We evaluated the effectiveness of zinc supplementation to prevent pneumonia in children aged from two to 59 months.

Background

Zinc is an essential element for children's growth and development. Too little zinc is associated with increased risk of infection, particularly diarrhoea and pneumonia. Children are more prone to zinc deficiency because they are less able to absorb dietary zinc and some children, especially in low-income countries, may not have received enough zinc from their mothers before birth. Zinc supplements for children has been reported to prevent pneumonia.

Search date

We searched the literature up to October 2016. This is an update of a review published in 2010. We did not find any new studies for this update.

Study characteristics

We included six studies that investigated zinc supplements to prevent pneumonia. The studies were conducted in Bangladesh, India, Peru and South Africa and involved 5193 children aged from two to 59 months. Children received either zinc or a similar-looking treatment that did not contain zinc. In two studies, children were also given vitamin A.

Study funding sources

All included studies were funded. Of these, three explicitly mentioned that funding agencies had no role in the design and results of the study.

Key results

Zinc supplementation was significantly associated with reducing the incidence and prevalence of pneumonia among children aged from two to 59 months. On subgroup analysis, we found that a more stringent diagnosis (radiological examination) increased the reduction in pneumonia incidence.

Quality of the evidence

Overall, evidence quality was assessed as low on GRADE assessment.

SUMMARY OF FINDINGS

Summary of findings for the main comparison. Zinc supplementation compared with placebo for the prevention of pneumonia in children aged 2 months to 59 months

Zinc supplementation compared with placebo for the prevention of pneumonia in children aged 2 months to 59 months

Patient or population: children aged 2 months to 59 months
Settings: Bangladesh, India, Peru, South Africa
Intervention: zinc supplementation
Comparison: placebo

Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	No of Participants (studies)	Quality of the evidence (GRADE)	Comments
	Assumed risk	Corresponding risk				
	Placebo	Zinc supplementation				
Pneumonia incidence	**343 per 1000**	**299 per 1000** (278 to 323)	**RR 0.87** (0.81 to 0.94)	5193 (6 studies)	⊕⊕⊖⊖ **low** [1,2]	
Pneumonia prevalence	**22 per 1000**	**13 per 1000** (8 to 22)	**RR 0.59** (0.35 to 0.99)	609 (1 study)	⊕⊕⊖⊖ **low** [3,4]	

*The basis for the **assumed risk** (e.g. the median control group risk across studies) is provided in footnotes. The **corresponding risk** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).
CI: Confidence interval; **RR:** Risk ratio;

GRADE Working Group grades of evidence
High quality: Further research is very unlikely to change our confidence in the estimate of effect.
Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.
Low quality: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
Very low quality: We are very uncertain about the estimate.

[1] Studies have unclear information on allocation concealment, blinding and reporting biases.
[2] Pneumonia diagnosis criteria was used differently.
[3] Studies have limited information on blinding of outcomes assessors and reporting bias.
[4] Total number of events were less than 300.

BACKGROUND

Description of the condition

Pneumonia is the largest cause of childhood mortality, accounting for 15% of all childhood deaths under five years (WHO 2015), and 19% of all childhood deaths in low-income countries (Bryce 2005; Rudan 2008). Pneumonia is diagnosed by the presence of either fast breathing or lower chest wall indrawing (WHO 2015) in children aged under five years. Presenting features in viral or bacterial pneumonia are similar, however wheezing is more common in children with viral pneumonia.

Pneumonia can be prevented by immunising against *Haemophilus influenzae* type B (Hib), pneumococcus, measles and pertussis (whooping cough) (WHO 2015). Nutrition including breastfeeding for the first six months of life plays a major role by boosting immunity against causative organisms of pneumonia (WHO 2015). Good hygiene and clean indoor air also help in preventing pneumonia (WHO 2015).

Rudan 2013 identified five risk factors for pneumonia: malnutrition, low birth weight, nonexclusive breast feeding, solid fuel use and overcrowding. By 2010, pneumonia episodes for children aged under four years in low- and middle-income countries (LMICs) decreased by 25% over the past decade to about 0.22 episodes per child per year when exposure to the five risk factors decreased by 20% to 30% (Rudan 2013). Therefore, any interventions that can improve child survival from pneumonia are important.

According to the World Health Organization (WHO), zinc deficiency accounts for 13% of all lower respiratory tract infection (LRTIs) (WHO 2009). Acute LRTI is a leading cause of mortality among children aged under five years (Bryce 2005; Rudan 2008), and which is responsible for nearly two million deaths annually, mainly in low-income countries.

Description of the intervention

In 2005, zinc intake was inadequate among 17.3% of the world's population; rates of zinc adequacy are lower in sub-Saharan Africa and South Asia (Wessells 2012). The World Bank described multiple factors such as low animal food intake, less bioavailability of dietary zinc, and zinc loss during events of diarrhoea (Bhutta 1999; Black 1998) that could potentially lead to zinc deficiency in low-income settings (World Bank 2016). The WHO estimated that zinc deficiency may be related to 800,000 deaths a year, with more than 50% occurring in children under five years of age. Children are more susceptible to zinc deficiency because of lower rates of intestinal absorption and from starting life with low body stores due to intrapartum under-nutrition (Krebs 2014).

Mild-to-moderate zinc deficiency is associated with impaired physical growth, delayed sexual maturity, behavioural disturbances, anorexia, affected permeability of the intestinal tract and decreased immunocompetence as well as subclinical inflammation; moderate-to-severe deficiency can lead to diarrhoea; and severe deficiency produces dermatitis and alopecia (Krebs 2014).

There is evidence that preventative zinc supplementation reduces pneumonia morbidity (Bhutta 1999; Yakoob 2011) and is beneficial in reducing diarrhoeal episodes in children with acute and persistent diarrhoea (Bhandari 1994; Zinc Group 2000). However, there is insufficient evidence to support preventive zinc supplementation or adjunctive zinc supplementation with antibiotics to reduce pneumonia-specific mortality (Haider 2011; Yakoob 2011). Zinc supplements (zinc sulphate, zinc gluconate, zinc acetate) can be administered as tablets, syrup or powder. However, zinc supplements need to be administered with caution because excess levels may cause toxicity.

How the intervention might work

Zinc plays an important role in cell regeneration, immunity and growth (Krebs 2014; Shankar 1998). Zinc deficiency decreases T-lymphocytes and T-helper, impairs macrophage function and reduced killer cells (Ibs 2003; Ravaglia 2000), and adversely impacts innate immunity affecting interferon (IFN) gamma production, interleukin-2 (IL-2) and tumour necrosis factor-α (TNF-α) (Krebs 2014). Zinc supplementation in children increases levels of complement in the blood that modulate the function of T-lymphocytes, T-helper, macrophages and neutrophils and hence improves the ability to fight infection. Zinc supplementation improves circulating levels of T-lymphocytes and other macrophages that enhance ability to fight infection (Fraker 1993). Zinc is not stored in the body, but repletion is straightforward. Children with diarrhoea can become zinc deficient quickly. Furthermore, if zinc deficiency occurs during periods of growth, it can be conducive to growth faltering as is shown by a review that found correlation between dietary zinc inadequacy and stunting among children aged under four years (Krebs 2014; Wessells 2012).

Why it is important to do this review

Bhutta 1999 showed that zinc was associated with a reduced incidence of pneumonia. Aggarwal 2007 included more recent studies, but included children aged between birth and 59 months who were given zinc supplements for at least a few months. Roth 2010 calculated the effect size by case definition of pneumonia, and included studies that administered zinc supplements to children aged between birth and 59 months. Yakoob 2011 focused on zinc supplementation for more than three months in children aged under five years and found evidence to support the positive impact of zinc supplementation on diarrhoeal and pneumonia morbidity and mortality to include it in the LiST tool. However Yakoob 2011 did not include low birth weight or small-for-gestational age infants, nor provide a specific case definition for pneumonia. Similarly, a review by Bhutta 2013 of diarrhoea and pneumonia interventions reported a non-significant impact of preventive zinc supplementation on acute lower respiratory infection (ALRI)-related mortality.

We investigated zinc supplementation for at least three months in children aged from two months to 59 months and conducted a meta-analysis of data published up to 2011. However, with new and upcoming trials, this review required updating.

OBJECTIVES

To evaluate the effectiveness of zinc supplementation in the prevention of pneumonia in children aged two to 59 months.

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

METHODS

Criteria for considering studies for this review

Types of studies

We included randomised controlled trials (RCTs) evaluating supplementation of zinc for the prevention of pneumonia in children aged from two to 59 months. We included studies that defined an episode of pneumonia in the following ways.

1. Reported cough or difficulty in breathing with a respiratory rate above the WHO-defined age-specific values (respiratory rate of 50 breaths per minute or more for children aged two to 11 months, or respiratory rate of 40 breaths per minute or more for children aged 12 to 59 months), and either documented fever over 38°C or chest in-drawing (WHO 1990).
2. A diagnosis of pneumonia based on chest examination by a physician.
3. A diagnosis of pneumonia based on a chest radiograph.

We included trials published in languages other than English. Quasi-RCTs were not eligible for inclusion.

Types of participants

We included children aged from two months to 59 months.

Types of interventions

Oral supplement containing at least the USA's recommended daily allowance of zinc versus either an oral supplement without zinc or placebo. We excluded trials in which children were given additional supplements unless the co-interventions other than zinc were the same in both groups. The recommended daily allowance for infants is 5 mg of elemental zinc per day and 10 mg per day for children aged from one to five years (RDA 1989). We included trials in which supplements were administered for at least three months and outcome surveillance was carried out for at least four weeks.

Types of outcome measures

Primary outcomes

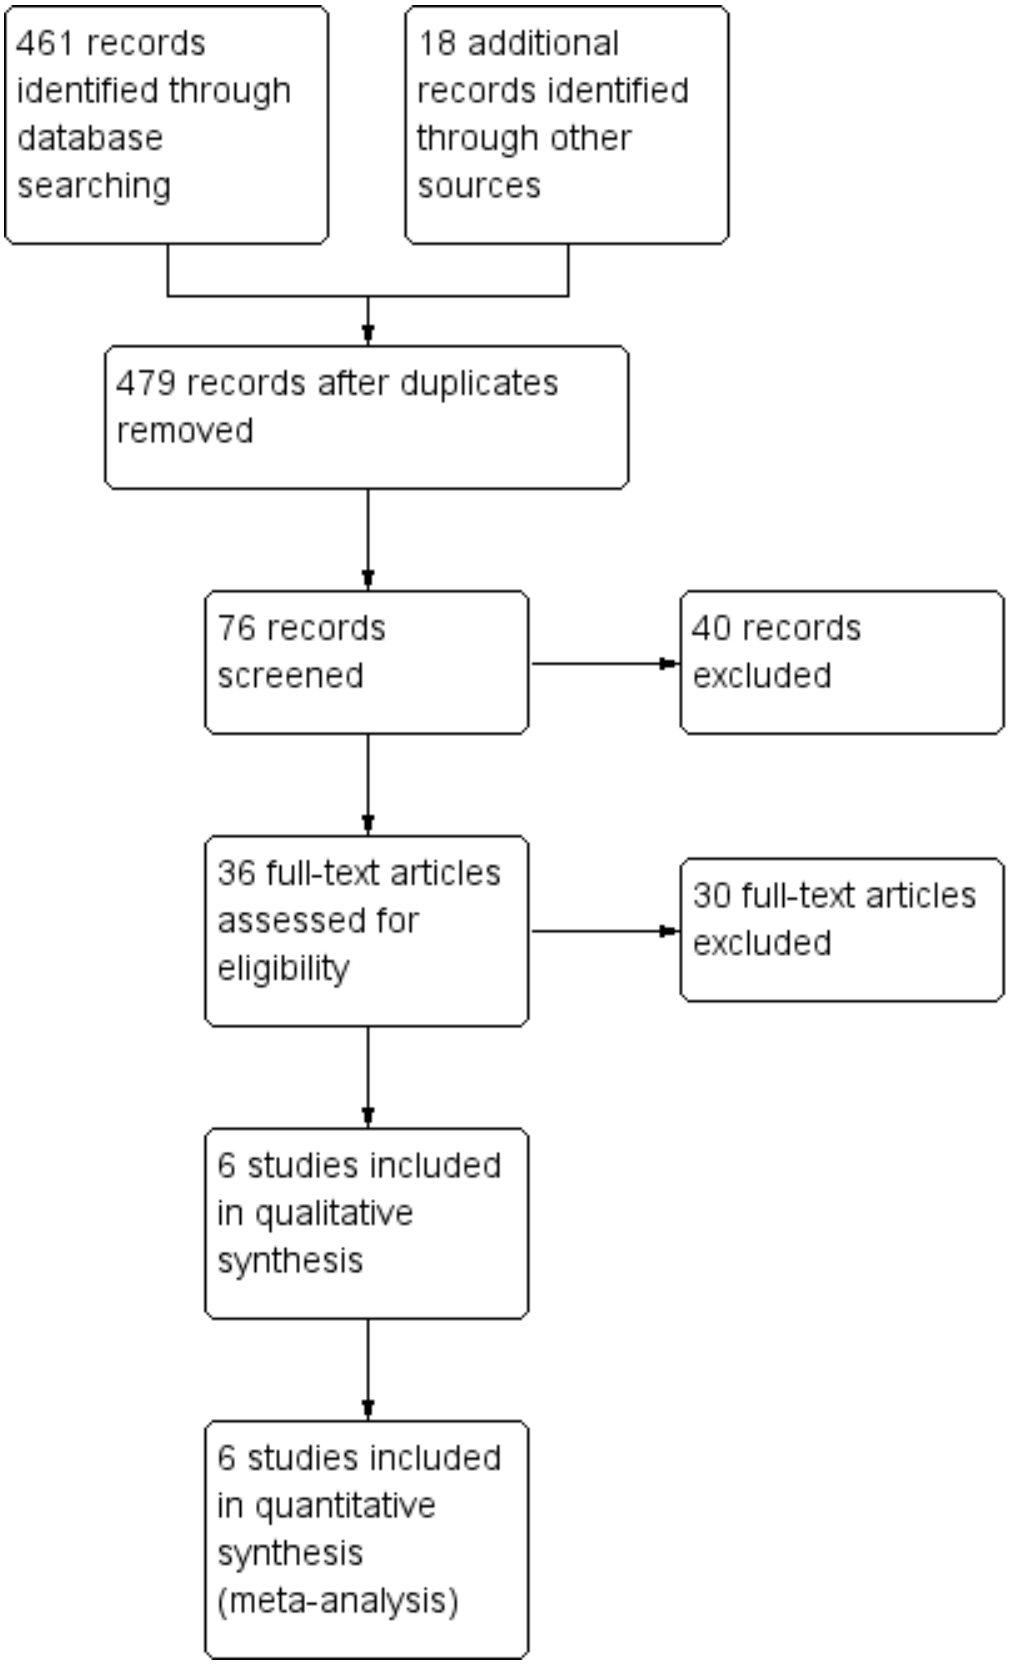
1. Numbers of new episodes of pneumonia in children aged from two months to 59 months.

Secondary outcomes

1. Prevalence (number of cases of pneumonia at a given time per total days of observation) of pneumonia in children aged from two months to 59 months.

Search methods for identification of studies

Electronic searches



We searched the Cochrane Central Register of Controlled Trials (CENTRAL), the Cochrane Library (www.thecochranelibrary.com, accessed 21 October 2016), which contains the Acute Respiratory Infections Group's Specialised Register, MEDLINE (November 2009 to 21 October 2016) and Embase (January 2010 to 21 October 2016). We searched LILACS (1982 to 21 October 2016) using a new search strategy. We also searched CINAHL (1981 to 21 October 2016) and Web of Science (1985 to 21 October 2016). Details of previous searches are presented in Appendix 1.

We used the search strategy described in Appendix 2 to search MEDLINE and CENTRAL. We combined the MEDLINE search with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision); Ovid format (Lefebvre 2011) . We adapted the search strategy to search Embase (Appendix 3), LILACS (Virtual Health Library) (Appendix 4), CINAHL (Appendix 5) and Web of Science (Appendix 6). We searched IMSEAR using the search terms "pneumonia" and "zinc". We imposed no language or publication restrictions.

Figure 1 illustrates the search and study selection processes.

Searching other resources

We searched the WHO ICTRP (www.who.int/ictrp) and ClinicalTrials.gov trials registries (latest search 8 July 2016). We also searched related conference proceedings for relevant abstracts. We also checked the reference lists of all trials identified.

Data collection and analysis

Selection of studies

Two review authors independently assessed all potential studies identified for inclusion. We resolved any disagreement through discussion, and if required, consulted the third review author.

Data extraction and management

We designed a data extraction form. Two review authors extracted data. We resolved discrepancies through discussion, and if required, we consulted the third review author. We entered data into Review Manager software (RevMan 2014) and checked for accuracy. There were no new studies identified for inclusion in this update.

Assessment of risk of bias in included studies

There were no new studies identified for inclusion for this update. For the 2010 version of this review (Lassi 2010), two review authors (ZSL, BAH) independently assessed risk of bias using the criteria outlined in the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2011). We resolved any disagreement by discussion with the third review author (ZAB).

Measures of treatment effect

For dichotomous outcomes, we extracted the total number of participants for each group and numbers of participants experiencing an event. We used risk ratio (RR) and 95% confidence intervals (CIs) to describe effect sizes.

Unit of analysis issues

We carried out statistical analysis using RevMan 2014). Initially, we used fixed-effect inverse variance meta-analysis to combine data where trials examined the same intervention, and study populations and methods were judged sufficiently similar. Where we suspected clinical or methodological heterogeneity between studies sufficient to suggest that treatment effects may differ between trials, we conducted random-effects meta-analysis. When we identified substantial heterogeneity in a fixed-effect meta-analysis, we noted this and repeated the analysis using the random-effects method.

Dealing with missing data

We noted levels of attrition among included studies. As far as possible, we performed analyses on an intention-to-treat (ITT) basis. We attempted to include all participants randomised to each group in the analyses.

Assessment of heterogeneity

We measured heterogeneity among the trials by calculating the I^2 statistic, and Chi^2 P value. If the I^2 statistic exceeded 50%, and the Chi^2 P value was less than 0.1, we would have considered heterogeneity to be substantial. We did not find any heterogeneity; therefore, we did not attempt subgroup analyses based on differences in zinc dosage, participants' age, supplementation in healthy children compared with children recovering from an episode of illness, and pre-intervention zinc levels. However, we attempted to look for the differential effect of zinc supplementation on the case definition of ALRI.

Assessment of reporting biases

We aimed to assess reporting bias by comparing published study reports with study protocols. We planned to assess for the presence of publication bias by looking for funnel plot asymmetry; however, the low number of included studies meant this was not feasible.

Data synthesis

We carried out statistical analysis using RevMan 2014 software. In the absence of significant heterogeneity, we used the fixed-effect meta-analysis model for combining data.

Subgroup analysis and investigation of heterogeneity

We planned to perform subgroup analysis based on diagnosis of pneumonia.

Sensitivity analysis

We planned to carry out a sensitivity analysis to explore the effect of trial quality (assessed by concealment of allocation), by excluding studies with clearly inadequate allocation concealment. However, only two studies had adequate allocation concealment, therefore we did not run the sensitivity analysis.

RESULTS

Description of studies

See Characteristics of included studies, Table 1 and Characteristics of excluded studies tables.

Results of the search

This is an update of a review previously published in 2010 (Lassi 2010). The most recent search (to October 2016) did not identify any new studies for inclusion.

Included studies

We included six trials. These studies were from Bangladesh (Brooks 2005), India (Bhandari 2002; Sazawal 1998), Peru (Penny 2004), and South Africa (Bobat 2005; Luabeya 2007).

Penny 2004 conducted a randomised, double-blind, placebo-controlled community-based trial in Lima, Peru that involved 238 children with diarrhoea for more than 14 days who were aged from six to 36 months. Children were randomised to receive zinc alone, zinc plus vitamins or placebo for two weeks. Childrens' characteristics at baseline were similar except for sex and length-for-age Z scores.

Brooks 2005 conducted a study in a low-income population in an urban setting of Dhaka, Bangladesh. The study included 1665 children aged from 60 days to 12 months who were randomly allocated to receive oral zinc (70 mg) or placebo once weekly. Children were assessed weekly in the children's homes. Children with suggestive respiratory disease or diarrhoea were referred to clinics where they were assessed and diagnoses made based on the WHO criteria.

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

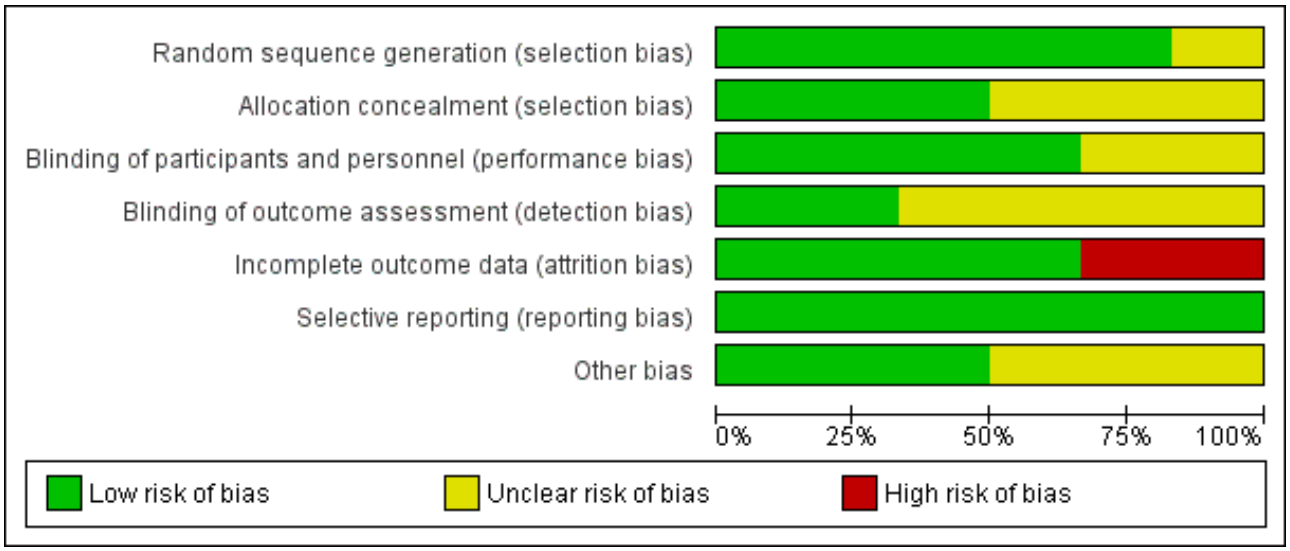
Bhandari 2002 included 2482 children aged six to 30 months who were from urban slums in New Delhi, India. Children received daily elemental zinc (10 mg for infants; 20 mg for older children) or placebo for four months. Both groups received single dose vitamin A (100,000 IU for infants and 200,000 IU for older children) at enrolment. Both groups were comparable on socio-demographic profile, anthropometry, child feeding practices, morbidity in the previous 24 hours, and plasma zinc concentration.

Luabeya 2007 included children aged from four to six months from the KwaZulu-Natal Province of South Africa. Children were randomised to two intervention arms and one control arm. Children in the control arm received vitamin A only; in the first intervention arm they were given vitamin A plus zinc; and in the second intervention arm children received vitamin A, zinc and multiple micronutrients. Children received supplements until 24 months of age, thus each child received zinc supplements for 18 to 20 months. Among the participants, 32 children were born with HIV positive status, and 154 were born without HIV infection to HIV positive mothers. Groups differed on weight-for-length scores.

The double-blind controlled trial by Sazawal 1998 was conducted in a low socioeconomic population of 609 children aged between six and 35 months in urban India. Children were assigned to zinc supplementation (n = 298) and placebo (n = 311) groups. Children in the treatment group received 10 mg elemental zinc and placebo group children received a substance similar in colour and taste. The daily fixed dose of 5 mL per child was given to all enrolled children for six months, but this was increased to 10 mL for children with diarrhoeal illnesses. The baseline characteristics of included children were similar for age, sex, nutritional status and baseline plasma zinc.

Bobat 2005 conducted a randomised, double-blind, placebo-controlled equivalence trial of zinc supplementation at Grey's Hospital in Pietermaritzburg, South Africa. The study included 96 children aged from six to 60 months with HIV 1 infection who were randomly assigned to receive 10 mg of elemental zinc sulphate or placebo daily for six months. Baseline characteristics of included children were similar.

Excluded studies



We excluded 30 studies that did not satisfy inclusion criteria. Seven studies included children outside the age limits of our review criteria (Lira 1998; McDonald 2015; Osendarp 2002; Sur 2003; Taneja 2009; Tielsch 2007 (also reported a different response to intervention definition than we used); Vakili 2009). We excluded seven studies that provided supplements for less than three months (Baqui 2002; Castillo-Duran 1987; Chandyo 2010; Feiken 2014; Rahman 2001; Roy 1999; Sempértegui 1996). We excluded 14 studies that applied different case definitions for ALRI/pneumonia, which were not based on WHO criteria, radiograph or chest examination by physician (Baqui 2003; Larson 2010; Long 2006; Lind 2004; Malik 2014; Mazoomar 2010; Ninh 1996; Reul 1997; Richard 2006; Sampaio 2013; Sanchez 2014; Soofi 2013; Rosado 1997; Umeta 2000). We excluded one study because children received zinc supplement in a fortified drink (Bates 1993). We also excluded one study (Adhikari 2016) because it had included children with recurrent infections.

Please refer to Characteristics of excluded studies for further details.

Risk of bias in included studies

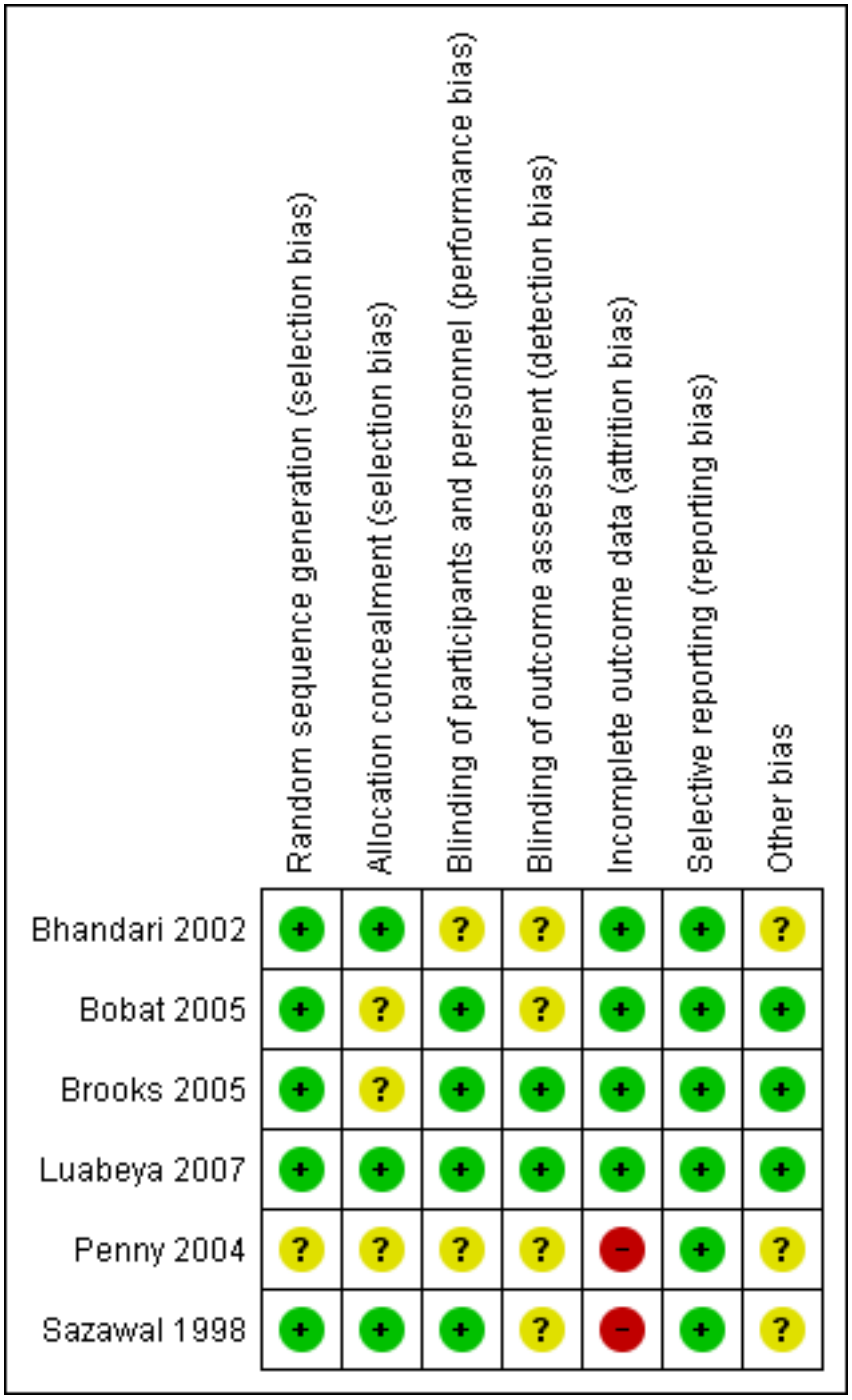


Figure 2 and Figure 3 provide graphical summaries of the 'Risk of bias' assessment for the six included studies. With one exception (Penny 2004), studies were assessed as providing low or unclear risk of bias in relation to methods. Luabeya 2007 had the lowest risk of bias; Penny 2004 was assessed at unclear risk of bias.

Figure 2. Methodological quality graph: review authors' judgements about each methodological quality item presented as percentages across all included studies

Figure 3. Methodological quality summary: review authors' judgements about each methodological quality item for each included study

Allocation

Most included studies were assessed as demonstrating adequate sequence generation and used computer-generated sequencing techniques (Bhandari 2002; Bobat 2005; Brooks 2005; Luabeya 2007; Sazawal 1998). Allocation concealment was adequate three studies (Bhandari 2002; Luabeya 2007; Sazawal 1998); the remainder did not report in sufficient detail to enable assessment (Bobat 2005; Brooks 2005; Penny 2004).

Blinding

Blinding of participants and study personnel was achieved in four studies (Bobat 2005; Brooks 2005; Luabeya 2007; Sazawal 1998). The remaining studies reported insufficient information to permit judgement (Bhandari 2002; Penny 2004).

Blinding of outcome assessors was achieved in Brooks 2005 and Luabeya 2007. Brooks 2005 reported that blinding was not affected because a proportion of children in both the zinc and placebo

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

groups reacted to the taste such that treatment could not be distinguished; Luabeya 2007 reported that outcomes assessors were blinded to assignment.

Incomplete outcome data

Attrition and exclusions were described in all except studies Penny 2004 and Sazawal 1998. The other four studies (Bhandari 2002; Bobat 2005; Brooks 2005; Luabeya 2007) reported reasons for exclusions; these included refusal to participate, moved outside the study site, taste of the syrup, and death.

Selective reporting

Only Luabeya 2007 was registered with a trials register. None of the other studies had published protocols (Bhandari 2002; Bobat 2005; Brooks 2005; Penny 2004; Sazawal 1998). However, all proposed outcomes were reported.

Other potential sources of bias

The funding agencies were reported to have had no input to design or study results in three studies (Bobat 2005; Brooks 2005; Luabeya 2007). Bhandari 2002; Penny 2004 and Sazawal 1998 did not mention the role of funding agencies explicitly.

Effects of interventions

See: **Summary of findings for the main comparison** Zinc supplementation compared with placebo for the prevention of pneumonia in children aged 2 months to 59 months

All six studies reported the incidence of pneumonia (Bhandari 2002; Bobat 2005; Brooks 2005; Luabeya 2007; Penny 2004; Sazawal 1998), while one study (Sazawal 1998) also reported prevalence rates.

Incidence of pneumonia

Administration of zinc supplementation showed a statistically significant impact on reducing pneumonia incidence by 13% (risk ratio (RR) 0.87, 95% confidence interval (CI) 0.81 to 0.94, fixed-effect model, six studies, n = 5193, low-quality evidence). There was no heterogeneity (I^2 statistic = 28%, Chi^2 test P = 0.20; Analysis 1.1).

We pooled studies that used similar case definitions. Studies that used clinical definitions of age-specific fast-breathing, with or without lower chest indrawing did not exhibit impact from zinc supplementation on reducing pneumonia (RR 0.95, 95% CI 0.86 to 1.06, fixed-effect model, four studies, n = 1932). There was no heterogeneity (I^2 statistic = 0%, Chi^2 test P = 0.74).

Studies that applied case definition for pneumonia based on chest examination or chest radiograph exhibited significant impact from zinc supplementation on reducing incidence of pneumonia by 21% (RR 0.79, 95% CI 0.71 to 0.88, fixed-effect model, four studies, n = 3261). There was no heterogeneity (I^2 statistic = 0%, Chi^2 test P = 0.44). Bobat 2005 included children with HIV. When this study was removed from the analysis there was no difference in results (RR 0.88, 95% CI 0.81 to 0.95, fixed-effect model, three studies, n = 3165). Evidence was low quality (Summary of findings for the main comparison).

Prevalence of pneumonia

Administration of zinc supplementation showed a statistically significant impact on reducing the pneumonia prevalence by 41% among children aged from two to 59 months (RR 0.59, 95% CI 0.35 to 0.99, fixed-effect model, one study, n = 609, low-quality evidence; Analysis 1.2). (Summary of findings for the main comparison).

DISCUSSION

Summary of main results

This is an update of a review first published in 2010 and included no new studies. Previous conclusions are unchanged.

We included six randomised controlled trials (RCTs) evaluating the impact of zinc supplementation in children aged from two to 59 months. Our meta-analysis indicated that zinc supplementation led to reductions in the incidence of pneumonia by 13% and pneumonia prevalence by 41%. The greater overall reduction of pneumonia prevalence result is due to prevalence data originating from one study.

We found that zinc reduced pneumonia incidence (defined by specific clinical criteria and confirmed by chest examination or chest radiograph) by 21%. We found an expected association of acute lower respiratory infection (ALRI) case definition with an effect size (P = 0.02). We found benefits of zinc supplementation when ALRI was diagnosed following clinical examination or chest radiography suggesting infection.

Reduction in pneumonia incidence supports the use of zinc supplements among children two to 59 months of age. Because zinc is not stored in the body, adequate zinc needs to be available in daily diet (Sanstead 1995). Children, particularly those from low-income countries who have inadequate intake of food that contains zinc (mainly foods of animal origin) should receive supplements to address deficiency.

Overall completeness and applicability of evidence

Our findings from can be extrapolated for children living in low- and middle-income countries because most included studies were from disadvantaged urban areas of low-income countries (Bangladesh, India, Peru, and South Africa). In two studies, either children or their mothers had HIV positive status (Bobat 2005; Luabeya 2007). In most studies, children were excluded if they had co-morbidities such as tuberculosis, congenital heart disease, less than 60% median weight-for-age Z score, and nutritional oedema. Penny 2004 recruited children on their breastfeeding status. The use of consistent and accurate definitions of pneumonia, with emphasis on clinical documentation of key signs or radiographic diagnosis, would avoid misclassification and lead to greater confidence in study findings.

Quality of the evidence

We assessed that review outcomes were low according to GRADE criteria. We downgraded evidence quality because outcomes were ascertained using different criteria and 'Risk of bias' assessment. Of note, half of the included studies reported pneumonia according to the WHO definition (WHO 1990); the remainder relied on clinical examination and chest radiographs. We therefore looked for differential effects on outcome estimates with respect to case definition and reported their impact separately.

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Allocation concealment was adequately described overall. All included studies were deemed to be adequately blinded for treatment assignment. Completion rates were greater than 90% in four included studies; Penny 2004 reported completion by 16% of participants and Sazawal 1998 did not report numbers of participants who dropped out. The low levels of missing data meant that we chose not to assess the impact on overall estimates because it was not anticipated to cause significant bias in the study results.

Potential biases in the review process

We undertook a systematic search of the literature to identify all studies that met our inclusion criteria. Study selection and data extraction decisions were cross-checked independently by the review authors. Included studies were not free from bias; only one study was assessed at low risk of bias for all domains. We could not assess reporting bias because of the limited numbers of included studies.

Agreements and disagreements with other studies or reviews

We found RCT evidence from both high- and low-income countries showing an effect of zinc in decreasing morbidity and mortality in children due to respiratory and gastro-intestinal infections (Hambidge 1999; Sazawal 1998). The effect of zinc against infectious diseases is therapeutic as well as preventive.

Findings reported by the Zinc Investigators' Collaborative Group in (Bhutta 1999) and Aggarwal 2007 were consistent with our review. Bhutta 1999 reported that children who received zinc supplements had positive effects for pneumonia (odds ratio (OR) 0.59, 95% CI 0.41 to 0.83). Moreover, Bhutta 1999 included trials that administered zinc supplements with therapeutic intent, which might have led to an overestimation of the potential preventive effects of zinc. Aggarwal 2007 included trials that recruited children aged from birth to 59 months who were provided zinc supplementation for at least three months; analysis showed 20% decreased incidence of respiratory illness among children supplemented with zinc compared with placebo. Similar findings were reported by Roth 2010 who also assessed specific case definitions for impact evaluation of children aged from birth to five years. Roth 2010 reported that zinc reduced ALRI incidence defined by specific clinical criteria (incidence rate ratio (IRR) 0.65, 95% CI 0.52 to 0.82), compared with no effect on lower-specificity ALRI case definitions based on caregiver reports (IRR 1.01, 95% CI 0.91 to 1.12) or WHO non-severe pneumonia (IRR 0.96, 95% CI 0.86 to 1.08).

AUTHORS' CONCLUSIONS

Implications for practice

We found sufficient evidence to support the use of zinc supplementation for children aged from two to 59 months to prevent pneumonia. Our analysis supports use of preventive zinc supplementation to improve child health.

Implications for research

More well-designed, large-scale randomised controlled trials (RCTs) are needed to establish the benefit of zinc supplementation for preventing pneumonia among children aged from two to 59 months. Development of effective and feasible interventions to improve zinc status in children is essential. Enhancement of bioavailable zinc in foods by genetic engineering, plant breeding and periodical supplementation are other possible intervention strategies that should be evaluated.

Given the rising burden of child mortality due to respiratory infections, particularly pneumonia, and considering its decreasing impact with zinc supplementation, further reviews should be considered in which the effectiveness of zinc supplementation should be assessed for acute pneumonia provided that cases are well-defined by strict clinical criteria.

ACKNOWLEDGEMENTS

The authors wish to thank Ammad Saeed, who assisted in the development of protocol and Ms Sarah Thorning for her assistance with the literature search. The review authors would like to thank the following people for commenting on the draft review: Abdullah Brooks, Robert Black, Teenah Handiside and Jiaan-Der Wang, Mark Griffin, and John Holden.The draft protocol was written by Dr Batool A Haider (BAH) who also took part in the initial stages of the 2010 review and assisted in data extraction.

CHARACTERISTICS OF STUDIES

Characteristics of included studies *[ordered by study ID]*

Bhandari 2002

Methods	RCT in which the children were individually randomised by a computer-generated simple randomisation scheme in blocks of 8. Zinc or placebo bottles were labelled with a unique child identification number according to the randomisation scheme. Six bottles, one for each month and two extra, for each child were produced and labelled before enrolment commenced. The supplies for each child were kept separately in labelled plastic bags. The zinc and placebo syrups were similar in appearance, taste, and packaging. Blinding was maintained during analyses by coding the groups as A or B.

Bhandari 2002 *(Continued)*

	The study took place in the urban slum of Dakshinpuri in New Delhi, India. For episodes to be counted as individual, there had to be at least 14 intervening days. The children in the two groups were comparable for age, anthropometry, child feeding practices, morbidity in the previous 24 hours, socioeconomic characteristics and plasma zinc concentration.
Participants	The study included children aged from 6 to 30 months. There were 1241 children in each group, and after dropouts, the number reduced to 1093 in the zinc and 1133 in the placebo groups. Children were excluded if consent was refused, were likely to move out of the study area within the next four months, needed urgent admission to hospital on the enrolment day or had received a massive dose of vitamin A (100,000 IU for infants and 200,000 IU for older children) within the two months before enrolment.
Interventions	Doses of elemental zinc were 10 mg for infants and 20 mg for older children (twice the recommended daily dosage) as zinc gluconate. Zinc or placebo was taken daily for four months. Both groups received single massive doses of vitamin A (100,000 IU for infants and 200,000 IU for older children) at enrolment. Immunisations and treatment for acute illnesses were provided as per WHO guidelines. Children with acute lower respiratory tract infections received cotrimoxazole. Amoxicillin was substituted if the child did not respond within three days. Children were sent to hospital if they had signs and symptoms that warranted referral according to WHO guidelines.
Outcomes	Incidence of ALRI ALRIs were defined by cough and fast breathing or lower chest indrawing as assessed by the physician; other clinical signs were not taken into account. Fast breathing was defined as 2 counts of > 50 breaths/minute for infants and > 40 breaths/minute for older children. Pneumonia was diagnosed either by a combination of cough with crepitations or bronchial breathing by auscultation or as an episode of ALRI associated with at least one of lower chest indrawing, convulsions, not able to drink or feed, extreme lethargy, restlessness or irritability, nasal flaring, or abnormal sleepiness.
Notes	Funding: European Union (Contract No IC18CT960045), Norwegian Council of Universities' Committee for Development Research and Education (PRO 53/96), Department of Child and Adolescent Health and Development (CAH), WHO.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Quote: "children were individually randomised by a simple randomisation scheme in blocks of eight. The randomisation scheme was generated by a statistician at Statens Serum Institut, not otherwise involved with this study, using the SAS software"
Allocation concealment (selection bias)	Low risk	Quote: "zinc or placebo syrups were prepared and packaged in unbreakable bottles by GK Pharma ApS Koge, Denmark, who also labelled bottles with a unique child identification number according to the randomisation scheme. The supplies of each child were kept separately in labelled plastic bags. The zinc and placebo were similar in appearances, taste and packaging. Masking was maintained during the analysis by coding the groups as A and B"
Blinding of participants and personnel (performance bias) All outcomes	Unclear risk	Quote: "the supplies for each child were kept separately in labelled plastic bags". "Masking was maintained during analyses by coding the groups as A or B"
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Insufficient information to permit judgment

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Bhandari 2002 *(Continued)*

Incomplete outcome data (attrition bias) All outcomes	Low risk	Exclusion (35%) with their reasons documented. Attrition was 12% in the zinc group and 8.7% in the control group. Loss to follow-ups were mainly because they refused further participation, moved and died (3 died in the placebo group only)
Selective reporting (reporting bias)	Low risk	We could not locate the protocol of this study. We could not find the trial registration number of the study. The outcomes mentioned in the methods were reported in the results
Other bias	Unclear risk	Sources of funding: Not mentioned if they had any role in design or results of study

Bobat 2005

Methods	Randomised, double-blind, placebo-controlled trial conducted in Grey's Hospital in Pietermaritburg, South Africa. Baseline measurements of plasma HIV-1 viral load and the percentage of CD4T lymphocytes were established at two study visits before randomisation, and measurements were repeated 3, 6, and 9 months after the start of supplementation.
Participants	96 children with HIV-1 infection between the ages of 6 months and 60 months, being cared for as outpatients at Grey's Hospital, and not receiving anti-retroviral therapy were recruited. Pneumonia was diagnosed by history and physical examination, including chest auscultation, and confirmed by chest radiograph.
Interventions	Children either received 10 mg of elemental zinc as sulphate or placebo every day for 6 months. The child's parent or guardian was given one packet at the first two visits and two packets at each monthly follow-up visit thereafter, and was instructed on how to give the tablet.
Outcomes	The primary outcome measure was plasma HIV-1 viral load and incidence of pneumonia.
Notes	Outpatient management of children with HIV-1 infection is provided by a team of paediatricians, medical officers, and nurses who care for about 20 to 30 children per week. After starting zinc or placebo, children were assessed at Grey's Hospital every 2 weeks for the first month, monthly for 5 months, and a final visit 9 months after zinc or placebo supplementation started. Pneumonia was diagnosed by history and physical examination, including chest auscultation, and confirmed by chest radiograph. Funding: This study was funded by the Johns Hopkins Family Health and Child Survival Cooperative Agreement with the Office of Health, Infectious Diseases, and Nutrition, Global Health Bureau, US Agency for International Development.

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Quote: "Children were block–randomised in three age strata (6 to 23, 24 to 41, and 42 to 60 months)"; "Randomisation lists were computer generated at the WHO in a fixed block size of eight"
Allocation concealment (selection bias)	Unclear risk	Quote: "Tablets of zinc sulphate or placebo were produced by the same manufacturer (Nutriset, Bierne, France) and supplied in blister packets of 14 dispersible tablets"; "An investigator at Grey's Hospital assigned children to the treatment groups. The investigators were unaware of the treatment allocation until follow up was completed"

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Bobat 2005 *(Continued)*

Blinding of participants and personnel (performance bias) All outcomes	Low risk	Quote: "An investigator at Grey's Hospital assigned children to the treatment groups. The investigators were unaware of the treatment allocation until follow up was completed."
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Insufficient information to permit judgement
Incomplete outcome data (attrition bias) All outcomes	Low risk	9/105 participants (8.6%) were excluded. 2/46 (4.4%) and 9/50 (18%) participants did not complete the trial in zinc and placebo groups, respectively. The reasons for lost to follow-up were mainly deaths and refused to participate
Selective reporting (reporting bias)	Low risk	We could not locate the protocol of this study. We could not find the trial registration number of the study. The outcomes mentioned in the methods were reported in the results
Other bias	Low risk	Sources of funding: funding agencies had no role in views and opinions mentioned in the study

Brooks 2005

Methods	RCT in which random assignment to zinc or placebo was done with permuted blocks of variable length between 2 and 8. Placebo was designed to be identical to the zinc syrup in colour, odour, and taste. The study was conducted at Kamalapur, southeastern Dhaka, Bangladesh. The medical officer diagnosed pneumonia if crepitations were heard on inspiration with a respiratory rate greater than 50 breaths per minute; severe pneumonia was diagnosed if there was also chest indrawing, or at least one other danger sign.
Participants	Children aged 60 days to 12 months at the time of enrolment and excluded those with known or suspected tuberculosis, chronic respiratory or congenital heart disease, or severe malnutrition requiring hospital admission. Pneumonia was diagnosed if crepitations were heard on inspiration with a respiratory rate greater than 50 breaths per minute; severe pneumonia was diagnosed if there was also chest indrawing, or at least one other danger sign. Children with wheezing or rhonchi with crepitations were also diagnosed with pneumonia. 809 children were randomly assigned to zinc and 812 to placebo. There were no significant differences between groups at baseline, except for a slightly higher proportion of boys in the zinc group. There was no difference between the groups in serum zinc values at baseline.
Interventions	Zinc was given orally as a syrup (35 mg zinc acetate per 5 mL). The placebo was non-nutritious and vitamin-free. Compliance required intake of two teaspoons of syrup (10 mL). Children with pneumonia were treated with co-trimoxazole (10 mg/kg trimethoprim, twice daily for 5 days) for pneumonia. Children on antibiotics were assessed within 72 hours of starting treatment; those who did not improve (i.e. the respiratory rate did not change by more than 5 breaths/minute from baseline) were switched to treatment with amoxicillin (40 mg/kg, three times daily for 5 days). If oral treatment failed, or if they had severe pneumonia, children were referred to hospital for parenteral treatment (ceftriaxone 75 mg/kg intramuscularly per day). Children with only expiratory wheezes or rhonchi were managed with salbutamol syrup (0.3 mg/kg, 3 times daily), or referred to hospital for danger signs.
Outcomes	Pneumonia incidence. Other outcomes included frequency of other illnesses and mortality.
Notes	Sources of funding: The research was funded by Johns Hopkins Family Health and Child Survival Cooperative Agreement with the US Agency for International Development, the Swiss Development Corporation, and a cooperative agreement between the US Agency for International Development (HRN-A-00-96-90005-00) and core donors to the Centre for Health and Population Research.

Brooks 2005 *(Continued)*

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Quote: "Random assignment to zinc or placebo was done with permuted blocks of variable length between two and eight"
Allocation concealment (selection bias)	Unclear risk	Insufficient information to permit judgement
Blinding of participants and personnel (performance bias) All outcomes	Low risk	Quote: "ACME Laboratories (Dhaka) prepared, labelled and masked the identity of both preparations. Both placebo and treatment were designed to be identical in colour, odour, and taste"; "identity of both the preparations were masked"
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Quote: "Blinding of FRAs was not affected because a proportion of children in both zinc and placebo groups reacted to the taste such that the treatment could not be distinguished"
Incomplete outcome data (attrition bias) All outcomes	Low risk	Loss to follow-up was 9.1%. Withdrawal from both groups was most commonly attributed to the child's reaction to the taste of the syrup, which sometimes resulted in regurgitation. Most of those who withdrew were young, primarily breast fed infants. The highest proportion (37·1%) of withdrawals for both groups occurred at age 2 months, with 77·1% younger than 6 months
Selective reporting (reporting bias)	Low risk	We could not locate the protocol of this study. We could not find the trial registration number of the study. The outcomes mentioned in the methods were reported in the results
Other bias	Low risk	Study seems to be free from other biases; the funding sources had no role in the study design, data collection, data analysis, interpretation of results, or decision to publish this research Funding: The research was funded by Johns Hopkins Family Health and Child Survival Cooperative Agreement with the US Agency for International Development, the Swiss Development Corporation, and a cooperative agreement between the US Agency for International Development (HRN-A-00-96-90005-00) and core donors to the Centre for Health and Population Research

Luabeya 2007

Methods	What was the study design? The study was conducted in northern KwaZulu-Natal Province, South Africa. Children were enrolled into the study by nurses at five government primary health care clinics. Pneumonia by maternal report was considered to have occurred if there was a history of either fast breathing or chest in-drawing. Confirmed pneumonia was defined as an elevated respiratory rate at rest measured by the fieldworker using WHO/UNICEF Integrated Management of Childhood Illness guidelines.
Participants	Add number of participants. Children eligible for study were 4 to 6 months old. Children were excluded from the study if they were: less than 60% of median weight-for-age using United States National Center for Health Statistics standards; had nutritional oedema; had received vitamin or micronutrient supplements in the previous month; had diarrhoea for more than seven days at the time of study enrolment; or were enrolled in another study of a clinical intervention. Confirmed pneumonia was defined as an elevated respiratory rate at rest measured by the fieldworker using WHO/UNICEF Integrated Management of Childhood Illness guidelines.

Luabeya 2007 *(Continued)*

Interventions	The 3 treatment arms were: vitamin A alone; vitamin A plus zinc; and vitamin A, zinc and multiple micronutrients. All supplements were given daily at home from entry into the study until 24 months of age.
Outcomes	Diarrhoea, pneumonia Incidence? prevalence?
Notes	Funding: Supported by grants from the US National Institute of Health (1 UO1 AI45508-01, 1 K24 AI/HDO1671-01, D43TW05572-01 to Dr Bennish) and the Wellcome Trust (Wellcome 62925 to Dr Bennish and Wellcome 063009 to Dr Van den Broeck. The sponsor for the study was the host institution, the Africa Centre for Health and Population Studies, which gave discretion in the investigative team in study design, data analysis, manuscript preparation, and decisions on manuscript submission and publication.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Quote: "An allocation list was prepared using computer-generated random numbers and a block size of six"; assignment to the three treatment arms was done separately for three cohorts of children stratified by HIV status of child and mother: HIV-infected children and mothers; HIV-uninfected children of HIV-infected mothers; and HIV-uninfected children of HIV-uninfected mothers
Allocation concealment (selection bias)	Low risk	Quote: "The manufacturer prepared numbered packs of tablets corresponding to the allocation list. Children enrolled in the study were assigned by a study physician to one of the three study cohorts after results of the HIV tests became available. The physician then allocated the next pack of tablets from the blocks assigned to that cohort to the participant"
Blinding of participants and personnel (performance bias) All outcomes	Low risk	Quote: "Investigators, study staff and participants were blind to the treatment assignments"
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Quote: "Investigators, study staff and participants were blind to the treatment assignments"
Incomplete outcome data (attrition bias) All outcomes	Low risk	Exclusion (12.7%) and attrition (8.1% in vitamin A + zinc and 8.9% in vitamin A group) data were reported along with their reasons. Thirty-seven children withdrew and one died before any home visits took place
Selective reporting (reporting bias)	Low risk	The study appears to be free of selective reporting. Trial Registration ClinicalTrials.gov NCT00156832. The outcomes mentioned in the methods were reported in the results
Other bias	Low risk	Sources of funding: The sponsor for the study was the host institution, the Africa Centre for Health and Population Studies, which gave discretion in the investigative team in study design, data analysis, manuscript preparation, and decisions on manuscript submission and publication

Penny 2004

Methods	This randomised, double-blind, placebo-controlled, community-based trial was carried out in Canto Grande, a shanty town on the outskirts of Lima, Peru. The study was carried out in two phases. During the first phase researchers evaluated the effect of zinc or multiple micronutrient supplementation

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Penny 2004 *(Continued)*

	on the recovery from persistent diarrhoea. During the second phase researchers assessed the effect of continued supplementation on morbidity from new infections during the following 6 months.
Participants	412 children aged 6 to 36 months with diarrhoea for 14 days were randomly assigned, after being stratified for breastfeeding status, to receive two weeks of daily supplementation with one of three indistinguishable supplements: placebo; 20 mg zinc daily as zinc gluconate (zinc group); or 20 mg zinc daily as zinc gluconate plus a mixture of other micronutrients, i.e. vitamins and minerals (zinc VM group). A subset of children consisting of the first 246 children enrolled who intended to remain in the study area subsequently received the same assigned supplement at one-half the initial daily dose (10 mg zinc daily) and continued under observation for a total of 6 months.
Interventions	Supplements were supplied as individual doses of a dry micronutrient mixture with added sugar, colouring and flavouring agents, which were dissolved in clean water in participants' homes and provided as a liquid beverage under the supervision of study personnel on Monday through Friday and by parents or other caregivers during the weekends. There were two intervention arms, zinc plus vitamins and minerals who were given 10 mg of zinc supplementation along with different combinations of mineral and vitamins. Another interventional arm was given zinc 10 mg and the control group was not given any supplementation.
Outcomes	Changes in plasma zinc, haematocrit, haemoglobin, plasma ferritin, pneumonia incidence.
Notes	In this review, groups with zinc and placebo are included for analysis. Examination included assessment of hydration status, measurement of rectal temperature and monitoring of respiratory rate, which was counted for 1 minute and repeated if the rate was greater than age-specific upper limits (50/minute for children aged 6 to 11 months and 40/minute for children aged 11 months). Children were referred to the study physician for diagnosis and treatment when the fieldworker or caregiver was concerned about the child's health status or if the child had any one of several predefined signs of illness, including fever, presentation or worsening of cough with elevated respiratory rate (i.e. fieldworker-defined acute lower respiratory infection), persistent diarrhoea, diarrhoea with signs of dehydration, or vomiting or skin conditions requiring diagnosis. Sources of funding: Supported primarily by the Thrasher Research Fund and the World Health Organization; additional funds were provided by the University of California Pacific Rim Program.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information to permit judgement
Allocation concealment (selection bias)	Unclear risk	Insufficient information to permit judgement
Blinding of participants and personnel (performance bias) All outcomes	Unclear risk	Quote: "double-masked"
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Quote: "double-masked"
Incomplete outcome data (attrition bias) All outcomes	High risk	14/81 (17.3%) in zinc and 13/83 (15.7%) placebo groups lost to follow-up but no reasons were reported

Penny 2004 *(Continued)*

Selective reporting (reporting bias)	Low risk	We could not locate the protocol of this study. We could not find the trial registration number of the study. The outcomes mentioned in the methods were reported in the results
Other bias	Unclear risk	Sources of funding: funding agencies had no role in views and opinions mentioned in the study

Sazawal 1998

Methods	Double-blind RCT in which the loss of follow-up was less than 2% The study was conducted in a low socioeconomic population of urban India.
Participants	Children, 6 to 35 months of age, presenting to a community-based clinic for acute diarrhoea and before enrolment, a parent of the child was given an explanation of the study and written informed consent was obtained. The baseline characteristics for the child-periods included in the analysis were similar between the two groups. The zinc group had 298 participants and the placebo one had 311.
Interventions	Children were randomised to receive either zinc or placebo in a liquid preparation containing vitamins A (800 units), B1 (0.6 mg), B2 (0.5 mg), B6 (0.5 mg), D3 (100 IU), and E (3 mg) and niacinamide (10 mg); the zinc preparation contained zinc gluconate (10 mg elemental zinc). The liquid preparation 5 mL was given daily for 6 months to all enrolled children; during diarrhoeal illness this was increased to 10 mL to provide for excess zinc losses.
Outcomes	Incidence and prevalence of ALRI. ALRI was diagnosed as using WHO criteria for respiratory disease episodes based on fast breathing alone. ALRI was also defined as child having cough and at least one assessment documenting: a) an elevated respiratory rate more than the age-specific value on both 1-minute estimations; and b) a recorded temperature of more than 101°F or lower chest indrawing.
Notes	Funding: This work was supported by grants from the WHO Diarrheal Disease Control Program, the Thrasher Research Fund, the Johns Hopkins Family Health and Child Survival Cooperative Agreement with funding from the US Agency for International Development and the US National Institutes of Health (R29 HD34724). The assistance of Ms Usha Dhingra and Mr Dharminder Kashyap in data management and of Sandoz India Ltd for providing the supplements is appreciated.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Quote: "Randomisation schedules with permuted blocks of 10 were used for children"
Allocation concealment (selection bias)	Low risk	Quote: "Supplements were prepared and coded by Sandoz India Ltd (Mumbai). Both formulation were liquid preparations, similar in colour and taste"
Blinding of participants and personnel (performance bias) All outcomes	Low risk	Quote: "double-blind"; "The Code, which was kept by WHO personnel, was not available to the investigator until the end of the study; "both formulation were liquid preparations, similar in colour and taste"
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Insufficient information to permit judgement

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Sazawal 1998 *(Continued)*

Incomplete outcome data (attrition bias) All outcomes	High risk	Exclusion and attrition rates with their reasons were not described in the study
Selective reporting (reporting bias)	Low risk	We could not locate the protocol of this study. We could not find the trial registration number of the study. The outcomes mentioned in the methods were reported in the results
Other bias	Unclear risk	Sandoz India provided the supplements. Not clear of their role and other funding agencies

ALRI: acute lower respiratory infection
IU: international unit
RCT: randomised controlled trial
WHO: World Health Organization

Characteristics of excluded studies *[ordered by study ID]*

Study	Reason for exclusion
Adhikari 2016	Wrong participants: included children with recurrent respiratory infections
Baqui 2002	Wrong duration: zinc supplementation was given for 2 weeks
Baqui 2003	Wrong diagnosis: ALRI was diagnosed if the child had reported symptoms of cough or difficulty in breathing with rapid breathing with or without chest indrawing
Bates 1993	Wrong mode of supplementation: zinc supplement was delivered in a fortified drink
Castillo-Duran 1987	Wrong duration; wrong outcomes: zinc was supplemented for 60 days; did not study effects on diarrhoea or respiratory illnesses
Chandyo 2010	Wrong duration: duration of intervention was 2 weeks
Feiken 2014	Wrong duration: duration of intervention was 10 days
Larson 2010	Wrong diagnosis: did not use this review's specific ARI definition
Lind 2004	Wrong diagnosis: considered ‘cough and fever’ as ALRI outcome
Lira 1998	Wrong intervention and outcomes: infants were recruited and supplemented from birth; short course supplementation was provided; only cough was reported
Long 2006	Wrong outcome: respiratory tract infection outcomes were defined as the occurrence of cough alone, cough and fever, or cough and rapid respiratory rate as reported by the mother
Malik 2014	Wrong diagnosis: considered "cough or cold with or without fever. ALRI was diagnosed if the child had symptoms of cough with difficult and/or rapid breathing or chest indrawing as informed by the caregiver" as ALRI
Mazoomar 2010	Wrong diagnosis: considered caregiver’s report of cough or difficulty in breathing along with rapid breathing
McDonald 2015	Wrong population: infants aged less than 2 months at start of intervention (5 to 7 weeks)

Copyright © 2017 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Study	Reason for exclusion
Ninh 1996	Wrong diagnosis: respiratory outcome was cough and fever
Osendarp 2002	Wrong population: Infants were recruited and supplemented from 4 weeks of age
Rahman 2001	Wrong duration: supplementation was given for 2 weeks only
Reul 1997	Wrong diagnosis: respiratory infections were defined as the presence of at least two of the following symptoms: runny nose, cough, wheezing, difficulty breathing, or fever
Richard 2006	Wrong diagnosis: ALRI was reported by parent as presence of cough and rapid respiration
Rosado 1997	Wrong diagnosis: respiratory illness was presence of runny nose, common cold, sore throat or cough
Roy 1999	Wrong duration: zinc supplementation period was 2 weeks
Sampaio 2013	Wrong diagnosis: study used Brazilian Ministry of Health Criteria as ARI definition
Sanchez 2014	Wrong diagnosis: presence of two or more of the following symptoms as ARI: "Cough, runny nose, shortness of breath and sore throat two or more days duration"
Sempértegui 1996	Wrong duration: zinc supplementation period was 60 days
Soofi 2013	Wrong diagnosis: definition of ARI: " Signs (fast breathing, chest indrawing) of acute respiratory illness were recorded as reported by the mother. An acute respiratory illness episode was defined as a minimum of 2 days with signs followed by a significant interval of at least 7 days"
Sur 2003	Wrong population: Infants were recruited and supplemented from within 7 days of birth
Taneja 2009	Wrong population: zinc supplementation was given to infants between 2 to 4 weeks and 12 months of age
Tielsch 2007	Wrong diagnosis and population: trial was on children aged 1 to 35 months with data not stratified by age, ARTI: episodes of acute respiratory illness were defined as one or more consecutive days of fever, cough, or difficulty breathing, with all three symptoms on at least 1 day during the episode and at least 7 days between episodes
Umeta 2000	Wrong outcomes: cough was only reported respiratory outcome
Vakili 2009	Wrong population: children included older than review's specified cut off (78 to 120 months)

ALRI: acute lower respiratory infection
ARI: acute respiratory infection
ARTI: acute respiratory tract infection

Table 1. Zinc supplement schedule and duration

Study	Supplement		Schedule	Duration	Surveillance
	Zinc	Control			
Bhandari 2002	**Zinc gluconate** 10 mg	Both groups vitamin A	Daily	4 months	Once weekly
Bobat 2005	**Zinc sulphate** 10 mg	Placebo	Daily	6 months	Every 2 weeks
Brooks 2005	**Zinc acetate** 35 mg to infants 70 mg to children aged > 12 months	Placebo	Weekly	12 months	Once weekly
Luabeya 2007	**Zinc gluconate** 10 mg	Both groups vitamin A	Daily	(Continued until 24 months of age)	Once weekly
Penny 2004	**Zinc gluconate** 10 mg	Placebo	Daily	6 months	Once weekly
Sazawal 1998	**Zinc gluconate** 10 mg	Placebo	Daily	4 months	Every 5th day

APPENDICES

Appendix 1. Previous search strategy

We searched the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2010, issue 2), which contains the Acute Respiratory Infections Group's Specialised Register, MEDLINE (1966 to January Week 2, 2010), Embase (1974 to January 2010) and LILACS (1985 to January 2010).

We used the following search strategy to search MEDLINE and CENTRAL. The search strategy incorporates the search strategy devised by Boluyt 2008 to identify child studies. Due to the small number of search results we chose not to use a search filter to identify randomised trials. We adapted the search strategy to search Embase (see Appendix 2) and LILACS (see Appendix 3).

Feedback comment by Joseph L. Mathew, 10 February 2011

Summary

Please note the following feedback.

1. The forest plot in Analysis 1.1 shows that participants in the trial by Bhandari et al, have been split to present two different outcomes. Half the participants in each arm are included for the outcome "Diagnosis based on age-specific fast breathing with or without lower chest indrawing" and half for the outcome "Diagnosis based age-specific fast breathing AND confirmed by chest examination or chest radiograph". Both outcomes have been presented as subgroup analysis in the same forest plot; although the trial report mentions that both outcomes were evaluated in all participants. Please confirm whether the procedure adopted in this review is standard practice; and the purpose of doing this.

Answer: We presented the findings after dividing the participants equally in the four cells so that participants do not repeat across analysis. The number of participants were 1241 in each group and we divided them as 620/621 for each of the four cells).

2. A similar adjustment seems to have been made with the participants in the trial by Sazawal et al.

Answer: Adjusted

3. The reference section mentions three citations under Sazawal 1998a; and one under Sazawal 1998b. The third citation in Sazawal 1998a is the same as Sazawal 1998b. Further, none of the citations reports 3300 participants in the trial; whereas this is the number included in the meta-analysis. Sazawal's 1995 publication in the New England Journal of Medicine mentions 937 participants; while the 1998 publication in Pediatrics reported 609 participants. Please confirm the basis for using the numbers in the meta-analysis.

Answer: Those were the two parts of the same study. We have now merged it and presented it as one study.

4. The meta-analysis has pooled data from children with HIV infection, along with otherwise healthy children. While it seems reasonable to pool children with unknown HIV status with otherwise healthy children, it would be better to analyse HIV infected children separately since pneumonia in immuno-compromised children could be quite different from otherwise healthy children.

Answer: In the text only, we presented the results on removing Bobat trial as well.

Anthelmintic Avermectins Kill *Mycobacterium tuberculosis*, Including Multidrug-Resistant Clinical Strains

Leah E. Lim,[a] Catherine Vilchèze,[b] Carol Ng,[a] William R. Jacobs, Jr.,[b] Santiago Ramón-García,[a] Charles J. Thompson[a]

Department of Microbiology and Immunology, and Centre for Tuberculosis Research, Life Sciences Centre, University of British Columbia, Vancouver, British Columbia, Canada[a]; Howard Hughes Medical Institute, Department of Microbiology and Immunology, Albert Einstein College of Medicine, Bronx, New York, USA[b]

Avermectins are a family of macrolides known for their anthelmintic activities and traditionally believed to be inactive against all bacteria. Here we report that members of the family, ivermectin, selamectin, and moxidectin, are bactericidal against mycobacterial species, including multidrug-resistant and extensively drug-resistant clinical strains of *Mycobacterium tuberculosis*. Avermectins are approved for clinical and veterinary uses and have documented pharmacokinetic and safety profiles. We suggest that avermectins could be repurposed for tuberculosis treatment.

Antibacterial drug discovery is a costly endeavor with a very limited probability of success (1). The need for new therapies is especially acute in the case of tuberculosis (TB). While *Mycobacterium tuberculosis* is notoriously resistant to most antibiotics and new drugs with novel modes of action are urgently needed, such compounds have proven to be rare and difficult to identify (2). An alternative approach to generate new TB treatment options in a timely and cost-effective manner is "repurposing," i.e., identifying new applications for existing, clinically approved drugs (alone or in combination) with known pharmaceutical properties (3). In a recent study, we validated the concept that drugs that do not inhibit *M. tuberculosis* at clinically relevant concentrations might be introduced for TB therapy if they could be administered within a synergistic combination (4).

In the course of this screening program, we found that selamectin, a commonly used anthelminthic veterinary drug of the avermectin family, effectively inhibited mycobacterial growth in agar and liquid cultures. The avermectins were discovered in the mid-1970s in an antinematode screening program led by Kitasato Institute and the Merck, Sharp, and Dohme (MSD) laboratories (5). The antimycobacterial activity we discovered was surprising because the avermectins were thought to be only effective against helminths, insects, and arachnids and to be inactive against flatworms, protozoa, bacteria, and fungi (5–9). However, we could not identify literature with specific information describing the (lack of) antibacterial activity of the avermectins. In all probability, these negative data remained proprietary information and were never published. We therefore examined the antibacterial effectiveness of four avermectins (doramectin, ivermectin, moxidectin, and selamectin) (Fig. 1) against representative Gram-positive and Gram-negative bacteria (Table 1). Inhibitory effects were not observed on any of these bacteria at concentrations as high as 256 μg/ml using the bacterial growth indicator MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide]. The avermectins were then tested for their inhibitory activities against various *Mycobacterium* species using the same MTT assay (Table 1). This assay has been previously used to test drug sensitivity of *M. tuberculosis*, and the results are entirely consistent with other well-established methods based on nitrate reductase (12), resazurin (12), [^{3}H]glycerol uptake (13), or the gold standard proportion method of viable CFU after treatment (12, 14). All four avermectins inhibited growth of *Mycobacterium bovis* BCG and *M. tuberculosis* laboratory strains (H37Rv, CDC 1551, and Erdman) at concentrations ranging from 1 to 8 μg/ml. Three of the four also inhibited growth of *Mycobacterium smegmatis* within this concentration range. All four avermectins were less active against *Mycobacterium avium*; doramectin had lower levels of activity against all *Mycobacterium* species. Recent reports have shown that the antimycobacterial activity of some drugs is dependent on the presence of glycerol in the assay medium, leading to the identification of leads that lack activity *in vivo* (15, 16). When the activities of ivermectin, moxidectin, and selamectin were assayed in the absence of glycerol against *M. tuberculosis*, only a slight decrease (twofold) in their MICs was observed, demonstrating a glycerol-independent mode of action for the avermectins. In summary, the avermectins were found to be active against each of the four *Mycobacterium* species tested, while all were inactive against bacteria belonging to diverse related and unrelated taxa. Although these structurally related compounds had detectable differences in their activities against the four *Mycobacterium* species, our results suggest that mycobacteria share an unknown essential target for avermectins.

In order to investigate the potential inclusion of avermectins in the limited repertoire of TB drugs that might be used against drug-resistant strains, the activities of avermectins were also surveyed against multidrug-resistant (MDR) and extensively drug-resistant (XDR) *M. tuberculosis* clinical isolates from different geographical locations (Table 1). The MICs of ivermectin, selamectin, and moxidectin were similar against a panel of 27 MDR and XDR clinical isolates having elevated drug resistance profiles including first- and second-line anti-TB drugs, such as ethambutol, ethionamide, isoniazid, kanamycin, rifabutin, rifampin, *p*-amino salicylate (PAS), pyrazinamide, and streptomycin (Table 1). Only three multidrug-resistant (CI15072, CI12081, and BC-MDR2) and two

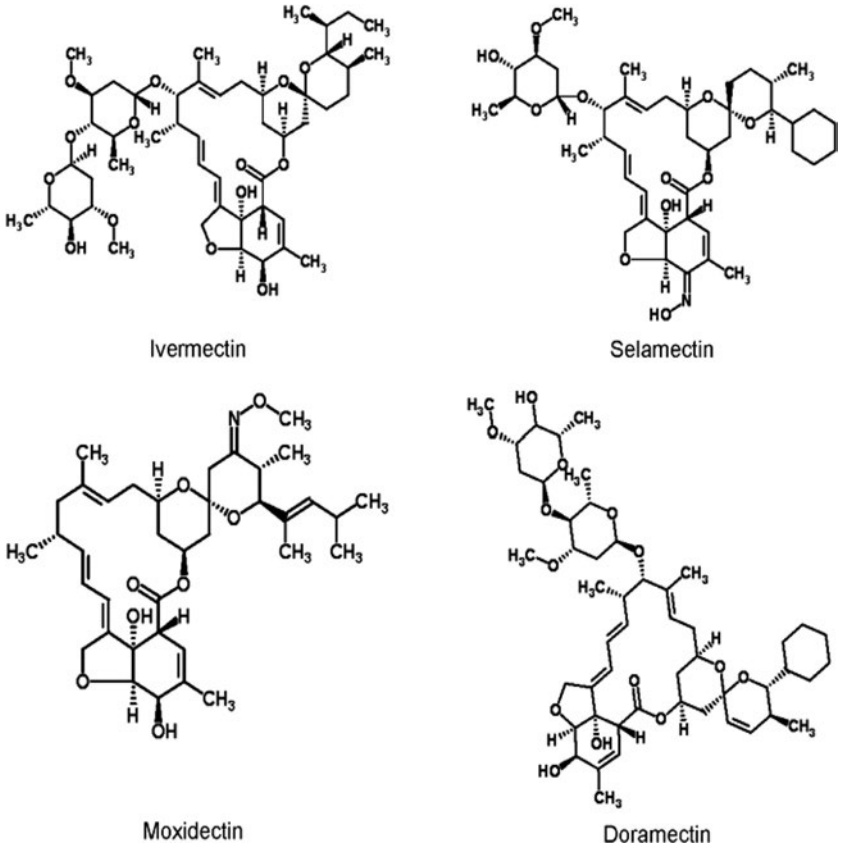

FIG 1 Avermectins used in this study. Images were obtained from ChemSpider.

drug-susceptible (BC-DS4 and BC-DS5) strains were less sensitive to ivermectin ($MIC_{90} > 24$ μg/ml). Nevertheless, inhibitory activity against these strains was reflected in low MIC_{50} values (<8 μg/ml). Importantly, the sensitivity of these strains to selamectin and moxidectin was unaffected. In summary, the avermectins were as effective against most drug-resistant *M. tuberculosis* clinical isolates as they were against *M. tuberculosis* laboratory strains.

To address the question of whether avermectins are bactericidal or bacteriostatic, survival kinetic experiments were done for ivermectin, selamectin, and moxidectin (Fig. 2). Two experiments performed independently, under similar but not identical growth conditions (see the Fig. 2 legend), measured kill kinetics. In the first experiment (Fig. 2A), 21-day kill curves were performed using various concentrations of ivermectin, selamectin, and moxidectin against the laboratory *M. tuberculosis* strain H37Rv. Here, selamectin showed the strongest bactericidal profile. All avermectins proved to be bactericidal, reducing initial bacterial viability up to 6 orders of magnitude (the limits of CFU detection). In the comparable kill kinetic experiment (Fig. 2B) performed independently at another location, the activity of the same dose (20 μg/ml) of each of the avermectins was measured over the same time period against *M. tuberculosis* H37Rv and $mc^2$5857 (an MDR strain; see Table 1 for details). Results were consistent with those described above (Fig. 2A). Moreover, all avermectins tested showed promising bactericidal activity against the MDR strain, reinforcing the MIC data and suggesting potential application of the avermectins for the treatment of MDR and XDR TB patients.

The *in vitro* pharmacodynamic parameters of the avermectins were further analyzed in a third experiment (Fig. 3). *In vitro* dose-response curves for the avermectins were obtained by plotting the change in $\log_{10}$ CFU of the inoculum against the drug concentration *C*/MIC. Using an alternative method to visualize kill kinetics, each avermectin concentration was multiplied by the time of exposure ($C \times T_{days}$) and then divided by the MIC to give the *in vitro* area under the concentration-time curve (AUC/MIC ratio), a standard measure of drug exposure. These analyses both showed that avermectins had exposure-dependent kill kinetics against *M. tuberculosis* under standard *in vitro* broth conditions. The AUC/MIC needed to achieve 1 $\log_{10}$ CFU/ml reduction varied between 2 and 4, while a bactericidal effect (4 $\log_{10}$ CFU/ml reduction, 99.99% killing) required AUC/MIC ratios between 12 and 14. From a TB drug treatment perspective, this value indicates the strong bactericidal effect of avermectins relative to rifampin, the standard frontline drug. The AUC at 24 h (AUC_{24})/MIC value required for a comparable 1 $\log_{10}$ CFU/ml reduction of the first-line antituberculosis drug rifampin is more than 10 times higher (18).

Ivermectin has been used to treat human onchocerciasis and lymphatic filariasis for over 20 years (19–21). Other avermectins (doramectin, moxidectin, and selamectin) used in veterinary medicine for nematode control in pets and livestock are known to be safe and well-tolerated for these indications (19). Selamectin can be administered topically, subcutaneously, or orally in the

[a] Mycobacterial strains were assayed in liquid 7H9 media containing 0.2% glycerol and 10% albumin-dextrose-saline. Nonmycobacterial strains were assayed in LB medium. The MTT assay was used to determine the concentration that inhibited growth by 90%. Values in parentheses indicate 50% growth inhibition (MIC_{50}). The *M. smegmatis* strain was incubated for 3 days, the *M. avium*, *M. bovis* BCG, and *M. tuberculosis* strains were incubated for 7 days, and the nonmycobacterial strains were incubated overnight before the addition of MTT.

[b] Strains V2475 and 1254 have been described previously (10, 11). CI strains are clinical isolates from Mexico. KZN strains are clinical isolates from KwaZulu-Natal, South Africa. BC strains are clinical isolates from British Columbia, Canada.

[c] WT, wild type (no resistance mutations); EMB, ethambutol; ETH, ethionamide; INH, isoniazid; KM, kanamycin; RBT, rifabutin; RIF; rifampin; PAS, *p*-amino salicylate; PZA, pyrazinamide; SM, streptomycin.

[d] ND, not determined.

veterinary setting to treat a number of ecto- and endoparasite conditions in dogs and cats, and it is not presently approved for human use (22). Moxidectin is also safe in humans (23), and it is currently undergoing a phase III clinical trial to compare its efficacy with ivermectin in subjects with *Onchocerca volvulus* infection (http://clinicaltrials.gov/ct2/show/NCT00790998). Because ivermectin is extremely well-tolerated, effective, orally active, and associated with long-term safety, Merck & Co. has donated it to patients with river blindness in needy areas throughout the world (24). Furthermore, the success of this longstanding give-away program indicates that industrial production processes are established and ivermectin could be distributed to large populations with high incidences of MDR TB, a distinct advantage for implementation of TB drug therapy programs. However, to introduce

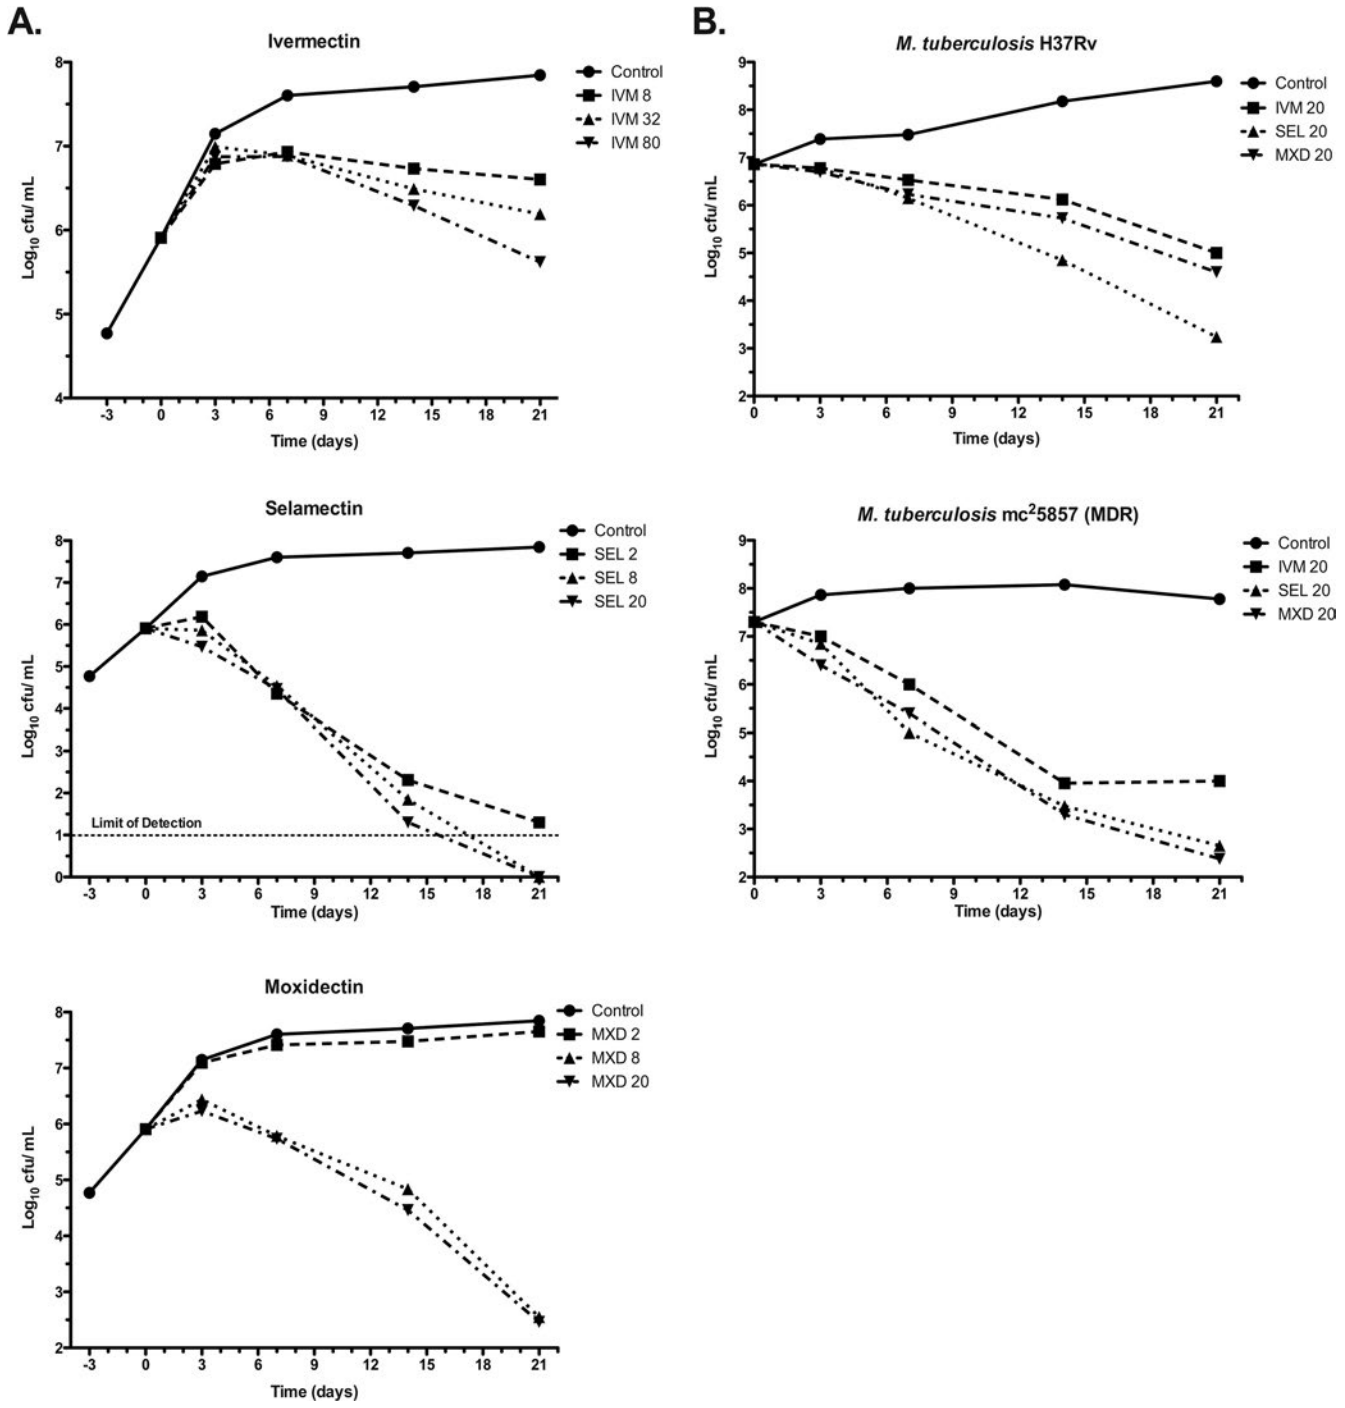

FIG 2 Time-kill kinetics of avermectins against *M. tuberculosis*. Two experiments were performed independently, at two different locations, under similar but not identical growth conditions. (A) Dose titration. Frozen stocks of *M. tuberculosis* H37Rv were cultured in 15 ml of 7H9 broth supplemented with 10% albumin-dextrose-catalase, 0.2% glycerol in standing 25-cm^2 tissue culture flasks at 37°C and 5% CO_2 for 3 days before the addition of avermectins. Cultures were agitated only during sampling. (B) Fixed dose strain comparison. Cultures (5 ml) of *M. tuberculosis* H37Rv and mc^25857 (an MDR isolate) were pregrown in shaking 35-ml bottles in 7H9 broth supplemented with 10% ADC, 0.2% glycerol, and 0.05% tyloxapol to an optical density at 600 nm (OD_{600}) of 0.8. To assess drug activity, cultures were washed once in phosphate-buffered saline (PBS), diluted (1/150) in the same medium (without tyloxapol), and grown at 37°C in shaking 15-ml conical tubes containing ivermectin, selamectin, or moxidectin at 20 μg/ml. Prior to plating, cell clumps were disrupted by sonication and viability was quantified by plating on 7H10 agar supplemented with 10% oleic acid-albumin-dextrose-catalase and 0.2% glycerol. Plates were incubated at 37°C, and colonies were counted after 2 weeks of incubation (microscopically) and reassessed after 4 weeks. Concentrations of avermectins are expressed in μg/ml. IVM, ivermectin; SEL, selamectin; and MXD, moxidectin.

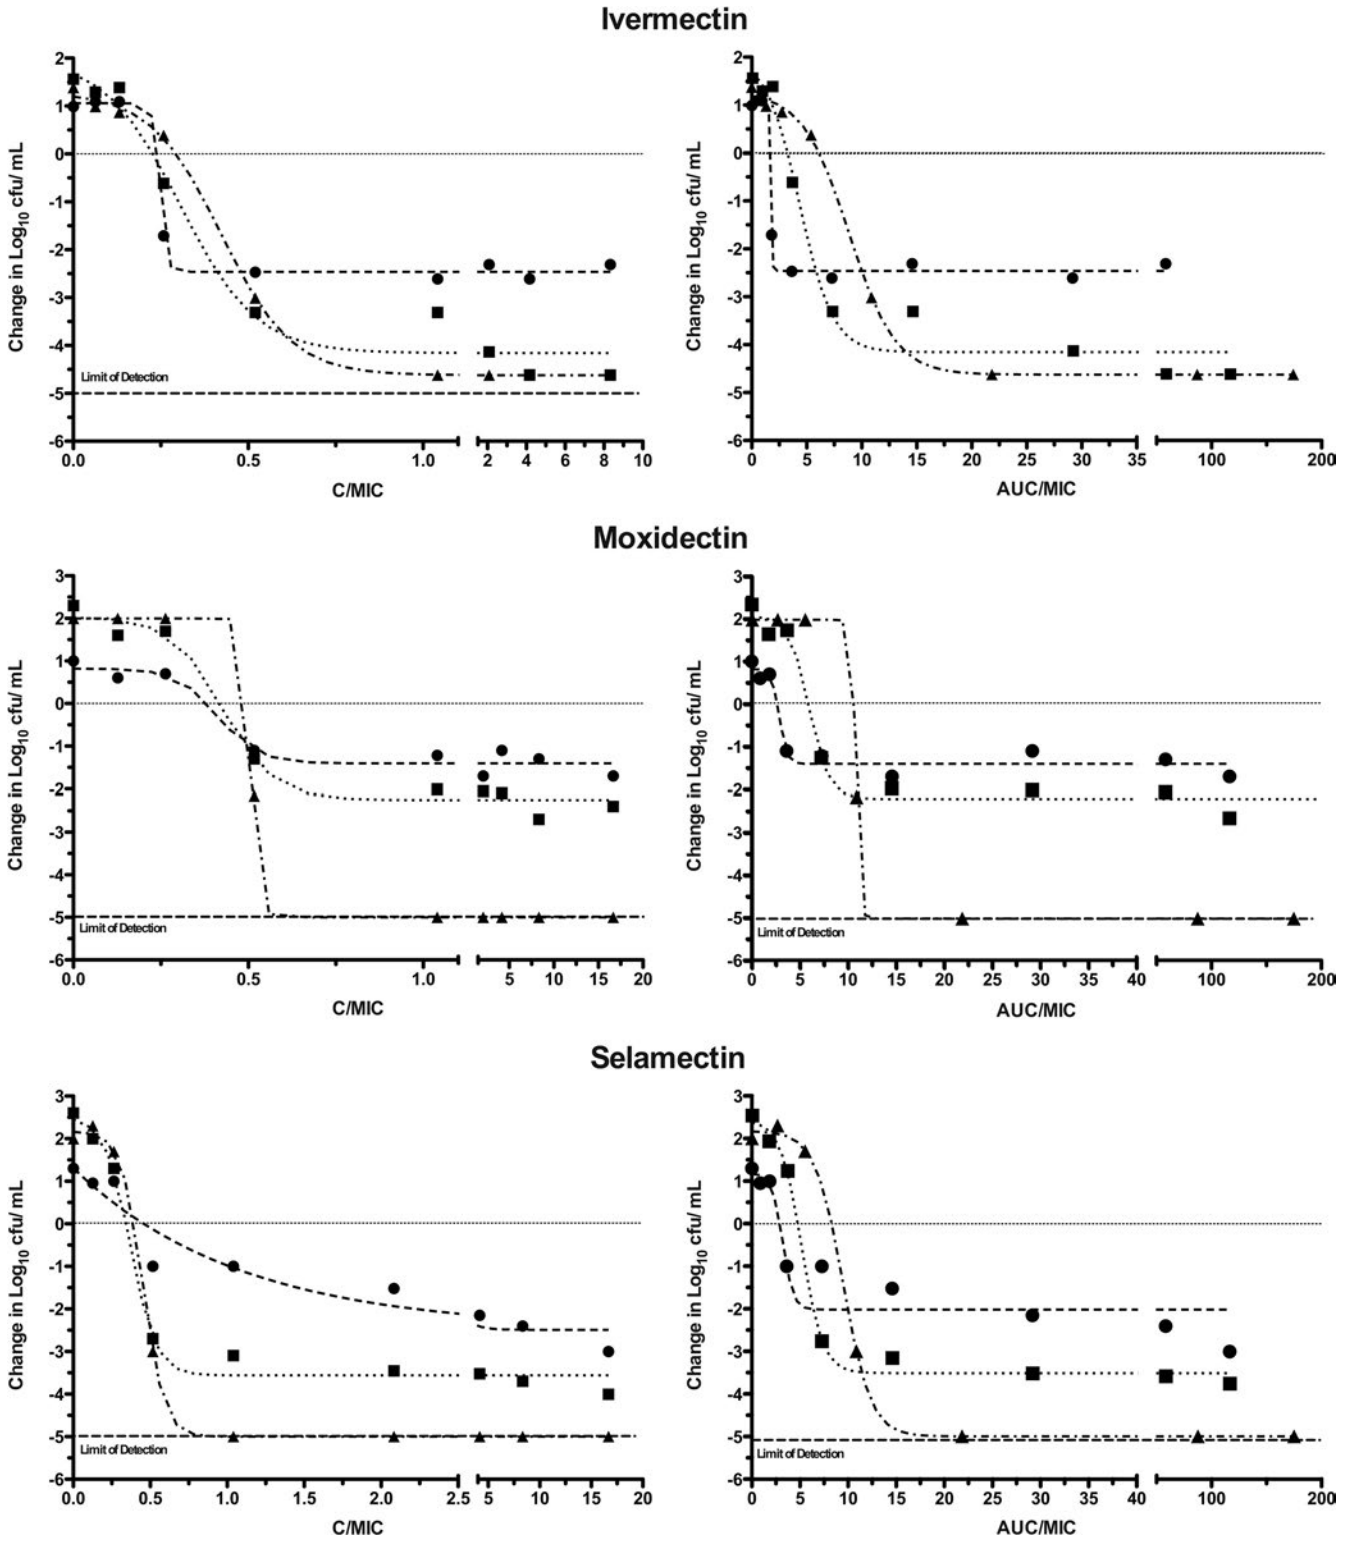

FIG 3 Effect of concentration and exposure on the bactericidal activities of avermectins against *M. tuberculosis*. Comparison of concentration and area under the curve over MIC ratios (C/MIC and AUC/MIC, respectively) on the bactericidal activities of the avermectins. The bactericidal effect was calculated on the basis of the initial inoculum prior to the addition of avermectins. Analysis of antimycobacterial activity was performed by comparing the rates of bacterial killing determined by nonlinear regression analysis with 95% confidence limits. The r^2 values on days 7 (filled circles), 14 (filled squares), and 21 (filled triangles) were 0.9959, 0.9766, and 0.9989 for ivermectin, 0.9591, 0.9827, and not available for moxidectin, and 0.88, 0.9949, and 0.9992 for selamectin, respectively. Cells were processed as described in the Fig. 2 legend for panel B but grown at 37°C in shaking 96-well plates containing 2-fold serial drug dilutions. The MIC values used for calculations were 6, 3, and 3 μg/ml for ivermectin, moxidectin, and selamectin, respectively, as calculated by the MTT assay.

any new TB therapy (especially for MDR or XDR TB), it is essential to establish that it is equal to or better than current treatment options; the promising 2- to 8-μg/ml range of MICs for avermectins in liquid cultures is comparable to that of second-line TB drugs, ranging from 1 to 25 μg/ml against *M. tuberculosis* H37Rv (25). The *in vitro* AUC/MIC ratios of avermectins are a pharmacodynamic predictor of effective bactericidal activity *in vivo*. Importantly, the low exposure needed to achieve this effect (AUC/MIC ratios of 10 to 15) indicates the potential of the avermectins for TB therapy. Thus, the avermectins might be readily adopted into the limited repertoire of drugs available to treat MDR and XDR TB. However, *in vivo* pharmacokinetic and efficacy studies will be needed to assess their clinical application for treating TB.

The apparent specificity of avermectins for mycobacteria implies that their target is unique to this taxon of bacteria. The remarkable complexity and uniqueness of the mycobacterial cell envelope, not present in other bacteria that are resistant to avermectins (including *Streptomyces lividans* and *Rhodococcus jostii*, both related actinobacteria), suggest this structure as a potential target (26). In invertebrate nematodes, avermectins specifically bind to glutamate-gated chloride channels present in nerve and muscle cells, causing paralysis and reduced ability to reproduce (27). Avermectins are orally active and distributed to most parts of the human body, including the lungs (24, 28). Ivermectin does not bind ligand-gated chloride channels in mammals, possibly due to impermeability of the blood-brain barrier and nonspecific pumps that prevent it from reaching the central nervous system (20, 27). Interestingly, moxidectin and selamectin, compounds used extensively in animals to treat a variety of parasitic indications without reported toxicity issues, were also highly active against *M. tuberculosis*. The specificity of avermectins for mycobacteria would be ideal for selectively targeting the pathogen while minimizing deleterious effects on resident gut flora after oral administration.

In summary, this is the first report demonstrating the antimycobacterial activity of avermectins. Their established safety profiles in humans and animals make them potential therapeutic options for treating TB. Future work will be done to identify the mycobacterial target of avermectins, to characterize pharmacokinetic and pharmacodynamic properties in animal models using dosages that are higher than that traditionally needed to treat river blindness, and to define the synergistic drug profiles for possible applications in combinatorial TB therapies.

Crystal structure analysis of Flavivirus methyltransferases uncovered a flavivirus-conserved cavity located next to the binding site for its cofactor, *S*-adenosyl-methionine (SAM). Chemical derivatization of *S*-adenosyl-homocysteine (SAH), the product inhibitor of the methylation reaction, with substituents that extend into the identified cavity, generated inhibitors that showed improved and selective activity against dengue virus methyltransferase (MTase), but not related human enzymes. Crystal structure of dengue virus MTase with a bound SAH derivative revealed that its N6-substituent bound in this cavity and induced conformation changes in residues lining the pocket. These findings demonstrate that one of the major hurdles for the development of methyltransferase-based therapeutics, namely selectivity for disease-related methyltransferases, can be overcome.

Methyltransferases (MTases)[3] play key roles in normal physiology and human diseases through methylating DNA, RNA, and proteins. Almost all MTases use *S*-adenosyl-L-methionine (SAM) as a methyl donor and generate *S*-adenosyl-L-homocysteine (SAH) as a by-product. Pharmacological modulation of MTases by small molecules represents a novel approach to therapeutic intervention in cancer and other diseases (1). However, because the core domains of various MTases are conserved, designing inhibitors that specifically block the disease-related MTase without affecting other MTases, has been challenging. The ability to rationally design and generate selective inhibitors would have profound implications for development of new medicines for many methyltransferase-mediated diseases.

[3] The abbreviations used are: MTase, methyltransferase; SAM, *S*-adenosyl-methionine; SAH, *S*-adenosyl-homocysteine; DENV, Dengue virus; hRNMT, human RNA MTase; RMSD, root-mean-square deviation; SAR, structure-activity relationship.

Dengue virus (DENV), from genus Flavivirus in the family Flaviviridae, is the most prevalent mosquito-borne viral pathogen that infects humans. The four serotypes of DENV (DENV-1 to -4) pose a public health threat to 2.5 billion people worldwide, and cause 50–100 million human infections each year. Neither vaccine nor antiviral therapy is currently available for DENV. The flavivirus MTase methylates the guanine N7 and ribose 2′-*O* positions of the viral RNA cap in a sequential manner (*i.e.* GpppA-RNA → m7GpppA-RNA → m7GpppAm-RNA) (2, 3). Recent studies have shown that flavivirus MTase is critical for viral replication and, therefore, represents a valid target for antiviral therapeutics (4–6). We therefore examined the feasibility to design inhibitors that specifically modulate flavivirus MTase.

EXPERIMENTAL PROCEDURES

Preparation of DENV-3 MTases—The DNA fragment representing the MTase domain of DENV-3 was cloned into expression vector pGEX4T1 (Amersham Biosciences). Ala-substitution mutant MTases were prepared using a standard overlapping PCR procedure. Recombinant MTases, containing an N-terminal GST, were expressed in *Escherichia coli*. BL21 cells and purified through a GSTPrep™ FF 16/10 column (GE Healthcare). The GST tag was then cleaved by thrombin and removed from the MTases using the GST column. The MTases were further purified through gel filtration to ensure protein purity was >95%. The proteins were then concentrated using Amicon Ultra tube (MW cut-off of 10 kDa; Millipore).

Construction and Analysis of Mutant DENV-2—DENV-2 (strain TSV01) genome-length cDNA clones with specific mutations were constructed by using an infectious cDNA clone pACYC FLTSV. The methods for mutagenesis of the cDNA clone, *in vitro* transcription, RNA transfection, immunofluorescence assay, and plaque assay were reported previously (7).

Preparation of Human RNA MTase (hRNMT)—The 1st strand cDNA of hRNMT was synthesized using primer hRNMT-RT-REV (supplemental Table S1) and cellular RNA extracted from HuH7 cells. The cDNA encoding hRNMT amino acids 1–476 was PCR-amplified using primers hRNMT-Xho-FOR and hRNMT-Bam-REV (supplemental Table S1) from the RT reaction. The PCR product was cloned into expression vector pET15b (Novagen). The hRNMT pro-

FOI 26-3132 - Document 5

tein, with an N-terminal His tag, was expressed in BL21 cells, and purified through a 5-ml HiTrap-chelating HP column (Amersham Biosciences).

DENV MTase Assays—Scintillation proximity-based N-7 and 2′-*O* methylation assays were used to determine the inhibitory activities of compounds, as previously reported (8, 9). The standard deviation is calculated by the non-biased *n*-1 method: Standard deviation (S.D.) = $\sqrt{((n\Sigma\times^2 - (\Sigma(\times)^2)/(n(n-1)))}$. Nonlinear regression (curve fit) and the equation below for sigmoidal dose-response (variable slope) from GraphPad Prism version 3.02 (GraphPad Prism, Inc.) were used to interpolate values for IC_{50} values in Equation 1,

$$Y = Bottom + \frac{(Top - Bottom)}{1 + 10^{(\{LogEC50 - X\}*Hill\ Slope)}} \quad \text{(Eq. 1)}$$

where *X* is the logarithm of concentration. *Y* is the response. *Y* starts at *Bottom* and goes to *Top* with a sigmoid shape. This is identical to the "four parameter logistic equation" (10). For determination of K_i values, the Cheng-Prusoff equation (11) shown as Equation 2 was used.

$$K_i = \frac{IC_{50}}{1 + S/K_m} \quad \text{(Eq. 2)}$$

Human DNA MTase 1A (hDNMT1A) Assay—The hDNMT1A reaction contained 2 units of hDNMT1A MTase (New England BioLabs), 1 pmol annealed double-stranded hemi-DNA oligonucleotide (supplemental Table S1), 320 nM [^{3}H-*methyl*]SAM in the hDNMT buffer (50 mM Tris/HCl, pH 7.8, 1 mM EDTA, 1 mM DTT, 5% glycerol, 100 μg/ml BSA, and 0.05% CHAPS). The reaction was assembled in a 96-well ½ area, white opaque plates (Corning). After incubation at 37 °C for 40 min, the reaction was stopped with 2× stop solution (containing streptavidin-SPA beads), and measured for [^{3}H]methyl incorporation. Dose-responsive experiments were performed to determine the K_i values of inhibitors. The double-stranded hemi-DNA oligonucleotide was prepared by annealing 40-μM hDNMT sense and antisense primers (supplemental Table S1) in 1× assay buffer through denaturing at 95 °C for 3 min and cooling to room temperature.

Human RNA guanine-7-MTase (hRNMT) Assay—The hRNMT reaction contained 40 nM hRNMT MTase, 1 pmole RNA substrate (5′-GpppAGAACCUG-biotin-TEG-3 (TriLink BioTechnologies), 640 nM [^{3}H-*methyl*]SAM in the hRNMT buffer (50 mM Tris/HCl, pH 7.5, 5 mM DTT, and 0.05% CHAPS). The RNA substrate and enzyme were first mixed in buffer in a single well in a 96-well ½ area, white opaque plates (Corning), followed by initiation of the reaction with [^{3}H-*methyl*]SAM. The reaction was carried out at 22 °C for 10 min, stopped with 2× stop solution (containing streptavidin-SPA beads), and quantified for [^{3}H]methyl incorporation.

Crystallization and Structure Determination—DENV-3 MTase was crystallized using the hanging-drop vapor diffusion method. 1 μl of reservoir solution (containing 22.5% PEG 8000, 0.2 M NaCl, 0.1 M Tris, pH 8.5, and 20 mM tri-sodium citrate) was mixed with an equal volume of MTase solution at 10 mg/ml. The unit cell parameters are given in Table 1. The asymmetric unit contains two MTase molecules. For the structure with compound, 4 mM of compound was first added to the protein solution from a stock of 50 mM (dissolved in 90% DMSO) prior to mixing with the reservoir solution. Crystals appeared overnight and grew to maximum size within a week. Crystals were frozen by transferring stepwise into a mother liquor containing an additional 10%, then 20% (v/v) glycerol as cryoprotectant, and frozen in liquid nitrogen. Diffraction data were collected at the PXII (X10SA) beam line of the Swiss Light Source, Paul Scherrer Institut, Switzerland. Indexing and scaling were performed using MOSFLM (12) and SCALA, part of the CCP4i suite (13). The structures were determined by molecular replacement using MOLREP from the CCP4i package using DENV2 MTase (PDB code 1L9K) (2) as a search probe. For the compound 10* structure, only one of the two molecules (molecule A) is bound to the inhibitor, while the other molecule C binds to the co-purifying SAH cofactor (Table 2). The bond restraints for the compound were built using SKETCHER from the CCP4i package. Manual rebuilding of the model was performed using COOT (14) and the structures were refined using REFMAC5. The quality of the structures was analyzed using PROCHECK (15).

Binding of RNA to DENV MTase Measured by Competitive Fluorescence Polarization—To measure the displacement of GTP-bodipy binding to DENV MTase by RNA, we adapted the method used by (17). Briefly, 100 nM GTP-bodipy and 300 nM MTase in 50 mM Tris/HCl, pH 7.5 plus 20 mM NaCl were incubated with 2-fold serial dilutions of RNA ranging from 0–3 μM in black 96-well ½ area microplate (Corning). Fluorescence polarization was measured using Synergy 4 microplate reader (Biotek) with λ_{ex} = 485 nm and λ_{em} = 528 nm. IC_{50} (concentration of ligand needed to displace 50% of GTP-bodipy) was determined by fitting the dose response curve with Equation 3,

$$FP = FP_0 + \frac{(FP_T - FP_0)}{1 + 10^{n(\log IC_{50} - \log[L])}} \quad \text{(Eq. 3)}$$

where FP_0 is the fluorescence polarization units (mP) obtained when no GTP-bodipy in bound and FP_T the fluorescence polarization units (mP) when all GTP-bodipy is bound. [L] is the ligand concentration and *n* represents the Hill slope obtained.

K_i for ligand was defined by the Cheng-Prusoff equation (11) shown in Equation 4,

$$K_i = \frac{IC_{50}}{1 + [GTP\text{-}bodipy]/K_d} \quad \text{(Eq. 4)}$$

where K_d is the dissociation constant of GTP-bodipy for MTase (K_d = 0.8 ± 0.2 μM).

Thermo-denaturation Assay—Three μM of MTase were incubated with 0.01X SYPRO® Orange protein gel stain (Invitrogen) in the absence or presence of 50 μM sinefungin (SF) in 1× assay buffer (50 mM Bis/Tris-HCl, pH 7.5 and 20 mM NaCl) for 10 min in a 96-well PCR white plate (Bio-Rad). The plate was then sealed with Microseal®B Adhesive sealer (Bio-Rad) and heated from 25 to 85 °C with increments of 0.5 °C using iQ^{TM}5 Multicolor Real-Time PCR Detection System (Bio-Rad). Excitation and emission wavelengths were 485 nm

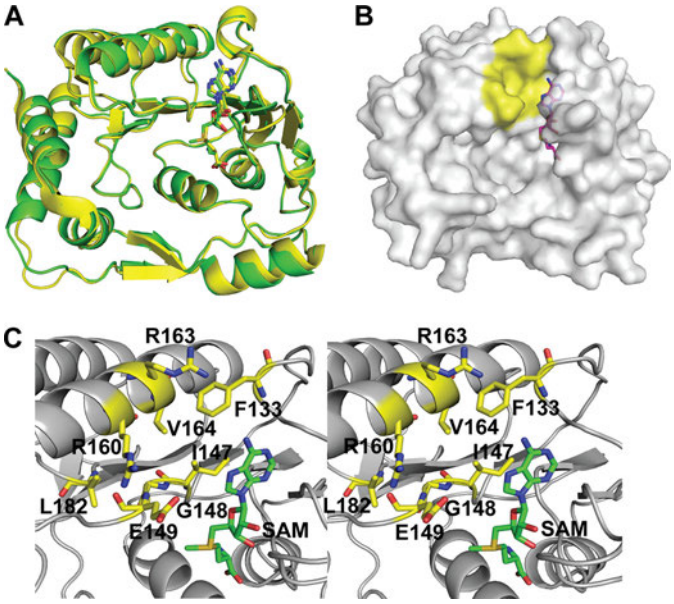

FIGURE 1. **A cavity in DENV MTase.** *A*, superposition of the crystal structures of the DENV-3 MTase-SAM complex (*yellow*) and the DENV-2 MTase-SAH complex (*green*; PDB code: 1L9K (2)). SAM and SAH are shown in *stick representation*. *B*, surface representation of the DENV-3 MTase. The additional cavity adjacent to the adenine of the SAM molecule is colored in *yellow*. The MTase protein was set to partial transparency to view the complete molecule of SAM. SAM is shown as *stick representation*. *C*, stereo view of amino acids involved in the formation of the additional cavity. Residues and the SAM molecule are labeled and shown in *stick representation*. The images were produced using PyMOL.

[b] $R_{merge} = \Sigma_h\Sigma_i|I_{hi} - <I_h>|/\Sigma_{h,i}\, I_{hi}$, where I_{hi} is the *i*th observation of the reflection h, while $<I_h>$ is its mean intensity.

and 625 nm, respectively. MTase melting temperature (T_m) in the presence or absence of SF was determined from the graph of -dRFU/dT *versus* temperature, where RFU is relative fluorescence unit, and T is the temperature in degree Celsius.

RESULTS

DENV MTase-SAM Co-crystal Complex—We determined the crystal structure of DENV-3 MTase (representing the N-terminal 272 amino acids of the viral NS5 protein) in complex with methyl donor SAM at a resolution of 1.7 Å (PDB code 3P8Z), with a final R_{factor} of 19.2% and an R_{free} of 22% (Fig. 1; Tables 1 and 2). The structure of the SAM-MTase complex is almost identical to that of the SAH-MTase complex (2), with an overall Cα root-mean-square deviation (RMSD) of 0.49 Å (Fig. 1*A*). The current structure also closely resembles MTase structures from other members of the Flavivirus family (reviewed in Ref. 18). All residues forming the SAM/SAH-binding pocket are well superimposed (data not shown), indicating that the extra methyl group in the SAM molecule does not affect the ligand-protein interaction. Because no SAM was present during the crystallization, its presence in the structure must have originated from *E. coli* during protein expression. Biochemical analysis of the purified MTase also suggested that the SAM molecule was co-purified with the protein (supplemental Fig. S1).

Mutation of Residues Lining the Hydrophobic Pocket Affect Virus Replication—Structure examination located the additional hydrophobic cavity (colored in *yellow*, Fig. 1*B*) above the adenine base that was previously identified in West Nile virus (WNV) MTase (19). As shown in Fig. 1*C*, the cavity is lined by the conserved amino acids Phe-133, Ile-147, Gly-148, Glu-149, Arg-160, Arg-163, Val-164, and Leu-182, among which Phe-133 and Ile-147 also contribute to the SAM-binding pocket. Functional analysis of the identified cavity was performed through Ala mutations of these residues in the context of genome-length RNA of DENV-2. After transfection into BHK-21 cells, wild-type (WT), and mutant RNAs generated varying amounts of envelope protein-expressing cells in the order of WT>F133A≈L182A >G148A>R163A>R160A (Fig. 2*A*). All RNAs produced infectious viruses with plaque sizes of WT≈F133A≈L182A>G148A≈R163A>R160A (Fig. 2*B*). Sequencing analysis showed that all mutant viruses retained the engineered changes with no other mutations (data not shown). The growth kinetics of F133A and L182A viruses was similar to that of WT virus, whereas the G148A, R160A, and R163A viruses replicated slower than the WT virus (Fig. 2*C*). At 24 h post-infection, the viral titers of these latter three mutant viruses were about 1,000-fold less than that of WT virus (Fig. 2*C*). Similar results were obtained

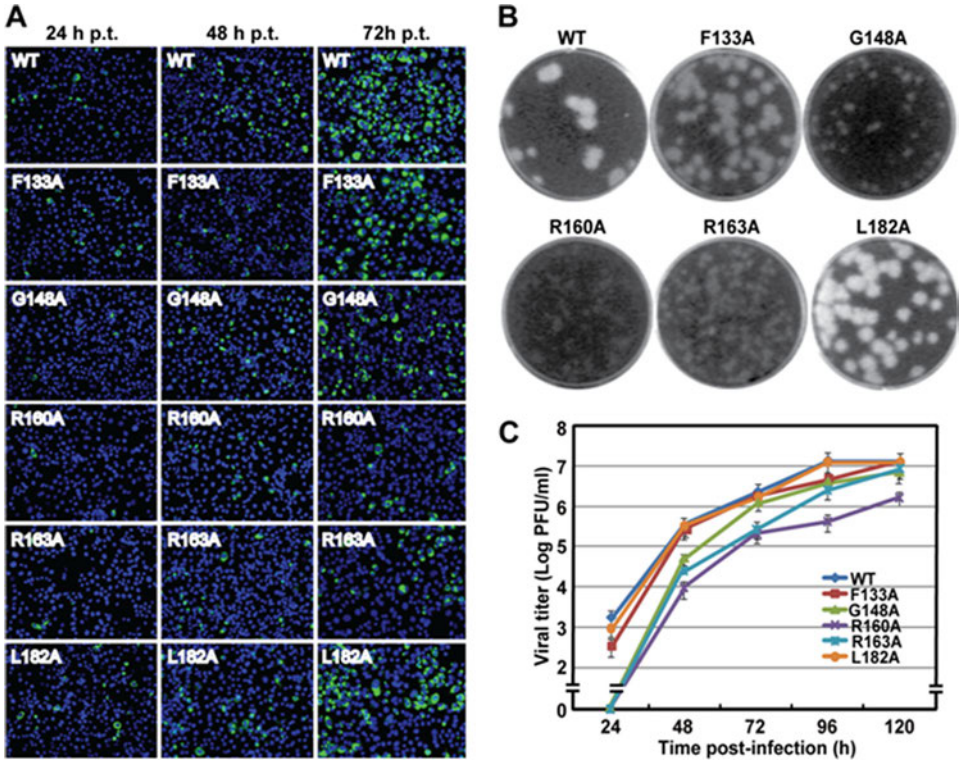

FIGURE 2. **Functional analysis of the identified cavity in DENV-2 replication.** *A*, immunofluorescence analysis (*IFA*). BHK-21 cells were electroporated with WT and mutant genome-length RNAs. The mutant genome-length RNAs contained Ala substitution at indicated positions. At various time points post-transfection (p.t.), the cells were subjected to IFA using mouse antibody 4G2 (against DENV E protein) and anti-mouse immunoglobulin G conjugated with FITC (*green*) as the primary and secondary antibodies, respectively. Nuclei were counterstained with DAPI in *blue*. *B*, plaque morphology of WT and mutant viruses from supernatants collected from Vero cells after 5 days post-infection. *C*, growth kinetics WT and mutant viruses. Vero cells were infected with the indicated viruses at an MOI of 0.1. Culture fluids of the infected cells were determined for viral titers using plaque assay. Note the scale of viral titer from 0 to 10^2 PFU/ml is different from the scale of 10^2 to 10^8 PFU/ml.

from three independent transfection experiments. The negative effect of the R160A or R163A substitution on viral replication was further confirmed using a luciferase-reporting replicon (supplemental Fig. S2). *In vitro* enzymatic assays using recombinant MTases (supplemental Fig. S3) showed that most of the mutations reduced either N-7 (R160A, R163A) or 2′-*O* (F133A, L182A) methylation activities, while both activities were significantly decreased in mutant G148A (Table 3). Thermo-denaturation analysis suggests that the defects in cap methylations are not due to misfolding of the mutant MTases as their melting temperatures are not significantly reduced compared with the WT protein. In addition, their ability to bind RNA and sinefungin was not markedly different from WT protein (Table 3). Overall, the data support results obtained with WNV that the identified cavity is important for Flavivirus cap methylations as well as replication in cells (19).

Design and Synthesis of Selective Inhibitors of Flavivirus MTase—The structural and functional results prompted us to design inhibitors that can specifically bind to the identified cavity of the flavivirus MTase. Because this cavity connects to the SAM-binding pocket at the adenine-holding site, we postulated that substituents extending from the adenine base of the SAH molecule would interact with the identified cavity. Such SAH derivatives would have the potential to selectively inhibit DENV MTase without suppressing host MTases. To test this hypothesis, we synthesized a series of SAH analogs, each with a substitution at the N-6 position of the adenine base (Fig. 3). This N6 position was selected for two reasons: (i) It is in the most optimal geometrical position for making extensions to occupy the hydrophobic cavity, and (ii) the N6 is the most chemically tractable group in the adenine ring for modifications. Compound synthesis was detailed in supplemental materials. The compounds were assayed as inhibitors of N7 and 2′-*O* methyltransferase activities using DENV-3

TABLE 3
Effects of Ala substitutions of DENV MTase hydrophobic pocket residues on DENV-3 MTase activities

DENV-3 MTase	N7 activity[a]	2′-O activity[a]	MTase melting temperature, T_m (°C) [+sinefungin, °C][b]	RNA binding[c], K_i
	%	%		μM
F133A	100 ± 1.2	65 ± 3.2	38 [+1.5]	0.017

R160A	63 ± 4.47	102 ± 5.0	40 [+4]	0.031
R163A	59 ± 4.8	100 ± 5.1	40 [+4]	0.021
L182A	95 ± 5.9	18 ± 5.0	37.5 [+1]	0.052
WT	100	100	40 [+4]	0.048

[a] Recombinant WT and mutant MTases were assayed for N7 and 2′-*O* methyltransferase activities by quantifying the conversion of GpppA-RNA → m7GpppA-RNA and m7GpppA-RNA → m7GpppAm-RNA, respectively (4, 8). Methylation efficiencies of mutant MTases were compared with that of the WT MTase (set at 100%). An average of three experiments is shown.

[b] The stabilities of the mutant and WT proteins were assessed by determination of their melting temperature, and their abilities to bind the SAM mimetic, sinefungin, and RNA substrate. Protein melting temperatures were obtained in thermo-denaturation assays in the presence or absence of 50 μM sinefungin containing SYPRO® Orange protein gel stain (10).

[c] RNA binding was measured with a competitive fluorescence polarization assay with GTP-bodipy and GTP capped RNA-211nt corresponding to DENV 5′-UTR (8, 16).

MTase. For ease of synthesis, initial structure-activity relationship (SAR) was assessed with compounds synthesized as epimeric mixtures, except for compounds 1* and 3* (Symbol * indicates enantiopure; Table 4). The SAR showed that, compared with SAH, a substitution with small alkyl groups (compounds 1* and 2) or a phenyl ring (compound 3*) reduced the anti-MTase activity. Further extension of the substituent showed that a benzyl group was optimal (compound 4), retaining the activity of SAH. Lengthening the spacer by one carbon between the phenyl ring and the adenine N6 reduced the activity (compound 5). Addition of a methyl group on the aryl ring at different positions indicated that the meta position is optimal, leading to an increase in potency of almost 4-fold over the starting point (compare compound 7 with 6 and 8). Next, halogen substituents were introduced at the meta position (compounds 9–12); these compounds exhibited potencies similar to the methyl substituent analog (compound 7). Compared with the SAH starting point, compounds 7 and 9–12 consistently showed better potencies; this conclusion was further supported by the results from enantiopure compounds 10* and SAH* (Table 5). For each compound, the K_i value for N-7 methylation was higher than that for 2′-*O* methylation; this difference could result from the distinct mechanisms of the two cap methylations (20, 21). The parent compound, SAH*, also displayed similar differences in N7 and 2′-*O* inhibition. Nonetheless, the general SAR trend was the same in N-7 and 2′-*O* methyltransferase activities. In stark contrast to SAH and compounds 1–3, the compounds with extended phenyl rings (compounds 4 and 5), and N-6 benzylic substituents (compounds 6–12) had either partially or completely lost the activity against human RNA guanine-7-MTase (hRNMT), DNA MTase 1A (hDNMT1A; Tables 4 and 5), and SET7/9 histone methyltransferases (hHMT; data not shown). These results demonstrate that the N6 modified SAH derivatives can selectively inhibit DENV MTase.

TABLE 5

Because the identified cavity is conserved among flavivirus MTases, we examined whether the SAH analogs would inhibit flavivirus MTase other than DENV. As shown in Table 5, compound 10* also inhibited WNV MTase but was about 2.2-fold less potent than SAH*. Nevertheless, compound 10* did not inhibit host hRNMT or hDNMT (Table 5), indicating its selectivity for flavivirus MTase.

Crystal Structure of DENV-3 MTase Compound Complex—To provide structural evidence for mode-of-action, we solved the crystal structure of DENV-3 MTase in complex with compound 10* at a resolution of 1.7 Å (PDB code 3P97; Tables 1 and 2). The overall structure of the compound 10*-MTase complex is almost identical to that of the SAM-MTase complex, with a Cα RMSD of 0.16 Å (Fig. 4*A*). As shown in Fig. 4, *A* and *B*, the N6 benzyl ring of compound 10* fits snugly into the identified cavity without changing the binding of the SAH moiety. Remarkably, the benzyl ring of the compound induces a local conformational change within the cavity (Fig. 4, *C* and *D*): the side chains of Phe-133 flips away from the cavity by 100 degrees (measured at the Cα and Cβ torsion angle) to create space for the N6 benzylic ring, and the side chains of Arg-163 shifted by 3.5 Å (measured at the NH1 atom) to stack onto the benzylic ring, resulting in the formation of a cation-π interaction. Fig. 4*E* summarizes the interactions established between compound 10* and the DENV-3 MTase.

Effect of Compound-induced Conformational Change on Efficacy—The observed flipping of Phe-133 in the co-crystal structure of DENV-3 MTase-compound complex suggests that this residue at its native conformation sterically blocks the binding of the N6 benzylic ring. If this is the case, substitution of Phe-133 to a residue with a smaller side chain would facilitate the binding of the benzylic ring of compound 10*;

FOI 26-3132 - Document 5

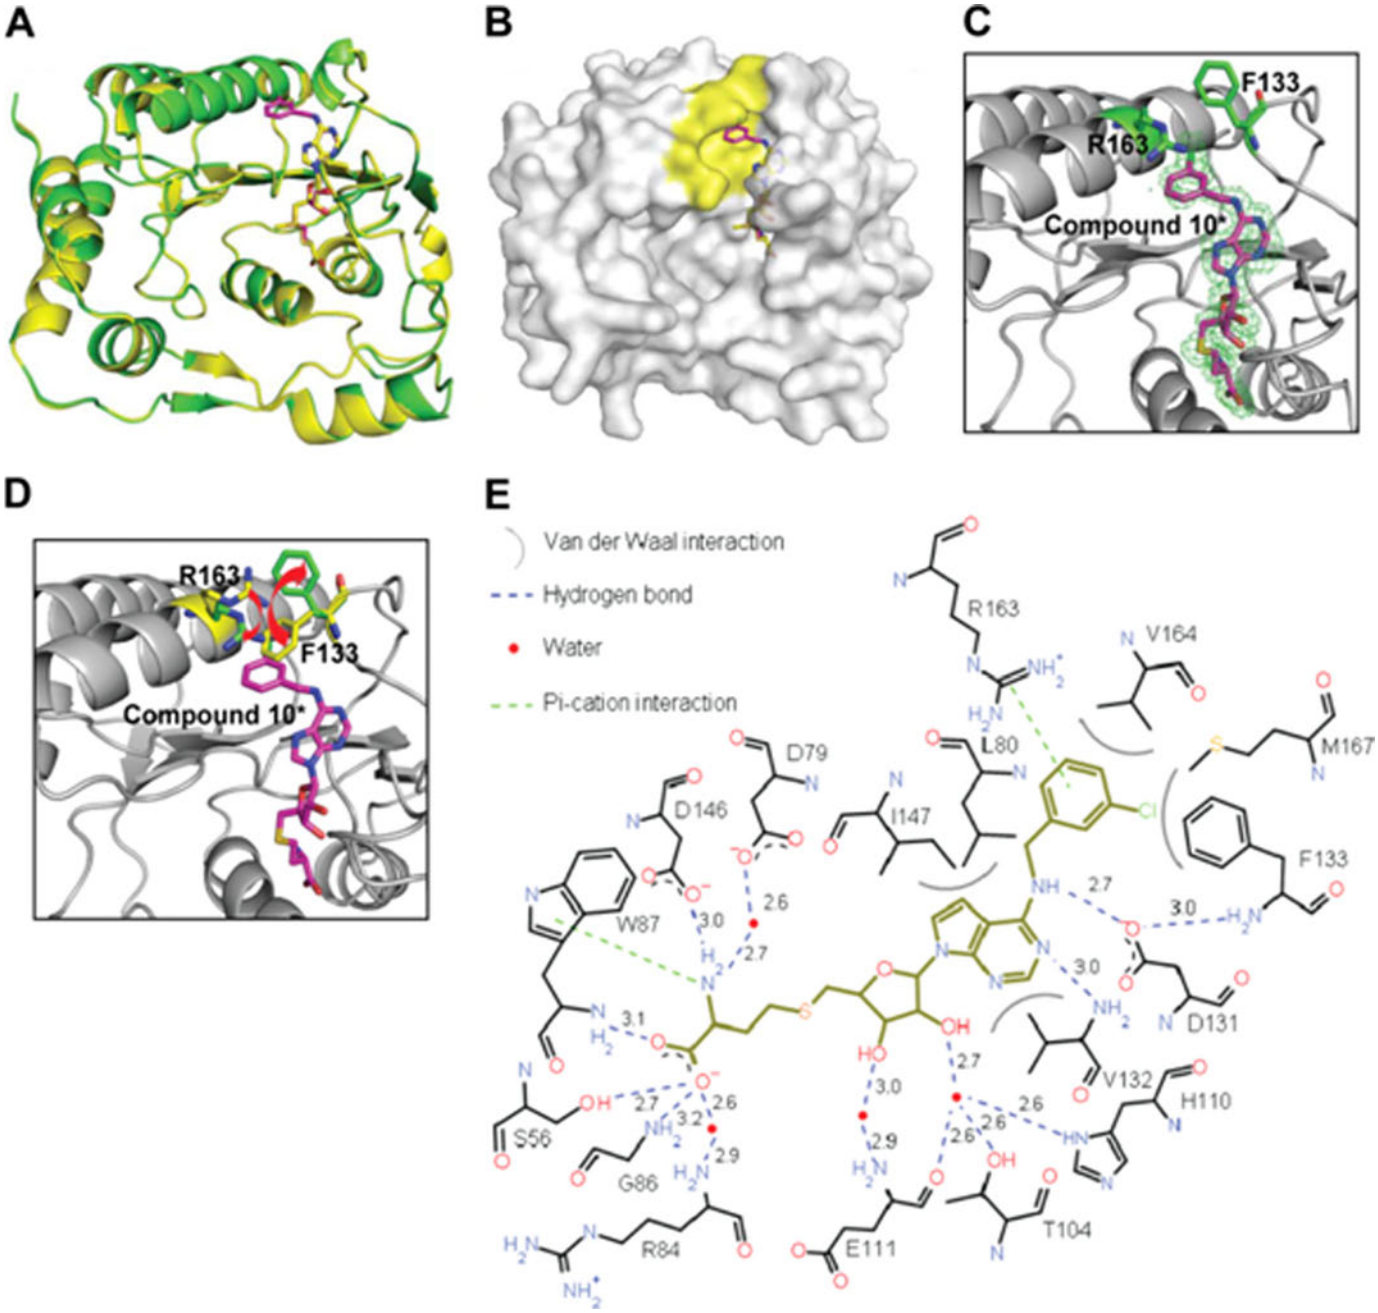

FIGURE 4. **Co-crystal structures of DENV-3 MTase in complex with compound 10*.** *A*, superposition of the crystal structures of compound 10*-DENV-3 MTase (*green*) complex and the MTase-SAM complex (*yellow*). SAM is shown in *stick representation*. Compound 10* is colored in *magenta*. *B*, surface representation of the DENV-3 MTase, showing the binding of compound 10* (in *stick presentation*) in the identified cavity. *C*, representative omit ($F_o - F_c$) electron density map (*green*) at a level of 2.5 σ showing the bound compound 10* molecule. Amino acids Phe-133 and Arg-163 are labeled. *D*, compound-induced conformational change of amino acids. Compound 10* is shown in stick presentation (*magenta*). Residues Phe-133 and Arg-163 in the SAM-MTase complex are colored in *yellow*; the same residues in the compound 10*-MTase complex are shown in *green*; two arrows (*red*) indicate the compound-induced conformational change. *E*, schematic view of the interactions between compound 10* (*brown*) and the DENV-3 MTase (*black*).

consequently, the mutant MTase would be more sensitive than the WT MTase to compound inhibition. To test this hypothesis, we prepared a mutant MTase containing a Phe → Ala substitution at amino acid position 133. Indeed, the K_i values of the F133A MTase were lower (120-fold for N7 activity and 11-fold for 2′-*O* activity) than that of the WT MTase (Table 5). These results demonstrate that the selective inhibition of compound 10* against DENV MTase is obtained through binding of the N6 benzylic ring to the identified pocket.

DISCUSSION

We used DENV MTase as a model to prove the concept that selective inhibitors of disease-related MTase could be obtained. The selectivity was accomplished through designing SAH derivatives with substituents in the adenine moiety that

FOI 26-3132 - Document 5

extend into a cavity located above the SAM-binding pocket. The newly identified pocket is unique to the flavivirus MTases (18, 19) and was not found in the crystal structures of several human MTases available in the Protein Data Bank (data not shown). The starting compound, SAH, is a well-known product inhibitor, which is non-selective and inhibits eukaryotic, bacterial, and viral MTases (22–24). In our hands, it showed similar inhibitory properties against DENV, WNV, human RNA, DNA, and histone MTases (data not shown). Attachment of small alky or phenyl groups to the N6-position in its adenine base failed to improve its potency against DENV MTase or hRNMT, but moderately enhanced its activity against hDNMT by 2–3-fold. Our findings contradicts a previous report in which compound 3 was found to be inactive against hDNMT (25). Introduction of a benzyl ring retained its activity against DENV MTase and strongly reduced its activity against hRNMT. No activity was observed against hDNMT. Thus, some gain in selectivity for DENV MTase was possible through this modification. This result is in agreement with the hDNMT data obtained by Saavedra *et al.* (25). Extension of the benzyl group with a second carbon chain significantly reduced inhibition against all enzymes tested. It is possible that the hydrophobic pocket does not accommodate this longer extension; alternatively, the loss of activity may be due to greater flexibility of the carbon linker and resultant poorer binding into the cavity. Further probing with substituents in the aryl ring revealed that additions in the meta-position provided moderate improved potency for DENV MTase but gained selectivity against hRNMT, DNMT and histone MTases (data not shown). Substitution with either a methyl-, chloro- or fluoro- group in the meta-position resulted in about 4-fold better inhibitory properties compared with SAH. Replacement of a bromo- or iodo-group in this position exhibited similar inhibitory properties on DENV MTase, as the un-substituted aryl ring, indicating that bulky groups on the aryl ring were not preferred. On the other hand, substitution in the ortho position was not advantageous, while the para position conferred some improvement against DENV N7 activity only. Remarkably, additions in all three positions rendered the compounds either inactive or poorly active against hRNMT, hDNMT, and hHMT (data not shown).

Residue Phe-133 is conserved in the several mosquito- and tick-borne Flaviviruses, including DENV, WNV, and JEV (19). Mutation of this amino acid to Ala did not affect DENV N7 and 2′-*O* activity *in vitro*, nor impaired DENV growth in cells. Thus, this residue is not critical for virus replication. Furthermore, Phe-133 is rather flexible, as binding of compound 10* in DENV MTase induced its side chain to rotate away from the cavity, to accommodate its N6-substituted aryl ring. It is possible that other residues lining the pocket may have similar mobilities. Indeed, the improved potency of compound 10* over SAH* can be partially explained by the movement of residue Arg-163, to form a strong cation-π interaction with the N6-aryl ring of compound 10*.

Although the benzyl-SAH derivatives were selective for both DENV and WNV MTases, confirming the importance of the hydrophobic pocket (19), the most active compound, 10*, was not more potent in WNV compared with SAH*. Detailed examination of the hydrophobic pockets in both MTases did not reveal any obvious difference between the two sites, and the reason for the discrepancy in the potency of the compounds for the two virus enzymes is unknown. Nevertheless, both SAH* and compound 10* are significantly more potent on WNV 2′-*O* activity compared with the same activity in DENV (14 and 18-fold better, respectively, in WNV). In contrast, the opposite is true for their N7 activities. Both compounds respectively, showed 4- and 24-fold less potency in WNV than DENV. Thus, the observed difference in the two viral MTases for this class of compounds may be related to variations in their N7 and 2′-*O* mechanisms (20, 21). In summary, using a structure-guided approach, we have designed DENV selective and potent inhibitors by taking advantage of a specific pocket found in Flavivirus MTases, and provided a paradigm that may facilitate pharmacological therapeutics targeting other disease-related MTases.

Acknowledgments—We thank Jan Jiricek, Cheah Chen Seh, Daying Wen, and colleagues at Novartis Institutes for BioMedical Research in Shanghai for help. We thank the beamline scientists at the Swiss Light Source for assistance.

Abstract

Objective: We evaluated whether ivermectin combined with doxycycline reduced the clinical recovery time in adults with COVID-19 infection.

Methods: This was a randomized, blinded, placebo-controlled trial in patients with mild-to-moderate COVID-19 symptoms randomly assigned to treatment (n = 200) and placebo (n = 200) groups. The primary outcome was duration from treatment to clinical recovery. Secondary outcomes were disease progression and persistent COVID-19 positivity by RT-PCR.

FOI 26-3132 - Document 5

Results: Among 556 screened patients, 400 were enrolled and 363 completed follow-up. The mean patient age was 40 years, and 59% were men. The median recovery time was 7 (4–10, treatment group) and 9 (5–12, placebo group) days (hazard ratio, 0.73; 95% confidence interval, 0.60–0.90). The number of patients with a $\leq$7-day recovery was 61% (treatment group) and 44% (placebo groups) (hazard ratio, 0.06; 95% confidence interval, 0.04–0.09). The proportion of patients who remained RT-PCR positive on day 14 and whose disease did not progress was significantly lower in the treatment group than in the placebo group.
Conclusions: Patients with mild-to-moderate COVID-19 infection treated with ivermectin plus doxycycline recovered earlier, were less likely to progress to more serious disease, and were more likely to be COVID-19 negative by RT-PCR on day 14.

Introduction

On 31 December 2019, the World Health Organization announced the outbreak of an atypical pneumonia in Wuhan City, China. Within weeks, the illness became a pandemic.[1,2] The presentation of the disease, named coronavirus disease 2019 (COVID-19), ranges from asymptomatic to fatal.[3] Death is mainly caused by pneumonia and potentially also by hyperinflammation associated with cytokine storm syndrome.[4] To date, treatment has relied mainly on supportive care.

Numerous clinical trials worldwide have explored the efficacy of existing medicines against COVID-19, including various antiviral and immunomodulatory drugs.[5] Australian researchers from Monash University established the efficacy of ivermectin, a broad-spectrum antiviral drug,[6,7] against severe acute respiratory syndrome-related coronavirus (SARS-CoV-2) in *in vitro* studies; viral replication was stopped within 24 to 48 hours.[8] Tetracycline, a widely available and well-tolerated antibiotic useful against atypical infections,[9] has known anti-inflammatory effects[10] and, along with its synthetic derivative, doxycycline, has been shown by Mohit et al.[11] to potentially be effective against COVID-19. The antiviral and anti-inflammatory properties of ivermectin combined with doxycycline may be beneficial in the treatment of COVID 19. Given that these two drugs have different modes of action, their synergistic effects may contain viral infection by targeting different sites of disease pathogenesis. In the present study, we sought to determine the efficacy of this combination in patients with mild-to-moderate COVID-19 symptoms.

Patients and methods

Patients

Patients were enrolled between 1 June 2020 and 30 August 2020. The inclusion criteria

FOI 26-3132 - Document 5

for enrollment were as follows: age >18 years, positive COVID-19 reverse transcription polymerase chain reaction (RT-PCR) test within 3 days prior to enrollment, and mild to moderately severe COVID-19 infection. Patients who were unable to receive oral medications, were pregnant or breastfeeding, had severe COVID-19 symptoms (defined as tachypnea [>30 breaths/minute] and hypoxia [oxygen saturation (SpO2) <90%] requiring supplemental oxygen), were admitted to intensive care or high-dependency units, or had known hypersensitivities to ivermectin or doxycycline were excluded from participation.

Trial design

This was an investigator-initiated, placebo-controlled trial. The independent data safety monitoring board of Dhaka Medical College monitored treatment safety and efficacy. Routine investigations were performed at the pathology laboratory of Dhaka Medical College. RT-PCR tests were performed at the virology laboratory of Dhaka Medical College and Bangabandhu Sheikh Mujib Medical University. Ivermectin, doxycycline, and placebo preparations were provided by Popular Pharmaceuticals Ltd. (Dhaka, Bangladesh).

Eligible patients were randomly assigned to the treatment group or the placebo group at a 1:1 ratio on day 1 of the trial. Group assignment was not stratified according to disease severity.

The allocation schedule was created with a list of random numbers generated using a random number generator program by the head of the Department of Medicine of Dhaka Medical College. Group assignment was concealed in sequentially numbered, opaque, sealed envelopes. The randomization code was maintained by the pharmaceutical company. Both the investigators and the patients were blinded to the treatment allocation. Decoding was performed at the end of the trial under the supervision of the principal of the institute. The trial was conducted in accordance with the principles of the Declaration of Helsinki and Good Clinical Practice guidelines, and was approved by the ethical review committee of Dhaka Medical College Hospital (ERC-DMC/ECC/2020/117). Dhaka Medical College is the largest tertiary care teaching hospital and the largest COVID-19 treatment hospital in Bangladesh. The trial was registered retrospectively at ClinicalTrials.gov (identifier: NCT04523831). Written informed consent was obtained from all patients prior to participation. The study is reported according to the Equator Network Guidelines.

Study interventions

The treatment group received a single dose of ivermectin 12 mg and doxycycline 100 mg, twice daily for 5 days, in addition to standard of care. Standard of care included administration of paracetamol, antihistamines, cough suppressants, vitamins, oxygen therapy according to indication and need, low molecular weight heparin according to indication, appropriate other broad-spectrum antibiotics, remdesivir injection, other antiviral drugs, and other drugs for associated comorbid conditions.

The placebo group received placebo in addition to standard of care.

Experimental procedures

The baseline demographic and clinical characteristics of patients were recorded. The date of random assignment was considered as day 1, and all patients received their initial study intervention on day 1. Outpatients were followed daily until at least 3 days of clinical recovery were observed. Clinical recovery was defined as a normal body temperature of 36.1°C to 37.2°C maintained for at least 3 days,

FOI 26-3132 - Document 5

significantly improved respiratory symptoms (respiratory rate <25 breaths/minute, no dyspnea), and oxygen saturation greater than 93% without assisted oxygen inhalation, as recommended by the World Health Organization and the national guidelines of Bangladesh.[12,13]

Hospitalized patients were followed from day 1 through day 14 or until discharge or clinical improvement, whichever occurred later. Clinical status and vital signs (including respiratory status) were recorded daily. Adverse events as defined by the Medical Dictionary for Regulatory Activities (MedDRA) were documented.

Laboratory tests were performed on day 1, and included the following: complete blood count, random blood glucose, creatinine, alanine transaminase, C-reactive protein, ferritin, and D-dimer. Chest radiography or chest CT scanning were performed as needed. For outpatients, test results were documented at the next visit. Hospitalized patients were tested on days 1 and 7 and when ordered by the treating physicians. COVID-19 RT-PCR testing was performed 14 days after the initial positive test in all patients.

Outcome measures

The primary outcome was the number of days required for clinical recovery from day 1. Clinical recovery was divided into three categories: early recovery within 7 days, intermediate recovery within 7 to 11 days, and late improvement requiring 12 or more days for recovery. Secondary outcomes were disease progression through mild, moderate, severe, or death, and the proportion of patients who continued to test positive for COVID-19 on day 14. Adverse drug reactions (adverse events assumed to be caused by the study intervention) were also recorded. Mild disease was defined as symptoms of an upper respiratory tract viral infection, including mild fever, dry cough, sore throat, nasal congestion, headache, muscle pain, anosmia, and malaise. Moderate respiratory symptoms such as cough and shortness of breath were observed without signs of severe pneumonia. Severe disease included severe dyspnea, tachypnea (>30 breaths/minute), and hypoxia (SpO_2 <90% at room air). These classifications were according to the World Health Organization and national guidelines of Bangladesh.[12,13] The co-investigators assessed the outcome, graded the disease, and documented adverse reactions.

Statistical methods

We sought to enroll as many patients as possible in a short time. As a result, a priori power calculations were not performed. Instead, 200 patients were enrolled in each group and it was assumed that 20% of patients in each group would be lost to follow-up. A post-hoc power calculation $[2SD^2 (Z_{\alpha/2} + Z_{\beta})^2/d^2]$[14], a two-tailed test, an alpha level of 0.05, and standard deviation (SD) 6 indicated that the enrollment of 141 patients in each group (170 before 20% attrition) would result in an 80% chance of detecting a 2-day difference in median recovery time.

Intention-to-treat analysis was performed. The difference in median recovery time was determined using Kaplan–Meier analysis and a log-rank test. Details of patients who were lost to follow-up, had died, or had withdrawn from the trial owing to adverse effects were censored on the final study day. Differences in the clinical improvement in the three disease categories were analyzed using logistic regression. Hazard ratios (HRs) were calculated using Cox regression analysis. Categorical variables are presented as n (%), normally distributed continuous variables as mean (SD), and skewed continuous

FOI 26-3132 - Document 5

variables as median (interquartile range [IQR]).

Subgroup analysis was performed using the logistic regression analysis. HRs were calculated using Cox regression analysis. Age group, sex, fever, cough, respiratory distress, hypertension, diabetes, and presence of any comorbidity were adjusted. Subgroups consisted of age (less than vs. more than 60 years), sex, presence or absence of any comorbidities, mild disease, moderate disease, hospital admission, and interval between disease onset and drug application interval (less than vs. more than 4 days from the onset of the disease). A forest plot was constructed to evaluate differences in the primary outcome among the subgroups. No corrections were made for multiple comparisons. All tests were two-tailed and the alpha was set at 0.05. Data were analyzed using SPSS software, version 20 (IBM Corp., Armonk, NY, USA).

Results

Sample characteristics

Of 556 screened patients, 400 were enrolled and randomly assigned to the treatment and placebo groups (Figure 1). Among the 200 patients in the placebo group, 17 were lost to follow-up, 3 died, and 180 completed the follow-up. Among the 200 patients in the treatment group, 15 were lost to follow-up, 2 discontinued owing to adverse effects, and 183 completed follow-up. None of the patients were receiving oxygen therapy when randomized because only patients with mild and moderate symptoms were

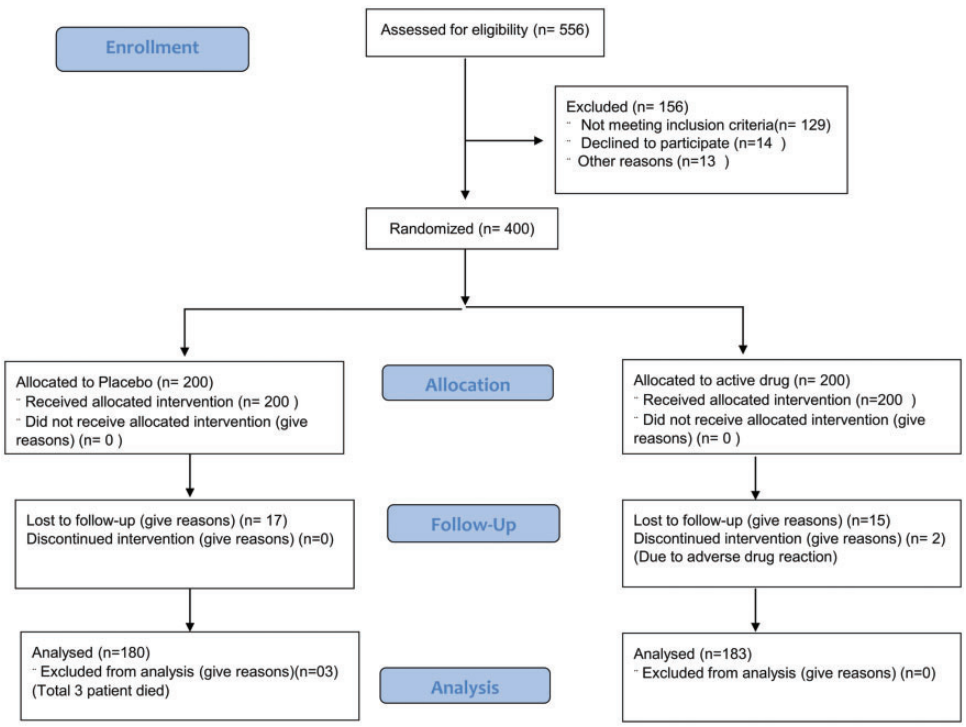

Figure 1. Enrollment, randomization, follow up, and analysis of patients according to the CONSORT 2010 flow diagram.

FOI 26-3132 - Document 5

included. A total of 132 (33%) patients required hospital admission during the study period. Among the hospitalized patients, 58% had moderate disease. The condition of 48 patients worsened during the study period: 5 patients worsened from mild disease to moderate disease but did not require oxygen and the remaining 43 patients worsened from mild/moderate to severe disease and required oxygen therapy.

Patient disposition and characteristics

The two groups were balanced in terms of demographics and disease characteristics (Table 1). The mean age of all patients was 40 years, and 59% were men. Most patients presented with fever (300, 75%) or cough (247, 62%). Respiratory distress (defined as shortness of breath and respiratory rate >25 breaths/minute) was noted in 123 (31%) patients at presentation. Furthermore, 277 patients (69%) had mild disease and 41 (10%) presented with at least one comorbidity (Table 2). Patients were randomly assigned to the trial within a median (IQR) of 4 (3–5) days of symptom onset (Table 2).

Primary outcome

The median (IQR) recovery period was 7 (4–10) days in the treatment group and 9 (5–12) days in the placebo group (hazard ratio [HR], 0.73; 95% CI, 0.60–0.90; p = 0.003 [Figure 2; Table 2]).

Secondary outcomes

The proportion of patients who recovered within 7 days of treatment initiation was higher in the treatment group than in the placebo group (111 [60%] vs. 80 [44%], HR, 0.06, 95% CI, 0.04–0.09 p = <0.001). The recovery rates between 7 and 11 days were not significantly different between the groups (treatment group, 47%; placebo group, 53%). The treatment group was significantly less likely to experience symptoms that persisted for more than 12 days (42 [23%] vs. 67 [37%], HR, 0.04, 95% CI, 0.03–0.07, p = <0.001) (Table 2). Patients in the treatment group were also less likely to experience disease progression and less likely to have a positive COVID-19 RT-PCR test result after 14 days (Table 2).

Post-hoc subgroup analysis

In the post-hoc analysis, differences in the primary outcome were determined in relation to the time interval between symptom onset and study intervention administration (<4 days vs. ≥4 days), age (<60 years vs. ≥60 years), sex, symptoms, disease severity, and presence of any comorbidities. No relationship was found between the outcome and patients who received study intervention after 4 days of symptom onset, were older than 60 years, were women, had moderately severe disease, and had comorbidities (Figure 3).

Safety outcomes

Among the 400 included patients, adverse drug reactions occurred in 9 patients (2.5%); of these, 2 patients discontinued intervention owing to erosive esophagitis. Non-ulcer dyspepsia developed in seven (1.75%) patients (Appendix 1). Three patients in the placebo group died; these patients had a higher mean age than those who survived (63 years vs. 39 years) (Appendix 2) and they died 8, 22, and 28 days after randomization of respiratory failure due to COVID-19-related pneumonia.

Discussion

In the present study, patients with mild or moderate COVID-19 infection treated with ivermectin in combination with doxycycline generally recovered 2 days earlier than

FOI 26-3132 - Document 5

Persistent COVID-19 RT-PCR positivity, n (%)[d]	50 (13.6)	14 (7.6)	36 (20)	0.61 (0.44–0.83)	0.002

[a] Clinical recovery was defined as a normal body temperature for at least 3 days, improved respiratory symptoms defined as no shortness of breath and respiratory rate <25 breaths/minute, and oxygen saturation >93% without supplemental oxygen.

[b] Response criterion was the recovery of patients as defined above. The day on which clinical recovery started was considered the response day.

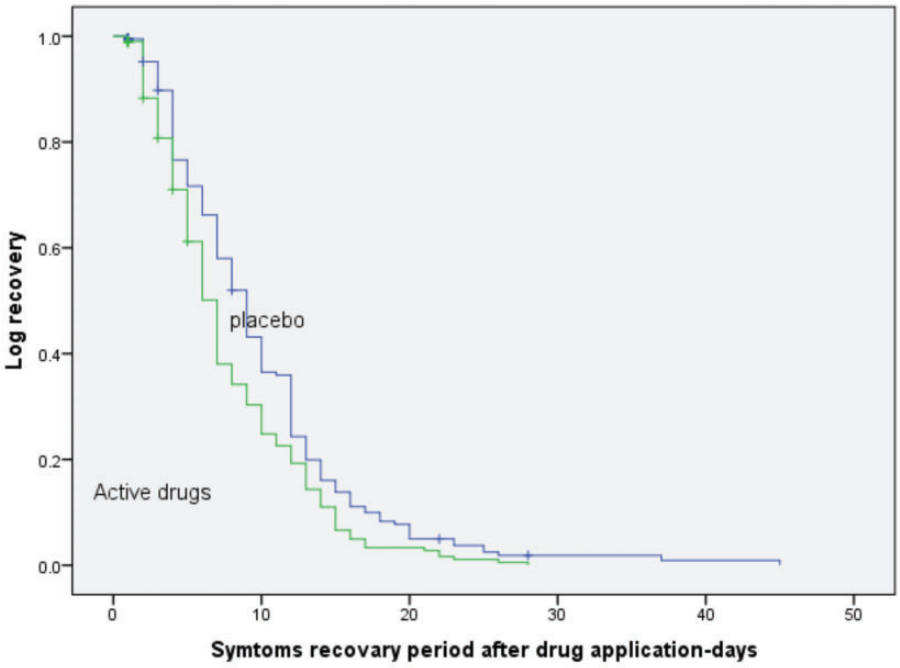
[c] Disease stages were defined as follows:

Mild: symptoms of an upper respiratory tract viral infection, including a mild fever, cough (dry), sore throat, nasal congestion, malaise, headache, muscle pain, anosmia, or malaise.

Moderate: respiratory symptoms such as cough and shortness of breath were present without signs of severe pneumonia (tachypnea >30 breaths/minute, and hypoxia: oxygen saturation <90% at room air.

Severe: tachypnea >30 breaths/minute and hypoxia: oxygen saturation <90% at room air.

[d] Persistent COVID-19 RT-PCR positivity: positive COVID-19 RT-PCR test at 14 days.



CI, confidence interval; COVID-19, coronavirus disease 2019; IQR, interquartile range; RT-PCR, reverse transcription polymerase chain reaction.

treatment group than in the placebo group. The proportion of patients who remained RT-PCR positive for COVID-19 was also lower in the treatment group than in the placebo group.

Effective vaccines and drugs for COVID-19 infection are still being researched. Potential therapies such as hydroxychloroquine[15,16] and tocilizumab[17] have to date been proved ineffective, while only remdesivir has shown some benefit in patients with moderate[18] or severe COVID-19 infection.[19] However, mortality from COVID-19 remained high, despite the use of remdesivir; therefore, treatment with an antiviral drug alone is unlikely to be sufficient. Moreover, remdesivir is expensive and can only be administered to hospitalized patients, and its effects on disease progression and viral clearance remain unclear.[18] Thus, there remains an urgent need for inexpensive and effective treatment for this highly infectious and serious disease.

We were encouraged by the in vitro research findings of researchers at Monash University, Australia;[6] the study revealed that ivermectin could reduce viral replication within 24 to 48 hours of treatment. There was a >5000-fold reduction in viral RNA with 5 μM ivermectin in cell culture, equating to a >99% reduction in viral RNA. Schmith et al.[20] stated,

FOI 26-3132 - Document 5

"The concentration resulting in 50% inhibition (IC_{50}; 2 μM) was >35× higher than the maximum plasma concentration (C_{max}) after oral administration of the approved dose of ivermectin 200 μg/kg when given fasted," and predicted that with the oral dose of ivermectin 200 μg/kg, lung concentrations would be approximately one-fourth of the IC_{50}.[20] The safety of higher doses has not been evaluated in humans. Therefore, we used the conventional dose of ivermectin in the present study.

Doxycycline, which may be used for the treatment of atypical bacterial pneumonia and community-acquired pneumonia,[21] exerts an anti-inflammatory effect mediated by chelating zinc compounds on matrix metalloproteinases (MMPs) in mammalian cells.[22] Doxycycline also has antiviral activity, especially against dengue virus[23] and Chikungunya virus.[24] A previous in vitro study showed that murine coronaviruses rely on MMPs for cell fusion and viral replication.[25] The pathologic features of COVID-19 closely resemble those of other SARS-CoV infections, where MMPs play an important role in disease pathogenesis.[26] Therefore, doxycycline may potentially be effective for the treatment of COVID-19 infection.

Ivermectin and doxycycline were co-administered in the treatment group because their synergistic action may increase the likelihood of efficacy in the treatment of COVID-19. We did not observe known drug–drug interactions between ivermectin and doxycycline;[27] therefore, no drug dosage modification was required in the present study.

The effective dose of ivermectin required to reach IC_{50} at a pulmonary level is considerably higher than that used in this study.[20] However, evaluation at higher doses requires detailed safety analysis, which was not within the scope of the present analysis. Therefore, approved dosing regimens of ivermectin and doxycycline were used in this study.

Most patients in our study received the study intervention within 3 to 5 days of symptom onset. No similar study of ivermectin for COVID-19 treatment could be identified in the literature. In the previous remdesivir trial,[19] treatment benefits were prolonged in severe cases (11 vs. 15 days). In the present study, most patients recovered in both the treatment and placebo groups. However, in the treatment group, a higher proportion of patients responded within 7 days than in the placebo group. The proportions of patients whose level of disease severity worsened and who showed virus persistence beyond 14 days were also lower in the active drug group than in the placebo group. Therefore, the ivermectin and doxycycline combination might play a role in early recovery and viral clearance, thus reducing the need for hospitalization and the quarantine period of patients.

This study was performed in patients aged >18 years, and most of the included patients were relatively young (aged <40 years). Therefore, the treatment response we observed might not be generalizable to all age groups. Moreover, the subgroup analysis showed heterogeneous responses; female sex, older patients, and patients with high disease severity showed no significant responses. Early intervention also influenced the response to treatment. Early in the course of the disease, viral replication is particularly high, and in patients with severe disease, viral pathogenicity plays a less dominant role in disease pathogenesis.[28] This observation explains the heterogeneity of the response in relation to the interval of drug administration and disease severity. Pharmacokinetic analysis of ivermectin[29,30] showed that the drug concentration varies according to species, age, sex, and physiological conditions. The effect size of the sample might also play a role in the heterogeneous findings we observed.

FOI 26-3132 - Document 5

Our study findings are suggestive of the efficacy of this combination treatment against COVID-19 infection. However, we speculate that earlier drug administration and a higher dose of ivermectin than that used in the present study might be more beneficial, as a higher dose will help reach the required IC_{50}[20] at the pulmonary level.

We used approved dosing regimens for both drugs and noted very few adverse reactions. Furthermore, most reactions were consistent with those associated with doxycycline,[31] which supports our assumption that the combination treatment was safe to use in the study population. The death rate observed (three of 200 patients in the placebo group; 1.5%) was consistent with the COVID-19 mortality rate in Bangladesh (1.4%).[32]

Our study was performed at a single center over a short period. Therefore, our findings need to be carefully interpreted. Furthermore, a priori sample size calculations were not performed, limiting the strength of our findings. We could not test for viral load, and therefore could not directly assess viral clearance. It remains unclear whether the early reductions in viral load we observed should be verified by repeated RT-PCR testing during follow-up. Our testing facilities did not allow us to test patients repeatedly. Finally, we evaluated the combination of doxycycline and ivermectin but did not determine their individual effects. Therefore, further studies are needed to clarify the results observed in the present study.

Conclusions

Adult patients with mild-to-moderate COVID-19 infection treated with ivermectin combined with doxycycline recovered earlier than those receiving placebo, were less likely to progress to a serious disease, and were more likely to test negative for COVID-19 at the end of the treatment period. Although additional research on the effects of ivermectin combined with doxycycline is warranted, the safety and efficacy of this combination are favorable compared with current standard of care.

Acknowledgments

We wish to thank Popular Pharmaceuticals Bangladesh Limited for supplying the study intervention and personal protective equipment. We also thank Mr. Monir Hossain, the triage room assistant, for assistance with triage, Thomas A. Lang of Tom Lang Communication and Training International for his kind review of the manuscript, and Editage (www.editage.com) for English language editing.

Declaration of conflicting interest

The authors declare that there is no conflict of interest. Popular Pharmaceuticals Limited, Bangladesh provided ivermectin, doxycycline, and placebo. The company was not involved in the planning or design of the study and had no role in the collection, analysis, or interpretation of the data.

Funding

This research received no specific grant from any funding agency in the public, commercial or not-for-profit sectors.

Objectives: Infection with yellow fever virus (YFV), the prototypic mosquito-borne flavivirus, causes severe febrile disease with haemorrhage, multi-organ failure and a high mortality. Moreover, in recent years the *Flavivirus* genus has gained further attention due to re-emergence and increasing incidence of West Nile, dengue and Japanese encephalitis viruses. Potent and safe antivirals are urgently needed.

Methods: Starting from the crystal structure of the NS3 helicase from Kunjin virus (an Australian variant of West Nile virus), we identified a novel, unexploited protein site that might be involved in the helicase catalytic cycle and could thus in principle be targeted for enzyme inhibition. *In silico* docking of a library of small molecules allowed us to identify a few selected compounds with high predicted affinity for the new site. Their activity against helicases from several flaviviruses was confirmed in *in vitro* helicase/enzymatic assays. The effect on the *in vitro* replication of flaviviruses was then evaluated.

Results: Ivermectin, a broadly used anti-helminthic drug, proved to be a highly potent inhibitor of YFV replication (EC_{50} values in the sub-nanomolar range). Moreover, ivermectin inhibited, although less efficiently, the replication of several other flaviviruses, i.e. dengue fever, Japanese encephalitis and tick-borne encephalitis viruses. Ivermectin exerts its effect at a timepoint that coincides with the onset of intracellular viral RNA synthesis, as expected for a molecule that specifically targets the viral helicase.

Conclusions: The well-tolerated drug ivermectin may hold great potential for treatment of YFV infections. Furthermore, structure-based optimization may result in analogues exerting potent activity against flaviviruses other than YFV.

Keywords: antiviral drug discovery, flavivirus helicase inhibition, new use of existing drug, *in silico* docking, structure-based drug design

Introduction

The genus *Flavivirus* comprises small single-stranded RNA viruses within the *Flaviviridae* family. The flavivirus group includes several pathogens of global medical importance, namely (i) haemorrhagic fever viruses such as yellow fever virus (YFV) and dengue viruses (DENV), and (ii) encephalitic viruses such as West Nile virus (WNV), Japanese encephalitis (JEV) and tick-borne encephalitis viruses (TBEV).[1] Infections by either of the last two neurotropic viruses may result in life-threatening aseptic encephalitis, with a high risk of life-long debilitating neurological sequelae.

YFV is the type member of the emerging and re-emerging vector-borne flaviviruses. Infections with YFV cause a severe febrile disease with haemorrhage, multi-organ failure and shock, and an exceedingly high mortality (up to 50% of

FOI 26-3132 - Document 5

cases).[2,3] YFV is a zoonotic agent that, even with the availability of a safe and efficient vaccine, continues to be reintroduced from sylvatic animal reservoirs into the human population, causing outbreaks in endemic regions of South America and Africa on a regular, yet poorly predictable, basis with an estimated annual number of cases of >200000.[4,5] Moreover, recent increases in the density and distribution of the urban mosquito vector, *Aedes aegypti*, as well as the rise in global air travel, increase the risk of introduction and spread of YFV to North and Central America, the Caribbean and Asia.[2] A major gap in our knowledge about YFV is how to manage and treat patients. Treatment of YFV by supportive care is essentially ineffective, and even improvements in intensive care have not changed the lethality.[3] Likewise, the four DENV serotypes have considerably expanded their geographic distribution in recent years. With billions of people at risk, more than 50 million cases, and ~12500–25000 deaths annually, DENV is considered an emerging pathogen in a growing number of countries.[6] In particular, the presence of four DENV serotypes has complicated the design of vaccines because incomplete protection against one serotype may influence the disease outcome once infection is established by a different serotype, through a process referred to as antibody-mediated disease enhancement.[7]

Annually there are ~30000–50000 cases of JEV reported in Asia. Case-fatality rates range from 0.3% to 60%. In Russia and Europe, TBEV causes ~10000–12000 human cases, which may present with severe clinical presentations and a significant rate (10%–20%) of long-lasting neurological sequelae in survivors. WNV was detected for the first time in the Americas in 1999; the virus is now endemic on this continent.[5,8] There is thus an urgent need for antiviral drugs to treat life-threatening infections with flaviviruses.

During the flavivirus replication cycle, the viral genome is transcribed into a negative-strand RNA, which in turn is used as a template for the synthesis of new viral genomic RNA. To maintain viral replication the nascent transcripts must be unwound from their complementary template RNAs by an ATP-dependent helicase activity. In flaviviruses this activity is provided by the C-terminal domain of non-structural (NS) protein 3 (NS3 helicase domain).[9–11] Since all flaviviral NS proteins are indispensable for viral replication, any of them may be considered a promising target for selective inhibitors of viral replication for therapeutic intervention.[12] Moreover, in addition to the commonly targeted viral polymerase and protease functions, the feasibility of interfering with viral replication by particularly inhibiting RNA helicase activity has been a successful proof of concept for hepatitis C virus (HCV)[13] and picornaviruses.[14] For flaviviruses, a number of nucleoside 5′ triphosphates (TPs), such as ribavirin-TP[15–17] (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide-5′-triphosphate), IDA-TP (4,6-diamino-8-imino-8*H*-1-β-D-ribofuranosylimidazo [4,5-e] [1,3]diazepine-5′-triphosphate) and ITA-TP[18] (5,8-dioxo-5,6,7,8-tetrahydro-4*H*-1-β-D-ribofuranosylimidazo[4,5-e][1,2,4]triazepine-5′-triphosphate) have been reported as weak inhibitors of the ATPase activity of helicases from HCV, JEV, DENV and WNV.[16,18,19] However, since ATP is a key nucleotide of host cell metabolism, ATP-mimetic molecules may result in adverse effects on the host cell. A more innovative helicase inhibitor development strategy (as demonstrated to some extent for HCV[20]) might be directed specifically against the RNA binding and unwinding mechanisms mediated by NS3, which have recently been unravelled in fine molecular detail.[11,21]

Based on the above considerations, we performed an *in silico* docking search targeting a selected region of the ssRNA access site in the crystal structure of the NS3 helicase domain[21,22] of Kunjin virus (an Australian variant of WNV, to which we refer as WNV[23]), using a library of mostly commercial small molecules. We identified the widely used anti-helminthic drug ivermectin as a molecule that not only displayed a high predicted binding affinity towards the modelled NS3 ssRNA binding pocket, but also inhibited the NS3 helicase activity of several flaviviruses *in vitro* at sub-micromolar concentrations. Most importantly, ivermectin proved to be a selective inhibitor of the replication of several flaviviruses in cell culture, such as JEV, TBEV and DENV (sub-micromolar EC_{50} values), and a highly potent inhibitor of YFV replication (sub-nanomolar EC_{50} values). Considering that this well tolerated drug has been licensed for >20 years for the treatment of parasitic infections in man, our results provide the prospect of the first specific anti-flavivirus therapy by the off-label use of ivermectin (patent application EP2010/065880).

Materials and methods

Chemical database for virtual screening and reagents

The virtual Library of Pharmacologically Active Compounds (LOPAC) used for the docking analysis was accessed from Sigma-Aldrich, and included 1280 commercially available compounds (www.sigmaaldrich.com). The compounds tested *in vitro*, paromomycin sulphate, ouabain and ivermectin, were obtained from Sigma-Aldrich; ribavirin (Virazole) was purchased from ICN Pharmaceuticals (Costa Mesa, CA, USA). The compounds were dissolved at 20 mM in DMSO and stored at −20°C. The compounds were used as provided, without further purification.

In silico search for NS3 helicase inhibitors

The AutoDock4 software package[24] was used for a docking search using compounds from the LOPAC library, and Python Molecule Viewer 1.4.5 (MGL-tools package, http://mgltools.scripps.edu/) for analysis of the data. The atomic coordinates from the crystal structure of the WNV helicase domain, solved in our laboratory, were chosen as the docking model (PDB 2QEQ[21]). After the addition of hydrogen atoms (PMV, MGL Tools package, http://mgltools.scripps.edu/), Kollman charges[25] were added to the model. A discrete grid with dimensions 23×19×15 Å^3 (AutoGrid4; step size 0.375 Å, 62×50×40=124000 points[26]) was then centred on the putative ssRNA access site between helices α2 in subdomain II and α9 in subdomain III. Twenty genetic algorithm searches were run using AutoDock4 for each compound (provided with Gasteiger charges[27]) in the LOPAC library (with 150 individuals in the population and 27000 generations[24]). The docking search produced a ranked list of compounds with predicted free energy of binding (ΔG) ranging between +9.0 and −11.5 kcal/mol. The best three molecules [paromomycin sulphate, ouabain and ivermectin (form B1a from Sigma-Aldrich, modelled with 11 rotatable bonds)], displaying ΔG values between −11.5 and −9.5 kcal/mol, were selected to be tested in *in vitro* activity assays.

Expression and purification of NS3 and NS5 domains

The WNV, DENV serotype 2 and YFV helicase domains were expressed and purified as previously described.[28,29] DENV RNA-dependent RNA polymerase (RdRp), DENV full-length NS5, WNV RdRp and WNV full-length NS5 were produced in an *Escherichia coli* Rosetta (DE3) pRos expression

Downloaded from https://academic.oup.com/jac/article/67/8/1884/747458 by guest on 15 March 2023

FOI 26-3132 - Document 5

system and purified through a Ni^{2+} column and gel filtration (Hi Load 16/60 Superdex 200, GE Healthcare) as described for the WNV helicase domain.[28,29]

Helicase inhibition assays using radioactive and fluorescent (FRET-based) labels

The helicase activity was assayed using radiolabelled dsRNA substrate in the presence of Mg^{2+} and ATP. The dsRNA substrate was prepared as described previously.[30] Briefly, primer 1 (5′-CACCUCUCUAGAGUCGACCUGCAGGCAUCG-3′) was labelled with [γ-^{32}P]ATP at its 5′ end using T4 polynucleotide kinase and annealed with the complementary primer 2 (5′-CGACUCUAGAGAGGUG-3′). WNV NS3 helicase (200 nM, see below) was preincubated with various concentrations of ivermectin (between 5 and 400 nM) in 50 mM Tris/HCl pH 8.0, 5 mM dithiothreitol, 10 mM KCl, 20 U/mL RiboLock Ribonuclease Inhibitor (Fermentas), 5 mM $MnCl_2$ and 5 mM $MgCl_2$. The reactions were initiated by adding the proteins to the reaction mixture containing 6 fmol of dsRNA, and were quenched after 30 min at 37°C by addition of 6 μL of loading dye (50 mM EDTA, 0.5% SDS, 50% glycerol and 0.1% bromophenol blue). The assay mixtures were resolved by electrophoresis through 17% polyacrylamide gels that were dried and analysed by phosphoimaging (Typhoon; GE Healthcare).

Fluorescence helicase assays were performed as described by Boguszewska-Chachulska *et al.*[31] Briefly, the substrate for the fluorescent helicase test was prepared by annealing, at a 1:1.2 molar ratio, a Cy3-labelled 30-mer (5′-CACCUCUCUAGAGUCGACCUGCAGGCAUCG-3) to a Black Hole Quencher (BHQ)-labelled 16-mer (5′-CGACUCUAGAGAGGUG-3′), by brief heating to 90°C then slow cooling to room temperature. Standard helicase assays were performed in 50 mM Tris/HCl pH 7.5, 5 mM dithiothreitol, 10 mM KCl, 20 U/mL RiboLock Ribonuclease Inhibitor (Fermentas), 5 mM $MnCl_2$ and 5 mM $MgCl_2$ (buffer 1), 20 nM substrate, 1 mM ATP and 250 nM capture strand (5′-CGACUCUAGAGAGGUG-3′) in a reaction volume of 200 μL. The YFV, YFV-double mutant, DENV, DENV-double mutant and WNV, WNV-double mutant helicase domains (200 nM) were pre-incubated with various concentrations of ivermectin. The unwinding reaction was started by addition of helicases or ATP. The fluorescent signal increase was measured using a Fluorescence Reader (Infinite 200; Tecan). Relative fluorescence was calculated by subtracting the mean fluorescence of the blank (assay without protein) from all samples, and the values obtained were converted to percentage of activity.

The HCV helicase activity assay in the absence and presence of eight concentrations of ivermectin (0.78, 1.56, 3.13, 6.25, 12.5, 25, 50 and 100 μM) was performed as described previously.[32] In brief, the reaction mixture [25 mM MOPS pH 6.5, 1.25 mM MgCl2, 5 nM Cy5-4-methylbenzhydrylamine hydrochloride (MBHA) substrate (DNA), 12.5 nM HCV NS3 helicase, 0.05 mM dithiothreitol, 0.01% Tween 20, 5 μg/mL BSA and 1 mM ATP] and ivermectin were added to a white half-volume 96-well microplate using EPmotion. Fluorescence was monitored using the VarioSkan. The reaction was incubated for 2 min before VarioSkan injection of ATP.

Helicase kinetics and inhibition by ivermectin

RNA unwinding was measured under the same experimental conditions as those described above, with dsRNA concentrations ranging from 0 to 100 nM, in the absence or presence of ivermectin at various concentrations. After blank subtraction (the same mixture in the absence of the enzyme), the curve was fitted linearly to get the rate of product formation. Different rates measured at varying substrate concentrations were plotted according to the Lineweaver–Burk equation, with amounts of dsRNA (substrate) ranging from 0 to 100 nM, to get V_{MAX} and K_m. The same experiment performed at increasing inhibitor concentrations yielded parallel lines in the double reciprocal plot, indicating that ivermectin behaves as an uncompetitive inhibitor. To estimate the inhibition constant (K_i) we used the Lineweaver–Burk equation for an uncompetitive inhibitor extrapolated for infinite substrate concentration:

$$\frac{1}{v} = \frac{K_m}{[S]v_{MAX}} + \frac{1}{v_{MAX}}\left(1 + \frac{[I]}{K_i}\right) \underset{[S]\to\infty}{\rightarrow} \frac{1}{v_{MAX}}\left(1 + \frac{[I]}{K_i}\right)$$

Double mutation of YFV, DENV and WNV helicase domain

The double YFV (T413I and D414E), DENV helicase mutant (T408I and D409E) and WNV double mutant (T409I and D410E) were produced using the primer design software provided by the Agilent Technologies web site (www.agilent.com/genomics/qcpd). The primers for YFV were as follows: sense (5′-GGGACTTTGTCGTCACAATAGAGATATCTGAGATGGGAGCA-3′); antisense (5′-TGCTCCCATCTCAGATATCTCTATTGTGACGACAAAGTCCC-3′).

The primers for DENV were as follows: sense (5′-GGGACTTCGTGGTCACAATTGAGATTTCAGAAATGGGTGCC-3′); antisense (5′-GGCACCCATTTCTGAAATCTCAATTGTGACCACGAAGTCCC-3′).

The primers for WNV were as follows: sense (5′-GGGACTTTGTCGTCACAATAGAGATATCTGAGATGGGAGCA-3′); antisense (5′-TGCTCCCATCTCAGATATCTCTATTGTGACGACAAAGTCCC-3′).

The proteins were expressed and purified as previously described.[28,29]

Biophysical characterization of the NS3–ivermectin interaction

Thermofluorimetric (thermal shift) assays for the evaluation of the YFV, WNV and DENV helicase domain melting temperatures (T_m) in the absence/presence of ivermectin were conducted in a MiniOpticon Real Time PCR Detection System (Bio-Rad), using the fluorescent dye Sypro orange. Solutions of 2.5 μL of the helicase domain (final protein concentrations ranged between 0.5 and 5 mg/mL) were diluted in 19 μL of buffer 1 and mixed with 3.5 μL of Sypro orange (Sigma) diluted 60× and 0.5 μL of 2 mM ivermectin. In control samples the inhibitor was replaced by DMSO. The sample plates were heated from 25 to 95°C with a heating rate of 0.2°C/min. Fluorescence intensities were measured within excitation and emission ranges of 470–505 and 540–700 nm, respectively. The experiments were repeated in the presence of 0.5 μL of 50 μM dsRNA, prepared by annealing at a 1:1 molar ratio of primer 1 (5′-CACCUCUCUAGAGUCGACCUGCAGGCAUCG-3′) and complementary primer 2 (5′-CGACUCUAGAGAGGUG-3′).

NS3 ATPase assay

The luciferase/luciferin-based ATP Detection Kit (Sigma–Aldrich) was prepared according to the manufacturer's instructions. Twenty microlitres of luciferase/luciferin was added to 185.5 μL of reaction buffer and the reactions were initiated by adding 10 μg of YFV, DENV or WNV helicase and 2.5 μL of ATP (100 mM). In parallel experiments, the YFV, DENV or WNV helicase domain was incubated with ivermectin to a final concentration of 1 μM at 30°C for 10 min. In control samples, the DENV or WNV helicase domain was omitted from the reaction mixture. All luminescence measurements were performed with a Cary Eclipse Fluorescence Spectrophotometer (Varian) at 25°C. Luminescence was measured continuously for 30 min (1 s reading time).

NS5 RdRp activity assay

In vitro RNA synthesis assays were performed using poly(C) (MP Biomedicals) as template annealed with oligo$(G)_{12}$ as primer (62.5 nM final concentration) and GTP (100 mM final concentration) as substrate, in a 200 μL reaction mixture containing buffer 1, PicoGreen Quantitation Reagent (Molecular Probes) and 1 μg of DENV RdRp, DENV full-length

Downloaded from https://academic.oup.com/jac/article/67/8/1884/747458 by guest on 15 March 2023

FOI 26-3132 - Document 5

NS5, WNV RdRp or WNV full-length NS5. Ivermectin was added to a final concentration of 1 μM. Standard assays were performed after enzyme/drug preincubation for 10 min at room temperature. Reactions were started by the addition of GTP and incubated for 15–20 min at 25°C following the fluorescence of the samples in a fluorescence reader (Cary Eclipse Fluorescence Spectrophotometer). Relative fluorescence was calculated by subtracting the mean fluorescence of the blank (assay without protein) from all samples.

Viruses and cells

YFV 17D vaccine strain (Stamaril) [Aventis Pasteur (MSD, Brussels, Belgium)] and DENV serotype 2 New Guinea were passaged once in Vero-B cells (ATCC CCL-81) to prepare a working virus stock and stored at −80°C until further use; JEV strain SA-14 (GenBank accession number U14163), TBEV strain Oshima 5-10 (GenBank accession number AB062063) and WNV strain NY99 (GenBank accession number NC_009942) were passaged once in Vero E6 cells (ATCC C1008) to prepare a working virus stock and stored at −80°C until further use.

Cytotoxic and cytostatic assays

Potential cytotoxic effects of the compounds were evaluated in uninfected quiescent Vero-B and Vero E6 cells. The cells were seeded at 5×10^4 cells/well in a 96-well plate (Becton Dickinson Labware, Franklin Lakes, NJ, USA) in the presence of 2-fold serial dilutions and incubated for 4 days. The culture medium was discarded and 100 μL of 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulphophenyl)-2H-tetrazolium/phenazinemethosulphate (MTS/PMS; Promega, Leiden, the Netherlands) in PBS was added to each well. Following a 2 h incubation at 37°C, the optical density was determined at 498 nm. The cytotoxic activity was calculated using the following formula: percentage host cell metabolism $=100\times(OD_{Compound}/OD_{CC})$, where $OD_{Compound}$ and OD_{CC} are the optical density at 498 nm of the uninfected cell cultures treated with the compound and of the uninfected, untreated cell cultures, respectively. The 50% cytotoxic concentration (i.e. the concentration that reduces the total cell number by 50%; CC_{50}) was calculated by logarithmic interpolation.

Antiviral cell-based assays

YFV-17D cytopathic effect (CPE)-based assay

Vero-B cells were seeded at a density of 2×10^4 cells/well (96-well plate, Falcon) in 100 μL of assay medium and allowed to adhere overnight. Subsequently, a compound dilution series was prepared in the assay medium on top of the cells, after which 100 μL of assay medium containing 100 $CCID_{50}$ (50% cell culture infectious dose) of virus was added. Plates were incubated for 6 days at 37°C (95%–99% relative humidity and 5% CO_2). The cells were fixed with 70% ethanol and stained with 1% methylene blue. Pictures were taken at ×100 magnification. Ribavirin was included as a reference compound. The potential cytotoxic effect of the compounds was evaluated in uninfected cells in a parallel assay with the same experimental setup.

Virus yield reduction assays

DENV serotype 2 and YFV-17D Vero-B cells (5×10^4) were seeded in 96-well plates. One day later, culture medium was replaced with 100 μL of assay medium containing a 2× serial dilution of the compounds and 100 μL of virus inoculums (50 $CCID_{50}$/μL). Following a 2 h incubation period the cell monolayer was washed three times with assay medium to remove non-adsorbed virus and cultures were further incubated for 4 days in the presence of the inhibitor. Supernatant was harvested and viral RNA load was determined by quantitative real-time PCR (qRT-PCR) as described previously.[33]

TBEV strain Oshima 5-10, JEV strain SA-14 and WNV strain NY99. Antiviral activity was assessed in Vero E6 cells grown in 24-well tissue culture plates. Viruses were used at a dilution of moi <1 (i.e. between 0.1 and 1). The compounds were used at a final concentration ranging between 0 and 5 μM. Pre-incubation in the presence of the antiviral was performed during the 90 min virus adsorption step. The cells were then washed once and incubated for 3 days in the presence of the antiviral compounds. All conditions were assayed in duplicate. Three days (72 h) post-infection, each corresponding cell culture supernatant was removed, clarified by centrifugation and stored at −80°C before analysis using a viral titre reduction assay.

The viral titre reduction assay was performed using BHK21 cells seeded in 96-well plates. When the cells reach 80% confluence, they were infected with 150 μL of 10-fold serial dilutions of the virus (derived from the Vero cell clarified supernatants) for 4 days before microscopic examination and positive cytopathic effect (CPE) well counting. For each supernatant sample, the infectivity titre was expressed as $TCID_{50}$/mL using the Karber formula. For each virus, titres of viral supernatants were then compared and represented as the percentage of the positive control (viral titre from infected cell supernatant sample without antiviral compound) for the calculation of EC_{50} values. For WNV, the viral RNA load was also determined by real-time qRT-PCR as described previously.[33]

Time-of-drug-addition study

One day prior to infection, Vero-B cells were seeded in a 24-well Falcon plate (2×10^5 cells/well). Ivermectin (50 nM) was added at 0, 2, 4, 6, 8 and 24 h after YFV-17D infection (50 $CCID_{50}$). In parallel experiments, ribavirin (400 μM) was used as a reference compound. Cells from each well were collected at 24 h after virus infection. For RNA extraction, at 24 h post-infection, cells were washed with PBS and lysed with lysis buffer (buffer RLT, RNeasy Mini Kit; Qiagen) to obtain cytoplasmic extracts. Cytoplasmic RNA was then extracted according to the manufacturer's instructions and analysed for the presence of viral RNA by RT-qPCR using a standard curve. Intracellular viral RNA production was monitored during one replication cycle in untreated cells. Confluent Vero-B cells in a 24-well plate were infected and incubated at 37°C for 1 h. After washing, 700 μL of assay medium was added and cells were harvested every 2 h. RNA replication was monitored by measuring intracellular RNA by RT-qPCR following reverse transcription. Time-of-addition studies using full-length dengue reporter virus expressing *Renilla* luciferase were performed as described previously.[33]

Results

Identification of ivermectin as putative flavivirus NS3 inhibitor by in silico docking

To identify potential NS3 helicase inhibitors, we chose to target the ssRNA access site of the enzyme in an *in silico* docking library search. Since the structure of DENV helicase in complex with RNA[11] was not available when we initiated this work, we modelled the flaviviral NS3 helicase/RNA interaction by superposition of the structure of WNV NS3 helicase (solved in our laboratory, PDB 2QEQ[21]) and the DNA-bound bacterial helicase PcrA (PDB 3PJR[34]). This model was used to locate the putative ssRNA access site within the WNV NS3 helicase domain (Figure 1a). This region is located between helices α2 in subdomain II and α9 in subdomain III (forming an 'α-helical gate'); this model-based identification was later confirmed by the

FOI 26-3132 - Document 5

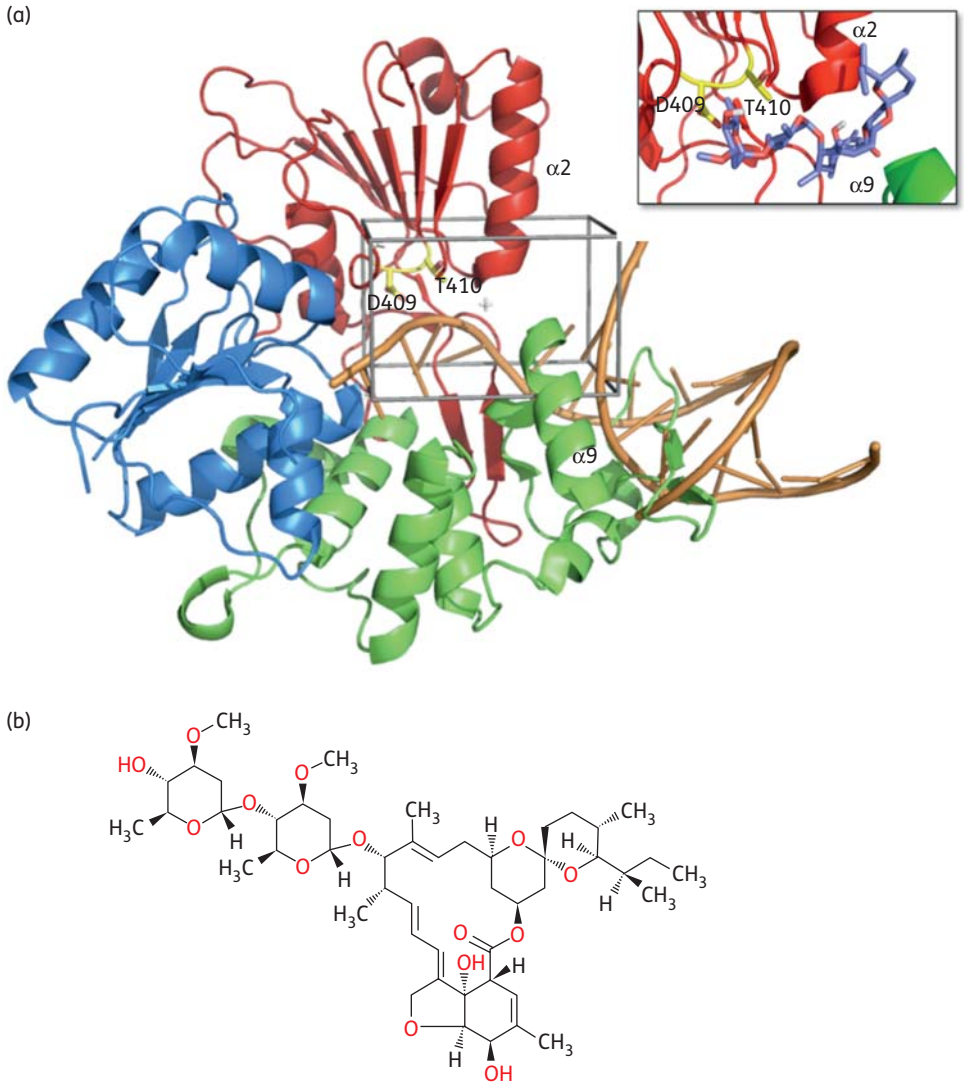

Figure 1. *In silico* docking of flavivirus helicase. (a) Model of the helicase/RNA interaction for WNV helicase domain. The crystal structure of free WNV helicase (PDB 2QEQ) was used to identify a potential ssRNA access site to the enzyme active site by superposition with the DNA-bound bacterial helicase PcrA (PDB 3PJR). The respective region is located between helices α2 in subdomain II (red) and α9 in subdomain III (green) of the WNV helicase, forming an α-helical gate for the entering RNA substrate (orange worm/sticks). This putative helicase ssRNA access site (enclosed in black) was then chosen as the target site for the *in silico* ligand search. The amino acids selected for mutation (Asp409 and Thr410) are shown in yellow. The close-up box shows a potential docking conformation of ivermectin in the ssRNA access site. The location of the molecule's macro ring is well established, having the two sugar rings of the compound located inside the protein. The region occupied by the inhibitor is conserved in all binding modes of the different docked conformations. (b) Chemical structure of ivermectin (B1a form; Sigma-Aldrich). Figures created using PyMol (http://www.pymol.org). This figure appears in colour in the online version of *JAC* and in black and white in the print version of *JAC*.

crystal structure of DENV in complex with ssRNA.[11] The selected target site was then explored *in silico* by docking low molecular weight compounds from the LOPAC library (see the Materials and methods section). This docking search (AutoDock4[24]) resulted in the identification of three molecules with calculated binding free energy (ΔG) for WNV NS3 helicase ranging from −11.5 to −9.5 kcal/mol; the compounds were ivermectin (a macrocyclic lactone antibiotic with broad-spectrum antiparasitic activity, Figure 1b), ouabain (a cardiac glycoside) and paromomycin sulphate (an aminoglycoside antibiotic used to treat, among others, cutaneous leishmaniasis). These molecules were selected for further biochemical evaluation in *in vitro* helicase activity assays.

Specific inhibition of flaviviral NS3 helicase unwinding activity

The inhibitory effects of the three selected molecules (ivermectin, ouabain and paromomycin sulphate) on flavivirus helicase activity were evaluated against the helicase domain of WNV. Helicase inhibition activity was assayed using a radiolabelled

Downloaded from https://academic.oup.com/jac/article/67/8/1884/747458 by guest on 15 March 2023

RNA substrate in the presence of Mg^{2+} and ATP.[30] For this purpose, the NS3 helicase domain was pre-incubated with various concentrations of the inhibitors. Ouabain and ivermectin inhibited the dsRNA unwinding activity of WNV helicase with an IC_{50} between 200 and 400 nM (not shown). Paromomycin sulphate showed strong inhibitory activity at all concentrations tested (as low as 0.5 nM), likely due, however, to its non-specific RNA-binding capacity, reported previously.[35]

Using a complementary FRET-based helicase assay (see the Materials and methods section), we demonstrated that the specific inhibitory activity of ivermectin extends further to the NS3 helicase of the YFV helicase with an IC_{50} of 122 ± 10 nM (Figure S1a, available as Supplementary data at *JAC* Online) and DENV with an IC_{50} of 500 ± 70 nM (Figure S1b, available as Supplementary data at *JAC* Online). Using this assay, the activity of ivermectin against the WNV helicase was confirmed, with an IC_{50} of 350 ± 40 nM (Figure S1c, available as Supplementary data at *JAC* Online).

To exclude any effect of the inhibitor on the ATP binding site, the influence of ivermectin on the ATPase activity of the YFV, WNV and DENV helicase domains was assessed. Ivermectin at a concentration of 1 μM did not affect the ATPase activity of the YFV, WNV and DENV helicase domains (Figure S2, available as Supplementary data at *JAC* Online), suggesting that the compound does not restrict the helicase ATP binding site located at a distance of ~25 Å from its predicted binding site in the helicase domain.

On the other hand, the inhibition of helicase activity does not result from ligand-induced protein destabilization/aggregation/denaturation, as demonstrated by thermofluorometric assays. In fact, YFV, DENV and WNV helicases displayed essentially the same T_m in the presence and absence of ivermectin, with or without dsRNA (not shown).

To rule out any off-target effect of ivermectin on the flaviviral NS5 RdRp, polymerase activity assays were performed using both the RdRp domains and the NS5 full-length proteins from DENV and WNV. The polymerase activity of any of the four proteins was not affected by the presence of 1 μM ivermectin (Figure S3, available as Supplementary data at *JAC* Online).

Finally, to verify the specificity of ivermectin for the flavivirus helicases, we performed activity assays on HCV helicase. The helicase of HCV, which belongs to the family *Flaviviridae*, is closely related to flavivirus helicases.[30] Tests using HCV helicase in the presence of ivermectin (up to 100 μM) did not show any inhibition of the dsRNA unwinding activity of the enzyme, indicating that ivermectin inhibition is exclusive for flavivirus helicases (not shown).

YFV, DENV and WNV helicase double mutants

In order to characterize extensively the part of the protein involved in ivermectin binding, we analysed, by *in silico* docking, all the possible helicase/ivermectin interactions in the ssRNA access site. Using all the known coordinates of the different flaviviral helicases, we produced a number of virtual conformations of the ligand in the chosen site using the program AutoDock4 (not shown). This virtual search pointed to possible mutations perturbing the predicted binding mode of the inhibitor to the selected site of the protein. In particular, we identified Thr408 and Asp409 (numeration as in DENV helicase PDB 2JLQ) as high-frequency interactors in the different conformations of ivermectin produced by virtual docking. This analysis suggested that the substitution of the two amino acids with others having slightly bulkier side chains could hamper ligand binding. Since the two amino acids are conserved among flaviviral helicases, in order to preserve activity we chose to make two minor mutations: Thr408Ile and Asp409Glu in the DENV helicase domain, Thr409Ile and Asp410Glu in the WNV helicase domain (Figure 1a) and Thr413Ile and Asp414Glu in the YFV helicase domain.

As expected, the mutated YFV, DENV and WNV helicases maintained good dsRNA unwinding activity. In contrast, the mutant helicases were not inhibited by ivermectin (up to 5 μM), indicating that binding of the inhibitor was strongly hampered by the inserted mutations (Figure S1a–c). This indicates that the two amino acids (or one of the two) selected for mutation strongly interact with the inhibitor and consequently that ivermectin actually interacts with the ssRNA access site as predicted by our structural analysis. Notably, both residues are conserved among all the flaviviruses and belong to the conserved motif V in helicase superfamily II.

Helicase kinetics and inhibition

In order to investigate the mechanism of helicase inhibition exerted by ivermectin we performed kinetic assays. It is possible to describe the helicase kinetics by a simple Michaelis–Menten model when neglecting the inhibitory effect due to ADP production during the first 10 min of reaction. The mechanism of inhibition proved to be uncompetitive for all three viral enzymes, with the inhibition constant being 19 ± 0.2, 354 ± 23 and 175 ± 25 nM for YFV, DENV and WNV, respectively (Figure 2a–c), indicating that ivermectin is able to bind effectively to the protein only when RNA is present (enzyme–substrate complex). The inhibition constants calculated by kinetic analysis are reported in Table 1.

Inhibition of in vitro viral replication

The potential inhibitory effects of the identified molecules on *in vitro* replication of different flaviviruses (YFV, DENV and WNV) were evaluated. Among the three compounds, only ivermectin inhibited the replication of the selected viruses. In particular, highly potent inhibition of YFV replication was observed. In a CPE reduction assay in Vero-B cell culture, the EC_{50} for inhibition of YFV replication was between 3.1 and 6.3 nM (Figure 3a), whereas in virus yield reduction assays the EC_{50} for inhibition of viral progeny formation was in the low sub-nanomolar range (~0.5 nM, Figure 3b and Table 1). Ivermectin proved less active against DENV in the CPE reduction assay (EC_{50} >1 μM, not shown), although inhibition in virus yield reduction assays was observed (EC_{50} 0.7 μM, quantified by qRT–PCR; Table 1). Ivermectin inhibited the production of infectious WNV, although with an EC_{50} of 4 μM (Table 1). Interestingly, the antiviral activity of ivermectin appears to be selective against flaviviruses, as demonstrated by its capability to inhibit the production of infectious TBEV and JEV viruses with EC_{50} ~0.2 and 0.3 μM (CC_{50} of ~10 μM, not shown), respectively, and its failure to inhibit bovine viral diarrhoea virus (BVDV) and HCV (which belong to the related genera pestivirus and hepacivirus, respectively, within the *Flaviviridae* family), but also Coxsackievirus B2

(CVB-2) and poliovirus 1 (Sb-1) (*Picornaviridae* family), herpes simplex virus 1 (HSV-1) and vaccinia virus (VV) (*Herpesviridae* and *Poxviridae* family, respectively), vesicular stomatitis virus (VSV) and respiratory syncytial virus (RSV) (*Rhabdoviridae* and *Paramyxoviridae* family, respectively) and Reovirus-1 (Reo-1) (*Reoviridae* family) (data not shown).

Time-of-drug-addition assays

Time-of-drug-addition assays (0–24 h) were performed to examine at which stage in the viral replication cycle (from virus binding to release) ivermectin exerts its antiviral activity on YFV replication. In the virus growth curve without inhibitor, onset of intracellular viral RNA synthesis was at 14 h post-infection (Figure 4a). Ivermectin and the reference molecule ribavirin were highly effective in inhibiting YFV replication when added during the first 14 h after virus infection, but when added at a later stage, i.e. after onset of intracellular viral RNA synthesis (as assessed in the untreated cultures) the molecule lost its antiviral effect (Figure 4b). Comparable results were obtained in the DENV serotype 2 time-of-addition study, performed using the full-length dengue reporter virus expressing *Renilla* luciferase (not shown).

Discussion

Infections with YFV and other emerging and re-emerging pathogenic flaviviruses (such as DENV, WNV and JEV) pose a serious global public health problem.[1] Potent and safe antivirals are urgently needed. Such drugs may be used for the treatment of life-threatening infections with YFV, or encephalitis induced by WNV or JEV infections. Substantial progress has been made in recent years in understanding the biology of replication of flaviviruses, in some cases even in great molecular detail,[12,36] allowing innovative approaches to drug discovery, such as structure-based drug screening and design.[12,37]

We undertook an *in silico* screen for potential inhibitors of the flaviviral NS3 helicase. Starting from the crystal structure of the NS3 helicase domain of WNV,[21] we identified the enzyme's putative ssRNA access site, located between helicase subdomains II and III (α-helical gate; Figure 1a). According to our mechanistic analysis this site might be crucial for the helicase enzymatic function, and thus be a target for inhibition of viral replication. Virtual docking of the LOPAC library to this site identified ivermectin (a broad-spectrum antiparasitic agent), ouabain (a cardiac glycoside) and paromomycin sulphate (an aminoglycoside antibiotic) as potential flavivirus helicase binding compounds. Using *in vitro* enzymatic assays employing recombinant NS3 helicases of flaviviruses from several distantly related serogroups (WNV from the JEV serogroup and YFV and DENV from the YFV serogroup), we could confirm that ivermectin inhibited the dsRNA unwinding activity of different flaviviral helicases (with IC_{50} values in the sub-micromolar range; Figure 2). For ivermectin, the specificity of this inhibition was corroborated by excluding any off-target effects on the helicase-associated ATPase activity and the overall native protein fold (by thermal denaturation analysis).

Extending our *in silico* analysis to all the available structures of flaviviral helicases, we simulated a number of possible conformations of ivermectin inside the ssRNA access site. The results

Table 1. Effect of ivermectin on the activity of recombinant flavivirus helicases, viral RNA formation in virus-infected cultures and host cell metabolism

Virus	Fluorescent helicase inhibition, IC_{50} (μM)[a]	Helicase kinetics, K_i (μM)[b]	qRT–PCR, EC_{50} (μM)[c]	CC_{50} (μM)[d]
YFV	0.12 ± 0.01	0.019 ± 0.002	0.0005	3.5
DENV	0.50 ± 0.07	0.354 ± 0.023	0.7	3.8
WNV	0.35 ± 0.04	0.175 ± 0.025	4	10

All cell data are presented as averages of three independent experiments and all standard errors were <10%.
[a]Compound concentration required to achieve 50% inhibition of the helicase activity using the fluorescent helicase inhibition assay; helicase domain of YFV = amino acids 184–623, helicase domain of DENV = amino acids 168–618 and helicase domain of WNV = amino acids 180–619.
[b]Inhibition constant calculated from helicase kinetic assays.
[c]Compound concentration required to inhibit viral RNA synthesis by 50% in Vero cells infected with the YFV 17D vaccine strain, the DENV serotype 2 New Guinea C or the WNV strain NY99.
[d]Compound concentration required to reduce the viability of Vero-B cells (for YFV and DENV) and Vero E6 cells (for WNV) by 50%.

allowed the identification of two conserved amino acids (T408 and D409 in DENV) often interacting with the different conformations of ivermectin. This suggests that a quasi-conservative substitution of both amino acids (with slightly bulkier side chains) could hamper ligand binding to the protein. Accordingly, a DENV helicase double mutant (T408I and D409E), a WNV helicase double mutant (T409I and D410E) and a YFV helicase double mutant (T413I and D414E) were generated. The mutated proteins preserved helicase activity but were not inhibited by ivermectin up to a concentration of 5 μM. This provides strong evidence that the two amino acids (or one of the two) strongly interact with the inhibitor, confirming the binding of ivermectin to the ssRNA access site. Notably, both residues are part of the motif V in helicase superfamily II and are conserved among the flaviviruses.

We later showed that ivermectin behaves as an uncompetitive helicase inhibitor, able to bind only to the protein/RNA complex blocking the enzymatic activity. This result is in agreement with the failure to measure binding of ivermectin to the enzyme using micro-calorimetry (not shown) or to obtain crystals of the protein–ligand complex (data not shown). On the basis of the available structures of DENV bound to ssRNA (PDB 2JLU) it is not possible to predict a plausible interaction site or a model of the ternary complex. Reasonably, during activity the helicase/RNA complex changes its structure,[38] allowing ivermectin to interact with the identified amino acids to block dsRNA unwinding.

Most importantly, we demonstrated that ivermectin (and not ouabain or paromomycin sulphate) inhibited the *in vitro* replication of different flaviviruses. Ivermectin proved most potent against YFV, but also inhibited, although less efficiently, the *in vitro* replication of DENV, JEV, WNV and TBEV. The highly potent antiviral effect of ivermectin against YFV (EC_{50} ~0.5 nM) is striking, considering that other recently reported inhibitors of flavivirus replication display activity that is several orders of magnitude lower (NITD008, EC_{50} 2 μM[39] and NITD-618, EC_{50} 1–4 μM,[40] both against DENV; 2′-*C*-methylcytidine, EC_{50} 100 μM[41] and T-705, EC_{50} 330 μM,[42] both against YFV).

We demonstrated in a time-of-drug-addition assay that ivermectin exerts its anti-YFV activity when administered during the first 14 h after virus entry into cells (Figure 4b). In fact, the compound gradually loses its antiviral potency when first added to YFV-infected cultures after onset of intracellular viral RNA synthesis (Figure 4a). Thus, the compound is effective only during that particular phase of the flaviviral replication cycle in which the viral helicase is functionally active.[36]

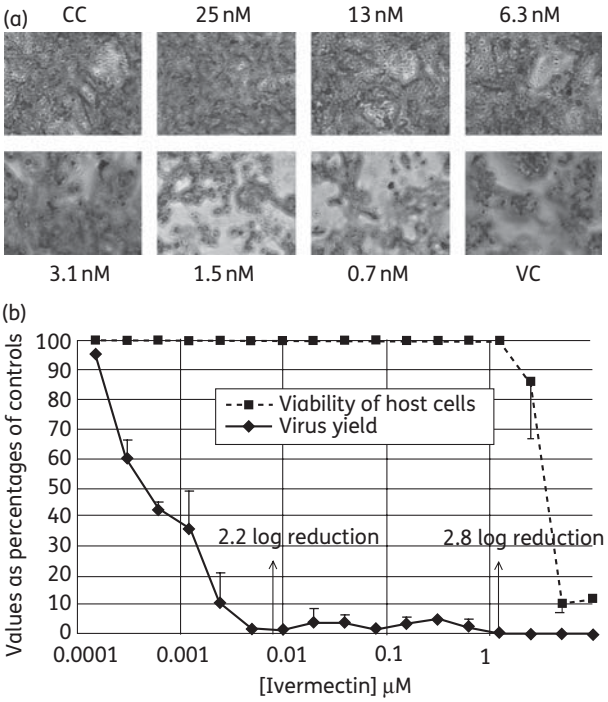

Figure 3. YFV-17D-induced CPE. (a) YFV-17D-induced CPE: concentration-dependent inhibition by ivermectin. At concentrations of >3 nM complete protection against virus-induced CPE formation (at 6 days post-infection) is observed. VC, virus-infected control without drug; CC, cell control (uninfected/untreated). Cells are shown at ×100 magnification. (b) Effect of ivermectin on the viability of uninfected host cells and on virus yield determined by RT-qPCR. Both results are reported as percentages of untreated controls. Arrows indicate the concentrations at which the reduction ('log reduction') in viral RNA levels was determined. Mean values of at least three independent experiments ± SD.

Despite the fact that ivermectin exerts *in vitro* anti-helicase activity (but neither anti-ATPase nor anti-RdRp activity), we cannot exclude the possibility that the molecule exerts its antiviral activity against flaviviruses via additional or other unrelated

FOI 26-3132 - Document 5

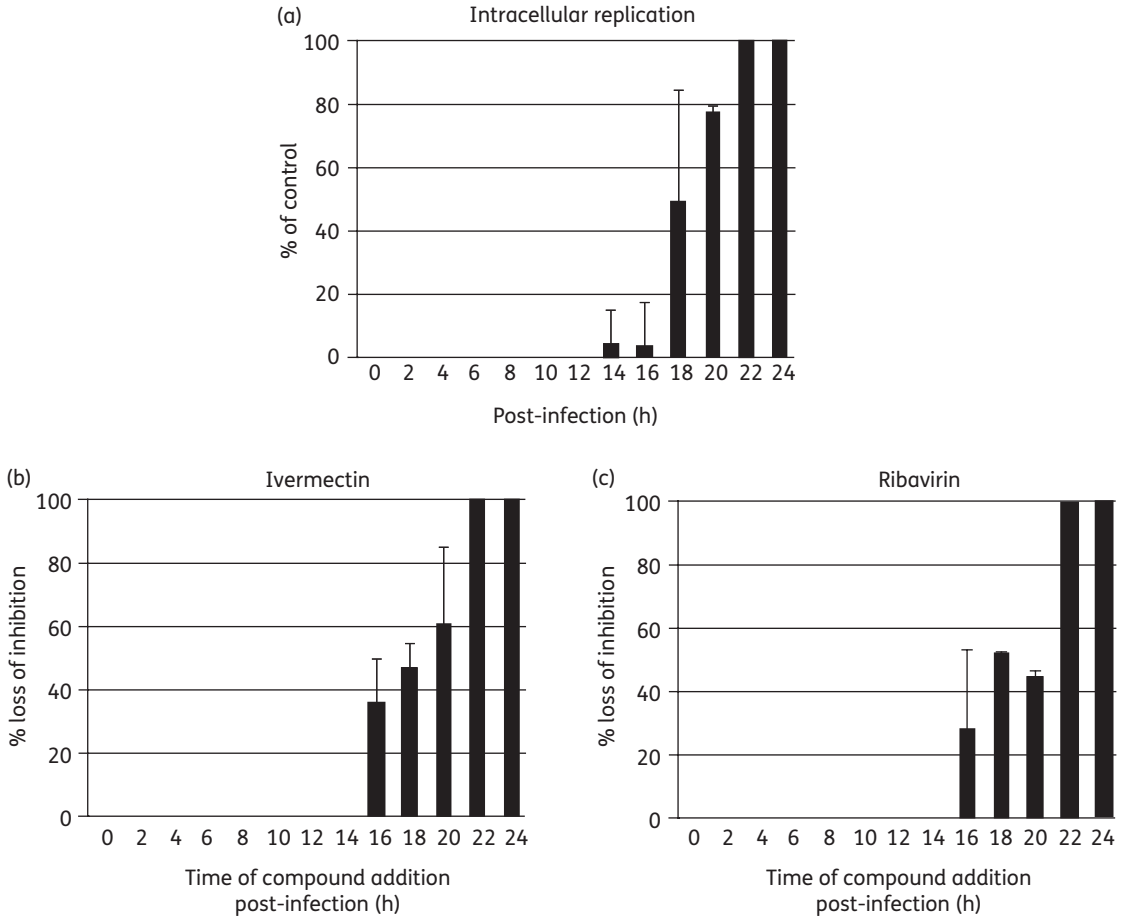

Figure 4. Time-dependent inhibition of YFV replication. (a) Kinetics of intracellular YFV-17D RNA synthesis following infection of Vero cells. Onset of viral RNA synthesis is detected at 14 h post-infection. (b) Effect of time of addition of ivermectin (left-hand panel) or ribavirin (right-hand panel) to YFV-17D-infected Vero cells. Both molecules gradually lost their protective activity when added at a timepoint (or later) that coincided with onset of viral replication in the control cultures.

mechanism(s). In particular for YFV, the net gap between the IC_{50} value against YFV helicase (120 nM) and the EC_{50} value in YFV cell cultures (0.5 nM) indicates that yet undiscovered process(es) other than helicase inhibition may contribute to the mechanism of action of ivermectin inhibition in cell culture. Besides, the mechanism behind the very selective and potent YFV activity may differ from that of the other flaviviruses (at least the ones we examined in our work), because of the different EC_{50} values observed in the three viruses. In fact, the lower EC_{50} value observed in DENV and, most strikingly, in WNV cell culture experiments could be related to different factors (i.e. compound solubility or permeability, metabolism, non-specific protein binding), including lower susceptibility of the viral replication complex (involving NS3 and NS5) with respect to the isolated helicase domain.

Our data, however, show that the mechanism of inhibition does not involve the early stages of the viral replication cycle (i.e. virus attachment and/or virus entry). The data presented nevertheless stress the key role played by helicase inhibition in the whole antiviral activity. To add independent proof that ivermectin acts in the infected cells by inhibition of the NS3 helicase, we tried to select ivermectin drug-resistant variants by serial passaging of YFV with increasing concentrations of the drug (expecting that adaptive mutations in the helicase domain would be selected). Unfortunately, even following extensive efforts, varying several experimental parameters (among others, multiplicity of infection, drug concentration increments and host cell type), drug-resistant virus variants were not selected after >30 serial passages of YFV, for >6 months in the presence of ivermectin. This may indicate that the barrier to resistance is high and that mutants may not emerge because they may not be viable.

Ivermectin is known as an anti-helminthic agent for oral administration. In the mid-1980s the compound was introduced as probably the most broad-spectrum anti-parasite medication ever,[43,44] which interferes with the parasite's nervous system and muscle function by binding and activating glutamate-gated chloride channels.[45] Ivermectin is used in humans mainly for the treatment of onchocerciasis, but is also effective against other worm infestations (such as strongyloidiasis, ascariasis, trichuriasis and enterobiasis). Ivermectin is also effective against most mites and some lice.

Considering that ivermectin has been used for the treatment of a variety of parasitic disease in man for >20 years, assessing its potential for the treatment of life-threatening flavivirus

infections in clinical trials may require a minimum effort. Mining of epidemiological records in tropical regions where flaviviruses are endemic and where ivermectin has been administered for decades during population-wide onchocerciasis eradication programmes may offer first insights into the protective roles offered by the new application of this old drug.

COVID-19
Hydroxychloroquine
Doxycycline
2019 novel coronavirus
Remdesivir

ABSTRACT

Coronavirus disease 2019 (COVID-19) is a major public health challenge, and the current antiviral arsenal for treatment is limited, with questionable efficacy. Major efforts are under way for discovery of new effective agents, but the validation of new potential treatments for COVID-19 may take a long time. Therefore, the repurposing of existing drugs for new indications is needed. In this article, we argue for the potential benefits of using doxycycline with either hydroxycholoroquine or other putative agents for COVID-19 treatment, as doxycycline has antiviral and anti-inflammatory activities by dampening the cytokine storm and to prevent lung damage.

Introduction

The 2019 novel coronavirus infection, dubbed COVID-19, has created an unprecedented public health crisis and threatened the lives of millions of people worldwide [1]. The immunopathogenesis of severe COVID-19 is partially understood and it is likely involves both a virus-driven damage and an exuberant host inflammatory response, both contributing to acute lung injury, acute respiratory distress syndrome (ARDS), and multiple organ failure [2]. Since there is no clear evidence of efficacy among available antivirals for COVID-19 and since the discovery and clinical testing of novel antiviral agents takes a long time, repurposing of existing drugs is of paramount importance. Priority should be given to drugs that combine antiviral and anti-inflammatory effects. In addition, candidate drugs should have an acceptable tolerability profile with no major adverse events or toxic effects.

Hydroxychloroquine with or without azithromycin

Several agents, including hydroxychloroquine have purported in vitro activity against severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus that causes COVID-19 [3]. The anti-viral mechanism of hydroxychloroquine has not been entirely elucidated, but likely occurs through a change in pH at the surface of the cell membrane that inhibits the fusion and assembly of the virus [3]. Recent uncontrolled clinical data by Gautret et al. demonstrated that hydroxychloroquine treatment is associated with rapid virologic clearance, which occurred at day 6 in 70 % of patients on monotherapy versus in 12.5 % of patients on supportive care; adding azithromycin slightly enhanced this effect, with virologic clearance occurring at day 5 in 100 % of patients given the combination [4]. Despite the notable limitations of that study, including small number of patients, absence of randomization, selection bias for controls, and use of treatment in less-ill patients, this antimicrobial combination has generated a great deal of interest [4].

However, the hydroxychloroquine and azithromycin combination has raised major safety concerns, specifically, drug-drug interactions and cardiotoxicity, including fatal arrhythmia, particularly among infected elderly patients with underlying cardiopulmonary chronic illness [5]. The heightened risk of cardiotoxicity among older patients is of particular concern [6]. Also, patients with COVID-19 may develop infection-related cardiomyopathy (frequency is unknown) with direct and indirect cardiovascular complications, including acute myocardial injury, fulminant myocarditis (with a mortality rate up to 40 %–70 %), arrhythmias, and venous thromboembolism [5,7–9].

Antiviral effects of doxycycline

Given the risks of hydroxychloroquine and azithromycin in combination, we suggest hydroxychloroquine with doxycycline as a better alternative to azithromycin. Doxycycline and other tetracycline derivatives such as minocycline exhibit anti-inflammatory effects along with *in vitro* antiviral activity against several RNA viruses. Use of these agents have been associated with clinical improvement, even reversal of cytokine storm in some infections caused by RNA viruses, such as dengue fever [10].

The mechanism of the antiviral effects of tetracycline derivatives may be secondary to transcriptional upregulation of intracellular zinc finger antiviral protein (ZAP), an encoding gene in host cells [11,12]. ZAP can also bind to specific target viral mRNAs and represses the RNAs translation [13,14]. Experimental studies have used tetracycline to induce the overexpression of host ZAP in HEK293, rats and monkeys cell lines (Vero cells), which contributed to inhibition of RNA viruses such as the Dengue, Ebola, Human Immunodeficiency Virus, Zika, and Influenza A viruses [11,12,15–18].

Also, in vitro studies have showed that doxycycline can repress Dengue virus infection in Vero cells through the inhibition of dengue serine protease enzymes and of viral entry [17,19]. Doxycycline showed the capacity to inhibit dengue virus replication in Vero cells culture and likely it interacts with the dengue virus E protein that is required for virus entry [19]. Similarly, doxycycline controls Chikungunya virus (CHIKV) infection through the inhibition of CHIKV cysteine protease of Vero cells and showed significant reduction of CHIKV blood titer of mice [20].

In addition, tetracycline derivatives such as doxycycline are highly lipophilic antimicrobials that chelate zinc compounds on matrix metalloproteinases (MMPs) of mammalian cells [21], and an in vitro study showed that murine coronaviruses rely on MMPs for cell fusion and viral replication [22]. Other mechanisms of viral fusion and replication by coronaviruses utilize host proteases [22], could be a possible target to doxycycline.

Anti-inflammatory effects of doxycycline

In COVID-19, elevated levels of blood interleukin (IL)-6 have been more commonly observed in severe COVID-19 illness and among non-survivors, suggesting that mortality might be due to virally-driven hyperinflammation and to cytokine storm [23]. Intense proinflammatory state has a central role in the pathogenesis of dengue and hemorrhagic fever, leading to cytokine storm [24]. Importantly, doxycycline reduced pro-inflammatory cytokines, including IL-6 and tumor necrosis factor (TNF)-α, in patients with dengue hemorrhagic fever, and the mortality rate was 46 % lower in the doxycycline-treated group (11.2 %) than in the untreated group (20.9 %) [24]. Moreover, doxycycline was more effective than tetracycline in the reduction of these pro-inflammatory cytokines [25].

Similarly, an in vitro study suggested that treatment with minocycline had dual anti-inflammatory effects and viral replication in cells infected with Enterovirus 71 infection, as minocycline reduced the viral cytopathic effect, viral protein expression, viral titers, levels of IL-6 and IL-8, and relative mRNA expression of TNF-α. Also, in a murine model, minocycline inhibited IL-6 and granulocyte colony-stimulating factor in plasma and TNF-α in the cerebellum [26].

In addition, severe acute respiratory syndrome–related coronavirus (SARS-CoV) encompasses a papain-like protease that significantly triggers an early growth response protein 1 (Egr-1)–dependent activation of transforming growth factor beta 1 (TGF-β1), resulting in upregulation of pro-fibrotic responses in vitro and in vivo in the lungs [27,28]. Recent computational methods study identified doxycycline among the drugs that could potentially be used to inhibit SARS-CoV-2 papain-like protease [29].

Severe COVID-19, ARDS, and pathophysiologic and therapeutic considerations

Respiratory failure from ARDS is the leading cause of mortality in COVID-19 patients [30]. Various pro-inflammatory cytokines and chemokines, including IL-6, TNF-α, and profibrotic factors (*TGFB1, CCN2,* and *PDGFA*), are also implicated in tissue damage and vascular leakage and can stimulate pulmonary fibrosis in SARS-CoV infection [31]. The pathologic features of COVID-19 closely resemble those of SARS-CoV infection, which causes massive lung tissue remodeling through the urokinase, coagulation, and wound-healing pathways and through extracellular matrix proteins, including MMPs [31]. MMPs are involved in lung remodeling and destruction of the extracellular matrix, leading to damage of the endothelial basal lamina and increased vascular permeability [32,33]. Importantly, mechanical ventilation, which has a primary role in ARDS management, is associated with further lung injury through activation of MMPs, leading to ventilation-induced lung injury [34].

As mentioned earlier, doxycycline is a strong and broad-spectrum inhibitor of MMPs (a family of more than 24 zinc-dependent proteases). Furthermore, experimental studies have showed that treatment with doxycycline conferred a protective role in lung injury [35,36]. A prophylactic use of doxycycline in mice infected with virulent influenza H3N2 virus attenuates the occurrence of acute lung injury [37]. The tetracycline class of antimicrobials overall has proven a clinically useful tool in MMP inhibition through their ability to chelate the catalytic Zn^{2+} ion, which is essential for MMP activity, independently of their antimicrobial properties [34]. Among the tetracycline derivatives, doxycycline is the most potent MMP inhibitor, even at a subantimicrobial dose (25 mg) [34]. As lung immune injury/ARDS is prominent in patients with severe COVID-19, inhibiting MMPs may help repair the damaged lung tissue and enhance recovery [38].

Future study design considerations

In light of these potential benefits, we propose the use of doxycycline (preferably) or minocycline as a partner agent with hydroxychloroquine or with other promising antiviral COVID-19 therapies such as remdesivir, particularly in elderly patients with multiple health conditions, especially cardiac comorbidities. Doxycycline is usually prescribed as a part of empiric treatment for atypical bacterial pneumonia or community-acquired pneumonia based on the recent evidence-based clinical practice guidelines [39]. Therefore, it may be useful to conduct a large retrospective cohort study assessing disease severity, co-infections, mortality rate, length of hospitalization, and the need for invasive ventilation among COVID-19–infected patients who received a doxycycline-based or other tetracycline-based empiric antimicrobial regimen.

In addition, placebo-controlled randomized clinical trials divided into two arms (treatment arm, antiviral (i.e. remdesivir) plus doxycycline versus the control arm, antiviral plus placebo) and should enroll COVID-19 patients regardless of the severity of illness at presentation. Primary end points, in addition to mortality rate, should include clinical improvement (defervescence), progression to respiratory failure, need for mechanical ventilation (duration and extubation), virologic clearance, and length of stay at the hospital.

Conclusion

Because patients with COVID-19 are in need of both antiviral and anti-inflammatory treatment as well as protection against lung damage, studies of proposed combination therapy is warranted. As doxycycline is inexpensive and widely available, has a safe tolerability profile, and is an attractive option for the treatment of COVID-19 as well as potentially alleviating the lung sequelae and also providing coverage against atypical bacterial pneumonia such as *Mycoplasma* pneumoniae and *Legionella pneumophilia*.

The current outbreak of the corona virus disease 2019 (COVID-19), has affected almost entire world and become pandemic now. Currently, there is neither any FDA approved drugs nor any vaccines available to control it. Very recently in Bangladesh, a group of doctors reported astounding success in treating patients suffering from COVID-19 with two commonly used drugs, Ivermectin and Doxycycline. In the current study we have explored the possible mechanism by which these drugs might have worked for the positive response in the COVID-19 patients. To explore the mechanism we have used molecular docking and molecular dynamics simulation approach. Effectiveness of Ivermectin and doxycycline were evaluated against Main Protease (Mpro), Spike (S) protein, Nucleocapsid (N), RNA-dependent RNA polymerase (RdRp, NSP12), ADP Ribose Phosphatase (NSP3), Endoribonuclease (NSP15) and methyltransferase (NSP10-NSP16 complex) of SARS-CoV-2 as well as human angiotensin converting enzyme 2 (ACE2) receptor. Our study shows that both Ivermectin and doxycycline have significantly bind with SARS-CoV-2 proteins but Ivermectin was better binding than doxycycline. Ivermectin showed a perfect binding site to the Spike-RBD and ACE2 interacting region indicating that it might be interfering in the interaction of spike with ACE2 and preventing the viral entry in to the host cells. Ivermectin also exhibited significant binding affinity with different SARS-CoV-2 structural and non-structural proteins (NSPs) which have diverse functions in virus life cycle. Significant binding of Ivermectin with RdRp indicate its role in the inhibition of the viral replication and ultimately impeding the multiplication of the virus. Ivermectin also possess significant binding affinity with NSP3, NSP10, NSP15 and NSP16 which helps virus in escaping from host immune system. Molecular dynamics simulation study shows that binding of the Ivermectin with Mpro, Spike, NSP3, NSP16 and ACE2 was quiet stable. Thus, our docking and simulation studies reveal that combination of Ivermectin and doxycycline might be executing the effect by inhibition of viral entry and enhance viral load clearance by targeting various viral functional proteins.

Abstract

The current outbreak of the corona virus disease 2019 (COVID-19), has affected almost entire world and become pandemic now. Currently, there is neither any FDA approved drugs nor any vaccines available to control it. Very recently in Bangladesh, a group of doctors reported astounding success in treating patients suffering from COVID-19 with two commonly used drugs, Ivermectin and Doxycycline. In the current study we have explored the possible mechanism by which these drugs might have worked for the positive response in the COVID-19 patients. To explore the mechanism we have used molecular docking and molecular dynamics simulation approach. Effectiveness of Ivermectin and doxycycline were evaluated against Main Protease (Mpro), Spike (S) protein, Nucleocapsid (N), RNA-dependent RNA polymerase (RdRp, NSP12), ADP Ribose Phosphatase (NSP3), Endoribonuclease (NSP15) and methyltransferase (NSP10-NSP16 complex) of SARS-CoV-2 as well as human angiotensin converting enzyme 2 (ACE2) receptor. Our study shows that both Ivermectin and doxycycline have significantly bind with SARS-CoV-2 proteins but Ivermectin was better binding than doxycycline. Ivermectin showed a perfect binding site to the Spike-RBD and ACE2 interacting region indicating that it might be interfering in the interaction of spike with ACE2 and preventing the viral entry in to the host cells. Ivermectin also exhibited significant binding affinity with different SARS-CoV-2 structural and non-structural proteins (NSPs) which have diverse functions in virus life cycle. Significant binding of Ivermectin with RdRp indicate its role in the inhibition of the viral replication and ultimately impeding the multiplication of the virus. Ivermectin also possess significant binding affinity with NSP3, NSP10, NSP15 and NSP16 which helps virus in escaping from host immune system. Molecular dynamics simulation study shows that binding of the Ivermectin with Mpro, Spike, NSP3, NSP16 and ACE2 was quiet stable. Thus, our docking and simulation studies reveal that combination of Ivermectin and doxycycline might be executing the effect by inhibition of viral entry and enhance viral load clearance by targeting various viral functional proteins.

Introduction

The current outbreak of the corona virus disease 2019 (COVID-19), has affected almost entire World and become pandemic. Because of its high rate of transmission and infectivity, World Health Organization (WHO) has declared it as a global disaster. Different therapeutics are currently being evaluated in clinical trials but there is no specific drug or vaccine that has been proven its effectiveness to date. Most of the current treatment options against COVID-19 are based on previous experiences/ lessons gain from the SARS-CoV and MERS-CoV epidemics. Like other CoVs, SARS-CoV-2 has a positive-sense single-stranded RNA as genome and four structural proteins, namely the spike (S), envelope (E), membrane (M), and nucleocapsid (N) proteins. As for mechanism of the CoVs infection is concerned, similar to other CoVs, it uses their surface spike proteins and interact with its cognate receptor i.e angiotensin-converting enzyme 2 (ACE2) receptor present on the host cell surface. Unlike, other CoVs, SARS-CoV-2 spike protein has high affinity to the host cellular ACE2 receptor (Zhang, Penninger, Li, Zhong & Slutsky 2020). Most of the current research for the development of effective therapeutics

against SARS-VCoV-2 are based on the screening of existing broad-spectrum anti-virals, small molecule libraries, FDA approved drug libraries and traditional alternative medicines (Maurya 2020; Maurya & Sharma 2020; Wu et al. 2020; Zhou et al. 2020). Very recently, a team of the doctors from Bangladesh Medical College Hospital, has reported that Ivermectin given single dose with doxycycline, yielded the near-miraculous results in curing COVID-19 patients.

Ivermectin is a FDA-approved broad spectrum anti-parasitic drug (González Canga et al. 2008). It affects a plethora of invertebrate species, including parasitic arachnids, nematodes and insects. It has been earlier shown to exert anti-viral activity in vitro against Dengue fever virus (DENV), influenza virus, West Nile Virus and Venezuelan equine encephalitis virus (Lundberg et al. 2013; Tay et al. 2013; Götz et al. 2016). Very recently, Caly et al (2020) have shown the efficacy of the Ivermectin in Vero-hSLAM cells infection with SARS-CoV-2 and observed an effective loss of viral material within 48h (Caly, Druce, Catton, Jans & Wagstaff 2020). Based on their finding, Caly et al (2020) hypothesised that it might we working by inhibiting Importin α/β1 (IMPα/β1)-mediated nuclear import of viral proteins, as shown for other RNA viruses (Caly, Wagstaff & Jans 2012; Lundberg et al. 2013; Tay et al. 2013; Caly et al. 2020; Yang et al. 2020). As for safety is concerned, Ivermectin has an established safety profile for human use (González Canga et al. 2008; Buonfrate et al. 2019). The second drug, doxycycline is a synthetic antibiotic derived from tetracycline and have broad spectrum antibiotic property. Doxycycline other than antibiotics, are known to inhibit M2-type polarization of macrophages (He & Marneros 2014). Doxycycline is a FDA approved antibiotic since 1967 and is extensively referred by most clinicians. As for its safety is concerned, doxycycline has a long history of safety.

In the current study, we have explored the possible mechanisms to explain the above experimental and clinical findings using molecular docking and molecular dynamics simulation studies. For this, Ivermectin and doxycycline were docked with different viral proteins (such as spike, Mpro, PLpro, RNA dependent RNA polymerase, Nucleocapsid, NSP3, NSP10, NSP15 and NSP16) and host cell receptor (ACE2). Our molecular docking study predicted that Ivermectin and doxycycline both have significant binding affinity for SARS-CoV-2 spike and ACE2 interacting region, indicating poor interaction for viral entry inside the cells. The binding affinity of the Ivermectin is much better than the doxycycline. At the same time, Ivermectin has significantly high binding affinity with the viral RNA dependent RNA polymerase (RdRp, NSP12), indicating poor viral genome replication for viral multiplication. Ivermectin significantly inhibited ADP Ribose Phosphatase (NSP3), Endoribonuclease (NSP15) and methyltransferase (NSP10-NSP16 complex) of SARS-CoV-2 which were involved in the virus escape from the host innate immune system. Ivermectin and doxycycline both bind with SARS-CoV-2 main protease (Mpro) adjacent to its active site. Our study provides the possible mechanism of the action of this combination and a scientific justification for their application in prevention and management of COVID-19 crisis.

Materials and Methods

Chemical structure of molecules and target proteins: Chemical structures information for Ivermectin and doxycycline were downloaded from PubChem (https://pubchem.ncbi.nlm.nih.gov). In order to study the mode of interaction of Ivermectin

and doxycycline with various SARS-CoV-2 proteins and receptors found on host cells, following PDB ID's 6lu7 (SARS-CoV-2 Mpro), 6m0j (SARS-CoV-2 spike), 6m71 (SARS-CoV-2 RdRp, NSP12), 6w02 (NSP3), 6w9c (PLpro), 6m3m (Nucleocapsid), 6w4b (NSP9), 6wkq (NSP10), 6vww (NSP15), 6wkq (NSP16) and 6m0j (ACE2) were used. All the protein structures were retrieved from protein data bank (https://www.rcsb.org/) and cleaned using USCF Chimera software (Pettersen et al. 2004).

Molecular docking: PyRx virtual screening tool was used for preparation of the ligands and receptor to perform the molecular docking. Molecular docking was performing using Vina wizard of PyRx virtual screening tool (Dallakyan & Olson 2015). For preparation of protein input files, all the water molecules, ligands and ions were removed from *.pdb files and polar hydrogens were added before saving *.pdbqt format. Both the molecules were energy minimized and saved in *.pdbqt format after adding polar hydrogens for further docking process. Following AutoDock Vina docking parameters such as (center_x = -26.2834, center_y = 12.5988, center_z = 58.9648, size_x = 66.124, size_y = 22.9423, size_z = 51.456), (center_x = -32.483, center_y = 26.077, center_z = 7.923, size_x = 52.974, size_y = 46.699, size_z = 30.699) and (center_x = -25.0997, center_y = 19.903, center_z = 3.047, size_x = 78.872, size_y = 67.603, size_z = 35.866) were used for SARS-CoV-2 Mpro (PDB ID: 6LU7), SARS-CoV-2 spike (PDB ID: 6m0j) and human ACE2 (PDB ID: 6m0j) respectively. For docking RdRp (PDB ID: 6m71) NSP7 and NSP8 was removed from the NSP12 and grid box for docking parameter was set at the NSP12-NSP7 and NSP12-NSP8 interface. Docking parameters used for NSP12 were center_x = 112.289, center_y = 131.245, center_z = 141.597, size_x = 83.597, size_y = 69.959, size_z = 45.240. A blind docking was performed for the remaining target receptor proteins.

Interactions of the ligand with critical residues: 2D interaction of docked complex were analysed for the visualization of the best binding poses. As the importance of hydrogen bonding is well documented in drug discovery and design, further hydrogen bond and other non-polar interactions of best binding poses were examined using Discovery studio software (Dassault Systèmes BIOVIA, San Diego, 2016).

Molecular dynamics simulation: The protein-ligand complex for spike, Mpro, NSP3, NSP16 and human ACE2 receptor with Ivermectin were obtained after the molecular docking study. The simulation systems for protein-ligand complex without or with the Ivermectin were performed using the GROMACS software (Abraham et al. 2015). Protein topology was prepared using pdb2gmx module of GROMACS. Whereas ligand topology was derived from Prodrg server (http://prodrg1.dyndns.org/)(van Aalten et al. 1996). MD simulation was performed with Gromos53a6.ff force-field using the GROMACS. Proteins were solvated using SPC (simple point charge) water model and counter ions were added to neutralize the system. After that, system was energy minimized and further water and ions were allowed to equilibrate around the protein in a two-step equilibration process. The first part of equilibration was at a constant number of particles, volume, and temperature (NVT). The second part of equilibration was at a constant number of particles, pressure, and temperature (NPT). NVT and NPT equilibration simulations were performed for 100 ps. Following

equilibration, the production simulation duration was performed for 5000 picoseconds (ps). The trajectory data were saved at different time points to analyse the change in the dynamics of protein-ligand complex. After completion of MD simulation, results for flexibility for protein-ligand complexes were analysed using root mean square deviation (RMSD) and root mean square fluctuation (RMSF) using GROMACS.

Results and Discussion

Different therapeutics have different targets for the prevention of the CoVs severity (Prajapat et al. 2020). Some may block virus spike interaction with host cell receptors, or some may interfere with viral genome replication and some other may obstruct the process of virus assembly (Prajapat et al. 2020). In the current study, drugs Ivermectin and doxycycline were evaluated for their binding affinities against SARS-CoV-2 spike, Mpro, PLpro, RdRp, nucleocapsid, NSP3, NSP9, NSP10, NSP15, NSP16 and human ACE2 receptor by molecular docking. Further binding stability of spike, Mpro, NSP3, NSP16 and ACE2 protein complexed with Ivermectin were evaluated by molecular dynamics simulation.

Molecular docking: Our molecular docking study revealed that both Ivermectin and doxycycline have significant binding affinity with various SARS-CoV-2 proteins i.e Mpro, spike, PLpro, RdRp, nucleocapsid, NSP3, NSP9, NSP10, NSP15, NSP16 and host ACE2 receptor (Table 1). Ivermectin showed better binding affinity with these target proteins compared to doxycycline. During SARS-CoV-2 infection, interaction of spike-RBD protein with the host cell receptor facilitate virus invasion and determine viral tissue or host tropism (Li 2016). Initial interactions of spike with host receptor (ACE2), and subsequent fusion of the host and viral membrane allows the viral genome to enter inside the host cells (Li 2016). It is now well established that, amino acid residues SER19, GLN24, THR27, PHE28, ASP30, LYS31, HIS34, GLU35, GLU37, ASP38, TYR41, GLN42, LEU45, LEU79, MET82, TYR83, ASN330, LYS353, GLY354, ASP355 and ARG357 of the human ACE2 interact with amino acid residues **LYS417,** GLY446, **TYR449, TYR453**, **LEU455, PHE456,** TYR473, ALA475, GLY476, GLU484, PHE486, ASN487, TYR489, PHE490, GLN493, **GLY496, GLN498,** THR500, ASN501, GLY502 and **TYR505** of SARS-CoV-2 spike-RBD protein (Wang et al. 2020). Our results show that, Ivermectin binds at the junction of spike-RBD and ACE2 interaction site indicating that it might have potential to inhibit the entry of the virus to the host cell (Fig 1a). Different amino acid residues of spike protein interacting with Ivermectin are ARG403, ASP405, ARG408, GLN409, GLY416, **LYS417, TYR449, TYR453, LEU455, PHE456,** SER494, TYR495, **GLY496, GLN498** and **TYR505** whereas amino acid interacting with ACE2 includes LYS26, LEU29, **ASP30,** ASN33 **HIS34, GLU37,** THR92, VAL93, GLN96, ALA386, ALS387, GLN388, PRO389, LEU392, ARG393, ARG559 and SER563. From the Figure 1A, it is clear that Ivermectin independently bind at the interacting region of viral spike and host ACE2 receptor indicating that it might hamper the interaction of spike and ACE2 receptor and inhibit the virus entry inside the cells. Figure 1B, shows the 2D interaction of Ivermectin and doxycycline with different protein residues of spike and ACE2. The

predicted binding energies of Ivermectin and doxycycline are -7.2 and -6.6 kcal/mol for spike protein and -7.5 and -7.6 kcal/mol for ACE2 receptor respectively.

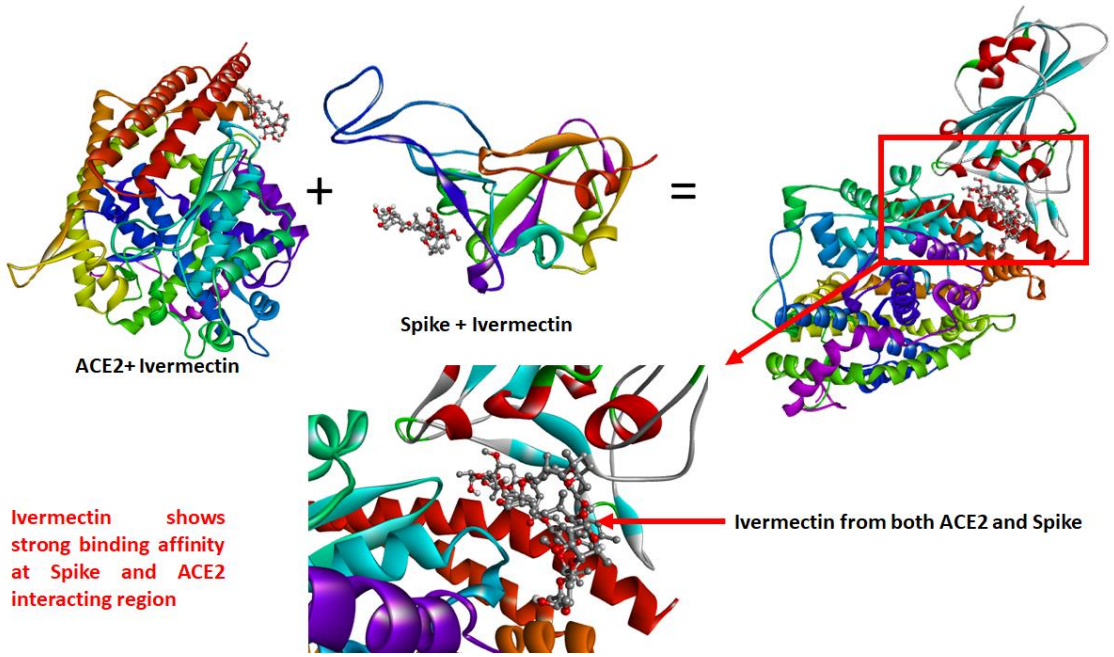

Table 1: *Predicted binding energy and inhibition constant of Ivermectin and Doxycycline for various SARS-CoV-2 target proteins and human ACE2 receptor*

Drugs	Targets, PDB ID's	Predicted binding energy (kcal/mol)	Predicted Inhibition constant, Ki (μM)
Ivermectin	Mpro, 6lu7	-8.4	0.69
	PLpro, 6w9c	-8.5	0.58
	Spike, 6m0j	-7.2	5.21
	Nucleocapsid, 6m3m	-8.2	0.96
	NSP3, 6w02	-8.0	1.35
	NSP9, 6w4b	-7.9	1.60
	NSP10, 6wkq	-8.9	0.69
	NSP12, 6m71	-9.1	0.21
	NSP15, 6vww	-8.4	0.69
	NSP16, 6wkq	-8.3	0.81
	ACE2, 6m9j	-7.5	3.14

	PLpro, 6w9c	-7.1	6.16
	Spike, 6m0j	-6.6	14.35
	Nucleocapsid, 6m3m	-6.3	23.82
	NSP3, 6w02	-7.1	6.16
	NSP9, 6w4b	-6.1	33.40
	NSP10, 6wkq	-6.9	8.64
	NSP12, 6m71	-7.9	1.60
	NSP15, 6vww	-7.5	3.14
	NSP16, 6wkq	-7.7	2.24
	ACE2, 6m9j	-7.6	2.65

The RdRp is the fundamental component of SARS-CoV-2 replication/transcription machinery. Figure 2, shows the predicted binding site and 2D interaction of Ivermectin and doxycycline for SARS-CoV-2 RdRp. The anticipated binding energies of Ivermectin and doxycycline for RdRp are -9.1 and -7.9 kcal/mol respectively. SARS-CoV-2 Mpro is considered as a promising druggable target because it plays vital role in viral gene expression and replication and are essential for maturation cleavage events of viral precursor polyprotein. The critical maturation cleavage events within the viral precursor polyprotein are mediated by the Mpro. Figure 3, shows the predicted binding site and 2D interaction of Ivermectin and doxycycline with SARS-CoV-2 Mpro. The predicted binding energies of Ivermectin and doxycycline for Mpro are -8.4 and -7.1 kcal/mol respectively. Our study shows that although both Ivermectin and doxycycline have strong binding affinity with the Mpro, but they bind off-site to the active site of the Mpro indicating they may not directly inhibit Mpro rather will decrease their activity by interfering with its flexibility (Figure 3).

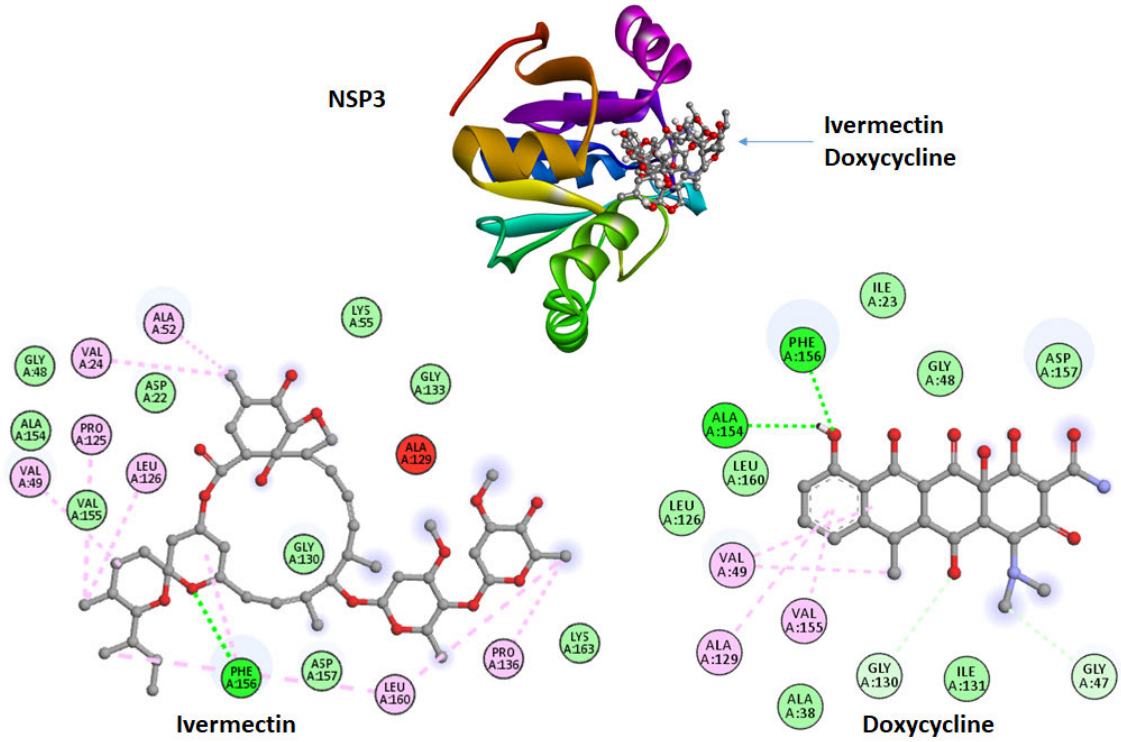
Ivermectin **Doxycycline**

The NSP3 is the largest multi-domain protein encoded by the CoVs and is a vital component of the replication/transcription complex (RTC). NSP3 function as an ADP-ribose-1'-phosphatase. Besides its macrodomain, NSP3 also contains a papain-like protease (PLpro) required during the processing of the CoVs NSPs. Ubiquitination is a posttranslational modification that, among many other functions, is very important in the regulation of innate immune pathways (Mielech, Chen, Mesecar & Baker 2014). PLpro is believed to antagonize the IFN response through its de-ubiquitinating enzyme activity, which allows the protease to remove ubiquitin from a substrate. Figure 4, shows the predicted binding site and 2D interaction of Ivermectin and doxycycline with SARS-CoV-2 NSP3 and PLpro. The predicted binding energies of Ivermectin and doxycycline -8.0 and -7.1 kcal/mol for NSP3 whereas -8.5 and -7.1 kcal/mol for PLpro. These observations show that, binding of Ivermectin with NSP3 and PLpro may block its enzymatic activity and thereby prevent SARS-CoV-2 from down-regulating the anti-viral interferon response. This may improve viral load clearance by host innate immune system and reduce the extent of viral pathogenesis in COVID-19 patients without any previous memory of the antigen.



Viral RNAs are capped to safeguard their stability, efficient translation, and evading the innate immune system of the host cell. The RNA capping tactic are employed by several RNA viruses to avoid immune detection by toll-like receptor 7 (TLR7) and toll-like receptor 8 (TLR8) (Hyde & Diamond 2015). The viral RNA capping machinery is anatomically and mechanistically different compared to eukaryotic mRNA capping system. The CoVs NSP16 protein is a RNA cap modifying enzyme and become active when complexed with its activating partner NSP10 (Decroly et al. 2011). NSP16 binds with NSP10 resulting a complex which exhibits RNA cap (nucleoside-2'-O)-methyltransferase activity. Figure 5, shows the predicted binding site and 2D interaction of Ivermectin and doxycycline with SARS-CoV-2 NSP16 and NSP10. Our study

shows that Ivermectin binds to the S-Adenosylmethionine binding site of NSP16 with a binding affinity of -8.3 kcal/mol. It also binds with the NSP16 cognate activation partners NSP10 with a binding affinity of -8.9 kcal/mol. This indicates that the binding of Ivermectin to the S-Adenosylmethionine binding site will hamper the essential methyl-group transfer and inhibit the methyltransferase activity of NSP16. In the absence of methyl group attachment to the 5'cap of viral RNA, it will get easily detected by host innate immune system. Strong binding affinity of Ivermectin with NSP10 may also interfere in the formation of NSP16-NSP10 complex.

Some of the other important CoVs proteins such as nucleocapsid (N), NSP9 and NSP15 were also used for molecular docking study. The CoVs N protein is a structural protein that forms complexes with viral genome, interacts with the viral membrane protein during virion assembly and plays an important role in enhancing the efficiency of virus transcription and assembly (McBride, van Zyl & Fielding 2014). N-terminal region of nucleocapsid protein consists of positively charged amino acids, which are responsible for its RNA binding. CoVs NSP9 is most likely involved in viral RNA synthesis. NSP9 binds with RNA and interacts with NSP8 to execute its essential functions (Sutton et al. 2004). Dimeric form of NSP9 is important

for viral infection. Any disturbance in the dimerization of NSP9 can be a way to overcome CoVs infection (Egloff et al. 2004; Hu et al. 2017). Whereas the function of NSP15 has a poorly defined but it was observed that a mutations in the active site of NSP15 abolish its endoribonuclease activity *in vitro* and reduces viral infectivity (Posthuma et al. 2006; Kang et

al. 2007). At the same time, any mutations outside of the active site are reported to have a larger effect on virus viability, indicating that NSP15 has role in CoVs infection apart from its function as an endoribonuclease (Ivanov et al. 2004; Kang et al. 2007; Bhardwaj, Liu, Leibowitz & Kao 2012). In our study, predicted binding energies of Ivermectin and doxycycline for N-protein are -8.2 and -6.3 kcal/mol respectively. The predicted binding energies of Ivermectin and doxycycline are -7.9 and -6.1 kcal/mol for NSP9 whereas -8.4 and -7.5 kcal/mol for NSP15. These finding show that Ivermectin have better binding affinity with N-protein, NSP9, and NSP15 compared to doxycycline. Altogether binding of Ivermectin with these proteins will hamper their individual function and decreases the viral genome replication, processing of virion packaging and ultimately viral load.

Molecular dynamics simulation: MD simulation is helpful in studying the stability of binding pose gained from docking, to rescore the inclusive binding energy as well as energy contribution by different residues, to study the conformational variations happening in protein due to ligand binding/unbinding etc. Thus, MD simulation was performed to examine the stability and dynamics of protein to confirm the docking results and get more insight into the stability of ligand-protein complex. MD simulations were carried out for SARS-CoV-2 spike, Mpro, NSP3, NSP16 and human ACE2 receptor and Ivermectin complex in the solvated states for 5000 ps. The results of MD simulations have been examined on the basis of root mean square deviation (RMSD) and root mean square fluctuation (RMSF). Based on the obtained MD trajectories, RMSD values of the protein backbone in complexes with the Ivermectin was computed. In all the cases, the RMSD values steadily increased from 0 to 200 ps, and reached equilibrium after that throughout the simulation period. RMSD was plotted with respect to time and showed stable behaviour throughout the simulation (Figure 6A). To explore the local protein flexibility, the time average of RMSF values of spike, Mpro, NSP3, NSP16 and ACE2 protein in presence Ivermectin over simulation period were calculated. RMSF with respect to amino acid was plotted and found no major fluctuation except few places where moderate fluctuation was observed (Figure 6B).

Most of the CoVs are known to bind with host metalloproteases (MMPs), predominantly for viral survival. Tetracyclines are known to chelate Zinc from MMPs (Aggarwal et al. 2010). Doxycycline being a tetracycline derivative, it will be beneficial in inhibition of SARS-CoV-2 infection because it chelates Zinc (Phillips, Gallagher & Weiss 2017). Tetracyclines also possess anti-viral activities and known to modulate innate immunity. Anti-viral activity of doxycycline had already been reported against retroviruses and dengue virus (Sturtz 1998; Yang, Chen, Tu, Yen & Yang 2007). They can decrease the expression of NF-kB and the release of inflammatory cytokines such as TNF-α, IL-1β and IL-6, independent of their antibiotic mechanism (Henehan, Montuno & De Benedetto 2017). Thus, they could participate in limiting the ‘cytokine storm’ induced in COVID-19 patients. The lipophilic nature of tetracyclines and their strong pulmonary penetration could allow them to inhibit viral replication at cellular level.

Figure 6. *Molecular dynamics simulation of Ivermectin complexed with Spike, ACE2, Mpro NSP16 and NSP3 proteins.*

Among tetracyclines, doxycycline has unique advantages such as long history of safety, the short duration of treatment and low cost. At the same time Ivermectin possess anti-viral activity for a range of the viruses. Very recently, it was observed that Ivermectin significantly inhibited SARS-CoV-2 under in vitro conditions (Caly et al. 2020).

In summary, the miraculous effect of combination of Ivermectin and doxycycline in COVID-19 patients is possibly by inhibition of spike-ACE2 interaction and inhibiting RNA dependent RNA polymerase, ADP Ribose Phosphatase, Endoribonuclease and NSP10-NSP16 complex mediated methyltransferase activities, anti-viral activity and chelation of the zinc & immunomodulatory property. Thus, the usage of Ivermectin and doxycycline combination will be an ideal choice in prevention and management of COVID-19.

Acknowledgement

The author would like to thank Dr S. Santosh Kumar, Radiation Biology & Health Sciences Division, Bhabha Atomic Research Centre, Mumbai for his valuable constructive suggestions and critical review of the article.

Declaration of Conflicting Interests

The author declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Attachment 1: Product information for AusPAR Stromectol Ivermectin Merck Sharp Dohme (Australia) Pty Ltd PM-2012-01113-3-2 Final 30 October 2013. This Product Information was approved at the time this AusPAR was published.

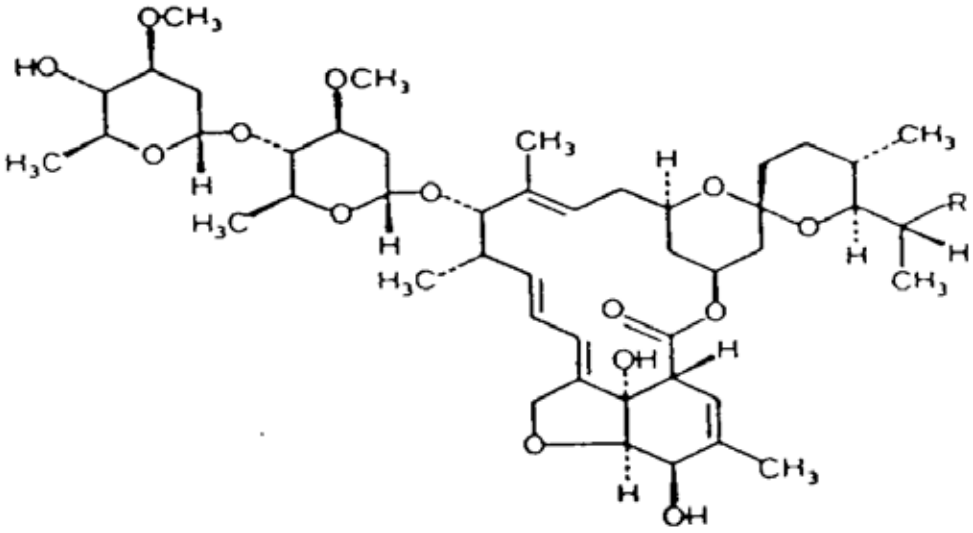
IPC-MK0933-T-062010

PRODUCT INFORMATION

STROMECTOL® TABLETS

(ivermectin 3 mg)

NAME OF THE MEDICINE



STROMECTOL® (ivermectin) 3 mg tablet

DESCRIPTION

Ivermectin is derived from the avermectins, a class of highly active broad-spectrum antiparasitic agents isolated from fermentation broths of *Streptomyces avermitilis*.

Ivermectin is a white to yellowish-white non-hygroscopic crystalline powder which is practically insoluble in water, freely soluble in methanol, and soluble in 95% ethanol.

The structural and molecular formulae follow.

Molecular Formulae:		Molecular Weight:
22, 23-dihydroavermectin B_{1a}	$C_{48}H_{74}O_{14}$ (R=C_2H_5)	875.10
22, 23-dihydroavermectin B_{1b}	$C_{47}H_{72}O_{14}$ (R=CH_3)	861.07

Ivermectin contains a minimum of 90% of 22, 23-dihydroavermectin B_{1a} (where the R group is ethyl) and a maximum of 10% of 22, 23-dihydroavermectin B_{1b} (the R group is methyl).

STROMECTOL is supplied as a 3 mg tablet. STROMECTOL tablets also contain microcrystalline cellulose, pregelatinised maize starch, magnesium stearate, butylated hydroxyanisole and citric acid anhydrous.

PHARMACOLOGY

Ivermectin inhibits signal transmission from the ventral cord interneurons to the excitatory motor neurones in nematodes by stimulating release of the inhibitory neurotransmitter, gamma-aminobutyric acid (GABA) from pre-synaptic nerve terminals. In arthropods, a similar mechanism inhibits signal transmission at the neuromuscular junction. Ivermectin does not readily penetrate the CNS of mammals, and thus does not interfere with mammalian GABA-dependent neurotransmission.

Pharmacokinetics:

Absorption and Distribution:

Ivermectin is incompletely absorbed (~50% bioavailable relative to an oral hydroalcoholic solution) following oral doses of ivermectin tablets, with a Tmax of ~4 hours. With 12 mg single dose tablets administered in healthy male volunteers, the mean peak plasma concentration of the major component was 46.6 (± 21.9) ng/mL (range 16.4-101.1 ng/mL).

Administration of 30 mg (333 to 600 µg/kg) ivermectin following a high-fat meal resulted in an approximate 2.5-fold increase in bioavailability relative to administration of 30 mg ivermectin in the fasted state in healthy volunteers.

Metabolism and Excretion:

Ivermectin is metabolised in humans, and ivermectin and/or its metabolites are excreted almost exclusively in the faeces over an estimated 12 days with less than 1% of the administered dose being excreted in the urine. The plasma half-life of ivermectin in man is about 12 hours (9.8-14.3 h) and that of the metabolites is about 3 days.

The pharmacokinetics of ivermectin has not been studied in patients with impaired hepatic or renal function.

CLINICAL TRIALS

Onchocerciasis in Adults:

A total of 758 adult patients with onchocerciasis received a single oral dose of 150-220 mg/kg ivermectin in three studies. In these studies, a significant reduction in microfilarial counts was reported in evaluable patients who received ivermectin, compared to those who received diethylcarbamazine or placebo. At 2-4 days after ivermectin dosing, microfilariae (mf) counts less than 5 per mg skin were reported in 29% to 96% of evaluable subjects, at 3 months after dosing < 5 mf/mg were reported in 88% to 96% of evaluable subjects, and at 12 months after dosing < 5 mf/mg were reported in 48% to 62% of evaluable patients. In patients with ocular involvement there was a significant reduction in intraocular microfilariae maintained for up to 12 months.

Onchocerciasis in Children:

In an open study, ivermectin reduced skin microfilaria in children with onchocerciasis for up to 12 months. One hundred and three (103) children aged between 5 to 12 years were treated with the targeted dose of 150 mm/kg ivermectin as a single oral dose. Resulting geometric mean microfilariae (mf) counts fell from a pre-treatment value of 36.4 mf/mg skin to 5.8%, 0.7%, 2.2% and 5.4% of the pre-treatment value on day 3, month 3, month 6 and month 12 respectively.

Intestinal Strongyloidiasis:

Two controlled clinical studies using albendazole as the comparative agent were carried out in countries where albendazole is approved for the treatment of strongyloidiasis of the gastrointestinal tract, and two controlled studies were carried out using thiabendazole as the comparative agent. Efficacy, as measured by cure rate, was defined as the absence of larvae in follow-up stool examinations post-therapy. Based on this criterion, efficacy was significantly greater for ivermectin (a single dose of 170 to 200 mg/kg) than for albendazole (200 mg b.i.d. for 3 days). Ivermectin administered as a single dose of 200 mg/kg for 1 day was as efficacious as thiabendazole administered at 25 mg/kg b.i.d. for 3 days.

Summary of Cure Rates for Ivermectin versus Comparative Agents in the Treatment of Strongyloidiasis

	Cure Rate* (%)	
	Ivermectin**	Comparative Agent
Albendazole***		
Comparative		
International Study	22/28 (79)	10/23 (43)
WHO Study	126/152 (83)	67/149 (45)
Thiabendazole†		
Comparative		
International Study	10/15 (67)	13/15 (87)
US Study	14/14 (100)	16/17 (94)

* Number and % of evaluable patients
** 170-200 mg/kg
*** 200 mg b.i.d. for 3 days
† 25 mg/kg b.i.d. for 3 days

Sarcoptes Scabiei:

Classic variety/Typical Scabies:

The clinical data evaluated for this indication were from a literature-based submission which uncovered 8 randomized controlled trials of ivermectin in typical scabies (see References), as well as a number of reviews, including a 2010 Cochrane Review (Strong and Johnstone, 2010).

Placebo-controlled studies

Macotela-Ruiz *et al*. (1993) conducted a trial comparing a single dose of ivermectin 200 µg/kg body weight with placebo in the treatment of scabies in 55 patients. The authors found that 26 (79.3%) patients were cured, defined as absence of itching and no dermatologically active lesions, with ivermectin on their first follow-up visit vs. 4 (16%) in the placebo group ($p<0.001$). The overall cure rates were 37 (74%) and 4 (16%) for ivermectin and placebo, respectively ($p<0.001$).

Active-comparator trials

Bachewar *et al*. (2009) conducted a non-blinded, prospective, randomized trial comparing benzyl benzoate 25% lotion (applied nightly for 2 nights), permethrin 5% cream (applied once), and a single dose of ivermectin 200 µg/kg body weight in 103 patients with noncrusted scabies. The primary outcome of interest was cure rate, defined as no lesions, measured after 1 and 2 weeks.

After 1 week, the cure rates were 76%, 82.1%, and 55.6% for benzyl benzoate, permethrin, and ivermectin, respectively ($p<0.05$ for permethrin vs. ivermectin). After 2 weeks, the cure rates were 92% for benzyl benzoate, 96.4% for permethrin, and 100% for ivermectin.

Chouela *et al*. (1999) compared ivermectin and lindane in a randomized, controlled, double-blind study in 53 patients with scabies. Patients received either a single oral dose of ivermectin 150-200 µg/kg body weight or topical application of 1% lindane solution. Treatment was repeated if clinical cure had not occurred, with clinical cure defined as absence of both pruritus and clinical lesions or a reduction in severity of signs and symptoms to 'mild'.

At day 15, 14/19 (74%) patients in the ivermectin group showed healing compared with 13/24 (54%) in the lindane group ($p=0.22$). At day 29, 18/19 (95%) patients receiving ivermectin were healed, and 23/24 (96%) receiving lindane were healed ($p>0.99$).Further analysis of the equivalence of therapeutic efficacy showed that ivermectin was statistically no less efficacious than lindane ($p<0.02$).

Ly *et al*. (2009) compared 2 regimens of benzyl benzoate (BB) and ivermectin in a randomized, open-label trial in 181 patients with scabies. BB was administered as either one application of 12.5% benzyl benzoate which was not removed for 24 hours (BB1), or as two such applications, each over 24 hours (BB2). Ivermectin was administered as a single oral dose of 150-200 µg/kg body weight.

The primary outcome measure was complete disappearance of visible lesions and itching at day 14. Patients who had clearly worsened at day 7 were given the same treatment as the week before. If no change was noted at day 7 or if the patient had improved, nothing further was done until day 14. If treatment failure was observed at day 14, the treatment was applied again. If treatment failure was observed again at day 28, patients in the BB1 and ivermectin groups were switched to the BB2 application, and those in the BB2 group were switched to ivermectin.

For the primary endpoint of efficacy at day 14, cure rates were 37/68 (54.4%) with BB1, 33/48 (68.8%) with BB2, and 16/65 (24.6%) with ivermectin, with a significance level of $p<10^{-6}$ overall. The comparison of BB1 and BB2 combined was also superior to ivermectin ($p<10^{-5}$). At day 28, cure rates were 52/68 (76.5%) for BB1, 46/48 (95.8%) for BB2, and 28/65 (43.1%) for ivermectin ($p<10^{-5}$ overall).

Madan *et al*. (2001) compared ivermectin and 1% topical lindane solution in a randomized trial in 200 patients with scabies. Patients received either a single dose of ivermectin 200 µg/kg body weight or 1% lindane topical solution applied overnight for 1 night. Efficacy was evaluated over the first 3 days, and at 2 weeks and 4 weeks. Improvement was measured on a categorical scale of: Complete/100% (no signs or symptoms of scabies); Good/75% (itching absent, lesions except burrows present; Moderate/50% (Itching markedly reduced, burrows +); Slight/25% (Itching slightly reduced, burrows ++); Poor/0% (no improvement); Negative (Further aggravation/exacerbation).

After 48 hours of treatment, no patients in either treatment group reported complete improvement, but 17.5% of patients in the ivermectin group and 7.1% in the lindane group reported good improvement. After 2 weeks, 36.1% of patients in the ivermectin group had complete improvement compared with 22.4% in the lindane group. At 4 weeks, 82.6% of patients in the ivermectin group had complete improvement compared with 44.4% in the lindane group. After 4 weeks, 2.8% of patients in the ivermectin group reported negative improvement compared with 4.9% in the lindane group.

Mushtaq *et al*. (2010) compared ivermectin and permethrin 5% cream in 100 patients with scabies. Patients received either a single dose of ivermectin 200 µg/kg body weight or a single application of topical permethrin 5% cream at night on the whole body for 12 hours. Patients not responding after the 1 week dose were given a second dose. Efficacy was determined by disappearance of itching, clearance of skin lesions, and absence of mites on microscopy of skin lesions.

Two weeks after the first dose, 24 (54.5%) patients in the ivermectin group were cured of disease, and 20 (47.6%) were cured in the permethrin group (p=0.5). Cure rates at 4 weeks were 79.5% and 88.1%, respectively (p=0.157). Itching at 4 weeks was mild in 6.8% of patients in the ivermectin group, and 2.4% in the permethrin group. No patients in either group had positive mite scrapings at week 2.

Nnoruka and Ague (2001) evaluated ivermectin and 25% benzyl benzoate topical application in an uncontrolled prospective study in 58 patients with scabies. Patients received ivermectin as a single oral dose at 200 µg/kg body weight or 25% benzyl benzoate applied from neck to toes for 72 hours. Clinical scores were calculated using skin lesions located in 16 different locations of the body. An area was given a score of 2 if there was at least one active lesion, a score of 1 if the most important lesion was healed, and a score of 0 if there was no lesion present. A classical burrow was scored a 2. A patient's clinical score was the sum off all individual area scores, which could range from 2 to 30 at study entry and from 0 to 30 at subsequent visits. In addition, pruritus was measured on a 10 cm visual analogue scale, where 0 = not present and 10 = extremely severe.

Mean clinical scores at baseline were 16.1 for ivermectin and 16 for benzyl benzoate. At day 7, scores were 5.4 and 10.3, respectively. At day 14 scores were 2.3 and 6.1, respectively, and at day 30 scores were 1.1 and 3.5 respectively. Analysis of variance showed a significant decrease in scores with ivermectin (p=0.004). At day 7, 31% of patients receiving ivermectin had complete disappearance of lesions and pruritus. On day 14, 65.3% of patients receiving ivermectin and 34.5% of patients receiving benzyl benzoate were healed. By day 30, 93.7% of patients receiving ivermectin were healed. By day 30, response to pruritus was rated as excellent in 93.1% of patients receiving ivermectin, and 48.3% in patients receiving benzyl benzoate.

Usha and Nair (2000) conducted a randomized trial comparing ivermectin and permethrin cream in the treatment of scabies in 85 patients and their family contacts. Ivermectin was administered as a single oral dose of 200 µg/kg body weight, and 5% permethrin cream was given as a single overnight topical application. Treatment was considered to be effective if, after 2 weeks, there was improvement in pruritus (measured on a visual analogue scale), clinical improvement in skin lesions with no new lesions, and absence of mites or the products on microscopy. Improvement was considered mild if there was less than 50% reduction in the number of lesions and pruritus; moderate if there was more than 50% reduction; and good if there was complete clearance. Treatment was considered a failure if, after 2 weeks, there was no improvement in pruritus and skin lesions, appearance of new lesions, or presence of mites or their products on microscopy. In the case of treatment failure, another dose of the randomized treatment was repeated. If the repeat treatment failed, patients were crossed over to the other treatment group. The primary endpoint was the complete disappearance of clinical signs and symptoms and no appearance of new lesions at the end of 2 months after the last dose was taken.

After the first week, 50% of patients in the ivermectin group and 84.3% of patients in the permethrin group had symptom improvement. By the second week, 70% in the ivermectin group and 97.8%, in the permethrin group improved. By the fourth week, 95% of patients in the ivermectin and 100% of patients in the permethrin groups improved. Two (5%) patients did not respond to 2 doses of ivermectin; both were cured after crossing over to permethrin after a single application. There was no recurrence of scabies at the end of 2 months of follow-up in either group. Complete clearance of lesions (graded as “good” improvement) occurred earlier with permethrin than with ivermectin, with significant differences at weeks 1 (p=0.03), 2 (p=0.003), and 4 (p=0.0005). At 8 weeks, all patients were completely cured (p=0.21).

Crusted variety:

No randomised controlled trials in crusted scabies have been reported in the literature. A systematic review of the literature on crusted scabies identified observational studies, case series and individual case reports in which 260 patients (mean age (range) 41.7 years (2-94 years)) received ivermectin. Of these cases, 182 received ivermectin at a dose of 200 µg/kg of body weight.

Seventy eight percent (78%) of all patients were managed in a clinic setting following confirmation of high mite count. The majority of patients for whom this was reported (70%) received ivermectin after proving refractory to classical topical treatments.

At least 72% of cases were treated with combination ivermectin and topical scabicide. In the large Australian cohort studies, all patients were administered topical keratolytic therapy in keeping with Australian clinical protocols.

Ivermectin was shown to have an overall clinical efficacy across these publications of an 87% cure rate, however, this must be interpreted with caution because of the potential for publication bias (i.e. publication of cases with good outcomes). The majority of patients presenting with mild to severe forms of crusted scabies were adequately managed with one to two oral doses of 200 µg/kg ivermectin. One to two doses may not be adequate in treating very severe cases of crusted scabies.

INDICATIONS

STROMECTOL (ivermectin) is indicated for the treatment of:

a) onchocerciasis and intestinal strongyloidiasis (anguillulosis).
b) crusted scabies in conjunction with topical therapy.
c) human sarcoptic scabies when prior topical treatment has failed or is contraindicated.

Treatment is only justified when the diagnosis of scabies has been established clinically and/or by parasitological examination. Without formal diagnosis, treatment is not justified in case of pruritus alone.

CONTRAINDICATIONS

Hypersensitivity to any component of the product.

PRECAUTIONS

If any hypersensitivity reaction to this product occurs, no further dose should be given.

Effects on fertility:

No data are available.

For treatment of onchocerciasis:

Ivermectin should be used only when infections with *O. volvulus* have been diagnosed or are suspected. No data are available to support its use prophylactically.

After treatment with microfilaricidal drugs, patients with hyperreactive onchodermatitis (sowda) may be more likely than others to experience severe adverse reactions, especially oedema and aggravation of onchodermatitis.

Rarely, patients with onchocerciasis who are also heavily infected with *Loa Loa* may develop a serious or even fatal encephalopathy either spontaneously or following treatment with an effective microfilaricide. In these patients, the following adverse experiences have also been reported: pain (including neck and back pain), red eye, conjunctival haemorrhage, dyspnoea, urinary and/or faecal incontinence, difficulty in standing/walking, mental status changes, confusion, lethargy, stupor, seizures or coma. This syndrome has been seen very rarely following the use of ivermectin.

Impaired Renal or Hepatic function:

Ivermectin has not been studied in patients with impaired hepatic function or impaired renal function. As ivermectin is extensively metabolised by the liver, caution should be exercised if ivermectin is administered to patients with impaired hepatic function.

Use in Pregnancy (Category B3):

Ivermectin should not be used in pregnancy as safety in pregnancy has not been established. Ivermectin caused cleft palates in mice and rats at oral doses of 0.4 and 10 mg/kg/day respectively, and cleft palates and clubbed feet in rabbits dosed at 3 mg/kg/day.

Use in Lactation:

Ivermectin is excreted in breast milk and safety in newborn infants has not been established. In rats, reduced survival occurred in control pups and pups exposed in utero that were cross-fostered to treated dams, but not in control pups or pups exposed in utero cross-fostered to control dams.

The drug should be given to nursing mothers only if the benefit to the mother outweighs the potential risk to the breast-fed infant, and the treatment of mothers who intend to breast-feed their infants should be delayed until at least one week after the birth of the child.

Carcinogenicity/Mutagenicity:

There have been no carcinogenicity studies with ivermectin. Ninety-four and 105 week carcinogenicity studies on mice and rats respectively were conducted with the closely related compound abamectin and were negative at up to 8 mg/kg/day in mice and up to 2 mg/kg/day in rats. Ivermectin was negative in three *in vitro* assays for geno toxicity (mutagen assays in bacteria and mouse cells, and unscheduled DNA synthesis in human cells). No tests have been done to test the potential of ivermectin for producing clastogenicity.

Paediatric Use:

Onchocerciasis:

Ivermectin should not be used in children under five years of age as safety in this age group has not been established.

The safety profile of ivermectin in children 5 to 12 years of age is similar to that observed in adults (see ADVERSE EFFECTS/Onchocerciasis).

Strongyloidiasis:

Efficacy has not been established in children under twelve years of age.

***Sarcoptes scabiei* (scabies):**

Ivermectin should not be used in children under 15 kg and under 5 years of age as safety in these groups has not been established.

Use in the Elderly:

Clinical studies of STROMECTOL did not include sufficient numbers of elderly subjects aged 65 years and over to determine whether they respond differently from younger subjects. In general, treatment of elderly patients should be cautious, reflecting the greater frequency of decreased hepatic, renal or cardiac function, and of concomitant disease or other drug therapy.

Effects on laboratory tests:

No data are available.

INTERACTIONS WITH OTHER MEDICINES

Interactions between ivermectin and other drugs have not been studied in clinical trials.

Very rare post-marketing reports of increased INR (International Normalised Ratio) have been reported when ivermectin was co-administered with warfarin.

ADVERSE EFFECTS
A. CLINICAL TRIAL AND PUBLISHED DATA

A.1. Strongyloidiasis:

Ivermectin has been demonstrated to be generally well tolerated in the treatment of strongyloidiasis.

In three clinical studies involving a total of 109 patients given either one or two doses of 170-200 mg/kg of ivermectin, the following adverse reactions were reported as possibly, probably, or definitely related to ivermectin:

Body as a whole: asthenia/fatigue (0.9%), abdominal pain (0.9%)

Gastrointestinal: anorexia (0.9%), constipation (0.9%), diarrhoea (1.8%), nausea (1.8%), vomiting (0.9%)

Nervous System/Psychiatric: dizziness (2.8%), somnolence (0.9%), vertigo (0.9%), tremor (0.9%)

Skin: pruritus (2.8%), rash (0.9%), and urticaria (0.9%)

Ivermectin was better tolerated than thiabendazole in comparative studies involving 37 patients treated with thiabendazole.

In a WHO sponsored study, children and adults (9-22 years) with strongyloidiasis were treated with ivermectin 200 mg/kg as a single dose or albendazole 200 mg twice daily for 3 days. The safety results are summarised in the following table:

WHO Study - Number of Patients Developing Adverse Effects Within 3 Days After Treatment, Regardless of Drug Relationship

Body System/ Symptoms	Ivermectin (n=163)	Albendazole (n=170)
Body As A Whole		
Abdominal Distension	7*	1
Chest Pain/Tightness	7*	0
Fever	10	7
Digestive System		
Loose Stools	16	17
Nausea	5	6
Watery Diarrhoea	2	3
Nervous System		
Headache	15	18
Dizziness, vertigo	5	10
Skin		
Diffuse Itching	3	6
Respiratory System		
Cough	11	8

* = $p < 0.05$

The Mazzotti-type and ophthalmologic reactions associated with the treatment of onchocerciasis or the disease itself would not be expected to occur in strongyloidiasis patients treated with ivermectin (See ADVERSE EFFECTS, Onchocerciasis).

Laboratory Test Findings:

In clinical trials involving 109 patients given either one or two doses of 170-200 mg/kg ivermectin, the following laboratory abnormalities were seen irrespective of drug relationship: elevation in ALT and/or AST (2%), decrease in leukocyte count (3%). Leukopenia and anaemia were seen in one patient.

A.2. Onchocerciasis:

Ivermectin has been demonstrated to be generally well tolerated in the treatment of onchocerciasis.

Historical data have shown that microfilaricidal drugs, such as diethylcarbamazine citrate (DEC-C), might cause cutaneous and/or systemic reactions of varying severity (the Mazzotti-type reaction) and ophthalmological reactions in patients with onchocerciasis. These reactions are probably due to allergic and inflammatory responses to the death of microfilariae. Patients treated with ivermectin for onchocerciasis may experience these reactions in addition to clinical adverse reactions possibly, probably, or definitely related to the drug itself.

In clinical trials involving 963 adult patients treated with 100 to 200 mg/kg ivermectin and 315 patients on placebo, worsening of the following Mazzotti-type reactions during the first 4 days post-treatment were reported (ivermectin, placebo, respectively): arthralgia/synovitis (9.3%, 4.4%), axillary lymph node enlargement (11.0%, 2.9%), axillary lymph node tenderness (4.4%, 1.0%), cervical lymph node enlargement (5.3%, 4.1%), cervical lymph node tenderness (1.2%, 0.6%), inguinal lymph node enlargement (12.6%, 6.7%), inguinal lymph node tenderness (13.9%, 5.7%), other lymph node enlargement (3.0%, 1.6%), other lymph node tenderness (1.9%, 0.6%), pruritus (27.5%, 17.2%), skin involvement including oedema, papular and pustular or frank urticarial rash (22.7%, 9.2%), and fever (22.6%, 4.8%).

In clinical trials, ophthalmological conditions were examined in 963 adult patients before treatment, at day 3 and months 3 and 6 after treatment with 100 to 200 mg/kg ivermectin. Changes observed were primarily deterioration from baseline 3 days post-treatment. Most changes either returned to baseline condition or improved over baseline severity at the month 3 and 6 visits. The percentages of patients with worsening of the following conditions at day 3, month 3 and 6, respectively, were: limbitis: 5.5%, 4.8%, and 3.5% and punctate opacity: 1.8%, 1.8%, and 1.4%. The corresponding percentages for patients treated with placebo were: limbitis: 6.2%, 9.9% and 9.4% and punctate opacity: 2.0%, 6.4% and 7.2%.

In clinical trials involving 963 adult patients who received 100 to 200 mg/kg ivermectin and 315 patients on placebo, the following clinical adverse reactions were reported as possibly, probably, or definitely related to the drug in ³ 1% of the patients (ivermectin and placebo, respectively): facial oedema (1.2%, 0%), peripheral oedema (3.2%, 0.6%), orthostatic hypotension (1.1%, 0%), and tachycardia (3.5%, 0.6%). Drug-related headache and myalgia occurred in < 1% of patients given ivermectin (0.2%, and 0.4%, respectively). However, these were the most common adverse experiences reported overall during these trials regardless of causality (22.3%, and 19.7%, respectively).

A similar safety profile was observed in an open study in paediatric patients ages 5 to 12.

The following ophthalmological side effects do occur due to the disease itself but have also been reported after treatment with ivermectin: abnormal sensation in the eyes, eyelid oedema, anterior uveitis, conjunctivitis, limbitis, keratitis, and chorioretinitis or choroiditis. These have rarely been severe or associated with loss of vision and have generally resolved without corticosteroid treatment.

Laboratory Test Findings:

In controlled clinical trials, the following laboratory adverse experiences were reported as possibly, probably, or definitely related to the drug in ³ 1% of the patients (ivermectin and placebo, respectively): oeosinophilia (3%, 0%) and haemoglobin increase (1%, 0%).

A.3. *Sarcoptes scabiei* (scabies):

Adverse effects reported in the literature review were similar to those reported in clinical trials for the other indications. The most common adverse drug reactions reported with ivermectin in the review involved the transient exacerbation of pruritus that can sometimes occur as a result of sensitisation of the human host to mite antigens, with a consequent immunologic reaction (1.4%). Sensitisation also frequently results in delayed resolution of symptoms. Patients should be warned that itching may persist for one to two weeks after treatment, even if the mite is successfully eradicated. Other frequently reported reactions consisted of headache (< 1.0%), arthralgia (< 1.0%) and anorexia (< 1.0%). Additionally, lethargy (< 1.0%), listlessness (< 1.0%), abdominal discomfort (< 1.0%), rash (< 1.0%), and dizziness (< 1.0%) were reported. Up to 1.86% of patients noticed that they had passed Ascaris worms during the week after treatment.

B. POST-MARKETING EXPERIENCE

Onchocerciasis:

Conjunctival haemorrhage

All Indications:

Very rarely, hypotension (mainly orthostatic hypotension), worsening of bronchial asthma, toxic epidermal necrolysis, Stevens-Johnson syndrome, seizures, elevation of liver enzymes and elevation of bilirubin.

DOSAGE AND ADMINISTRATION

STROMECTOL is available as white tablets each containing 3 mg ivermectin. Treatment is administered as a single oral dose given with water.

The dose is determined by the patient's weight as shown below.

Strongyloidiasis - the dosage aims to provide approximately 200 µg ivermectin/kg body weight.

Dosage in Strongyloidiasis:	
Body Weight (Kg):	Dose (Number of 3 mg tablets):
15-24	One
25-35	Two
36-50	Three
51-65	Four
66-79	Five
≥ 80	Approx 200 mg/kg
In general, additional doses are not necessary, however, a follow-up examination of stool to verify efficacy should be performed.	

Onchocerciasis - the dosage aims to provide approximately 150 µg ivermectin/kg body weight.

Dosage in Onchocerciasis:	
Body Weight (Kg):	Dose (Number of 3 mg tablets):
15-25	One
26-44	Two
45-64	Three
65-84	Four
Alternatively, the dose of ivermectin for use in mass chemotherapy campaigns may be determined by the patients height, as follows:	
Height (cm):	Dose (Number of 3 mg tablets):
90-119	One
120-140	Two
141-158	Three
> 158	Four
[Reference: Alexander, N.D.E., ivermectin dose assessment without weighing scales. Bulletin of the World Health Organisation, 71 (3/4): 361-366 (1993)]	
The suggested dose interval for most patients is 12 months. At some sites it may be preferable to use a 6 months interval depending on such considerations as density of skin microfilariae and/or prevalence.	

***Sarcoptes scabiei* (scabies)** - the dosage aims to provide approximately 200 µg ivermectin/kg body weight per dose.

Dosage in Sarcoptes scabiei (scabies)	
Body Weight (Kg):	Dose (Number of 3 mg tablets):
15-24	One
25-35	Two
36-50	Three
51-65	Four
66-79	Five
> 80	Approx 200 mg/kg

Classic/typical scabies: 2 doses (1 dose on day 1 and another dose between day 8 and day 15). Ivermectin can be used alone or in combination with a topical scabicide.

Crusted scabies (ivermectin in combination with a topical scabicide administered as):

- Mild cases: 2 doses (1 dose on day 1 and another dose between day 8 and day 15)
- Moderate to severe cases: More than 3 doses may be required for effective treatment.

Patients with crusted scabies should use keratolytics on days they are not treated with topical scabicides to assist with the reduction of scaling that harbours the mite. Consultation with a dermatologist or infectious diseases physician is recommended.

The life cycle of *S. scabiei* begins with the pregnant female laying two to three eggs a day in burrows several millimetres to several centimetres in length in the stratum corneum (outermost layer) of the skin. The eggs hatch in two weeks. The larvae form intra-epidermal lesions whilst they mature into the adult form. This maturation takes 2-3 weeks.

OVERDOSAGE

There are reports of accidental overdosing of ivermectin, but no fatalities have been attributable to ivermectin overdosing.

In significant accidental intoxication with unknown quantities of a veterinary formulation, symptoms have resembled those seen in animal toxicology studies, which were chiefly rash, contact dermatitis, oedema, headache, dizziness, asthenia, nausea, vomiting, diarrhoea, mydriasis, somnolence, depressed motor activity, tremors and ataxia. Other adverse effects that have been reported include: seizure, dyspnoea, abdominal pain, paraesthesia and urticaria.

In case of accidental poisoning, supportive therapy, if indicated, should include parenteral fluids and electrolytes, respiratory support (oxygen and mechanical ventilation if necessary) and pressor agents if clinically significant hypotension is present. Induction of emesis and/or gastric lavage as soon as possible, followed by purgatives and other routine antipoison measures may be indicated if needed to prevent absorption of ingested material. Although data are not available for man, it would appear advisable to avoid GABA-agonistic drugs in the treatment of accidental ivermectin intoxication.

In a study in which healthy volunteers were orally administered up to 2000 µg/kg ivermectin in a fasted state or up to 600 µg/kg ivermectin following a high-fat (48.6 g of fat) meal, there were no indications of central nervous system toxicity observed at any dose irrespective of food intake.

For information on the management of overdose, contact the Poison Information Centre on 131126 (Australia).

PRESENTATION AND STORAGE CONDITIONS

Presentation:

STROMECTOL is available as white, round, flat tablets with a bevelled edge, engraved with MSD on one side and 32 on the other side and containing 3 mg ivermectin. The tablets are packaged in aluminium foil blister packs in cardboard cartons. Pack size: 4 tablets.

Storage Instructions:

Store below 30°C.

Serum zinc and pneumonia in nursing home elderly

Simin N. Meydani, DVM, PhD, **Junaidah B. Barnett, PhD**, **Gerard E. Dallal, PhD**, **Basil C. Fine, MD**, **Paul F. Jacques, PhD**, **Lynette S. Leka, BS**, and **Davidson H. Hamer, MD**

Abstract

Background—Zinc plays an important role in immune function. The association between serum zinc and pneumonia in the elderly has not been studied.

Objective—To determine if serum zinc concentrations in nursing home elderly are associated with incidence and duration of pneumonia, total and duration of antibiotic use, and pneumonia-associated and overall deaths.

Design—This observational study was conducted in residents from 33 nursing homes in Boston, MA, who participated in a one-year randomized, double-blind, and placebo controlled vitamin E supplementation trial; all were given daily doses of ½ RDA of essential vitamins and minerals including zinc. Participants with baseline (N=578) or final (N=420) serum zinc concentrations were categorized as having low (<70 μg/dL) or normal (≥70 μg/dL) serum zinc concentrations. Outcome measures included incidence and number of days with pneumonia, number of new antibiotic prescriptions, days of antibiotic use, death due to pneumonia, and, all-cause mortality.

Results—Subjects with normal final serum zinc concentrations had lower pneumonia incidence, total antibiotic use (by almost 50%), and shorter duration of pneumonia and antibiotic use (by 3.9 and 2.6 days, respectively) (all p-values ≤0.004) relative to those with low zinc concentrations. Normal baseline serum zinc concentrations were associated with decreased all-cause mortality (p=0.049).

Conclusion—Normal serum zinc concentrations in nursing home elderly were associated with decreased incidence and duration of pneumonia, and decreased use and duration of antimicrobial therapy. Zinc supplementation to maintain normal serum zinc concentrations in the elderly may help reduce pneumonia incidence and associated morbidity.

INTRODUCTION

Pneumonia is a major public health problem in the elderly (1). An important predisposing factor to the increased incidence of infections such as pneumonia in the elderly is the age-associated decline in immune function (2). Such changes in immune response with age, in addition to malnutrition, contribute to the increased frequency and severity of pneumonia, as well as mortality due to pneumonia in the elderly (1-4).

Zinc has been shown to play an important role in regulation of the immune response particularly T cell-mediated function (5-7). Zinc deficiency has been shown to cause thymus involution and to depress lymphocyte proliferation, interleukin-2 (IL-2) production, delayed type hypersensitivity skin responses, and antibody response to T cell-dependent antigens (5,8). Similar defects in T cell function have been observed with aging (2). Several investigators have reported low zinc status or decreased intake in elderly subjects (9-11). Furthermore, low zinc status in the elderly has been shown to contribute to age-associated dysregulation of the immune response (3,12) and zinc supplementation has been shown to improve T cell mediated function in elderly (9,12-15) . In children, low concentrations of circulating zinc have been shown to be associated with an increased risk of respiratory morbidity (16), and zinc supplementation has been shown to reduce both the risk and duration of pneumonia and deaths due to pneumonia in children (17,18). The association between serum zinc and pneumonia in the elderly, however, has not been studied.

From April 1998 to August 2001, a randomized controlled trial was carried out in order to investigate the effect of vitamin E supplementation on respiratory infections in a nursing home elderly population (19). We found a high proportion (about 30%) of nursing home elderly with low serum zinc concentrations at baseline, and after a year of follow up despite all participants' receiving ½ RDA of essential vitamins and minerals, including zinc, during the trial. Because recently published studies in children (17,18) have shown zinc supplementation to be beneficial in reducing morbidity and mortality from pneumonia and past research has demonstrated the negative impact of zinc deficiency on immune function in the elderly, we examined the relationships between serum zinc concentration and the incidence and duration of pneumonia, total antibiotic use, and duration of antibiotic use and death due to pneumonia, as well as overall deaths in this population of elderly nursing home residents.

SUBJECTS AND METHODS

Study design and intervention

A total of 617 subjects was enrolled (approximately 1/3 enrolled in each of 3 successive years) into a randomized, double-blind, placebo-controlled trial of the effect of one-year vitamin E supplementation (200 IU/day) on respiratory infections in a nursing home population (19). The Tufts-New England Medical Center Institutional Review Board approved the study protocol and informed consent form.

Nursing home residents have a heterogeneous intake of micronutrients (20), some of which are necessary for proper immune function. To reduce variability in the vitamin E trial, all subjects received a daily capsule containing 50% of the Recommended Dietary Allowance (RDA) (21) for essential micronutrients, including zinc. Fifty percent RDA was selected since few subjects meeting our eligibility criteria would have dietary intakes <50% of the RDA for micronutrients (22).

FOI 26-3132 - Document 5

NIH-PA Author Manuscript
NIH-PA Author Manuscript
NIH-PA Author Manuscript

At baseline as well as at follow-up, about 30% of subjects were found to be deficient in zinc. Other micronutrient deficiencies were much less prevalent at baseline (from 0 to 10%) and their prevalence did not significantly change at follow up (19).

Selection of study subjects

Detailed information on the screening and recruitment of participants has been described previously (19). The eligibility criteria included age ≥65 y, life expectancy >6 months, no anticipated discharge within 3 months, not room-bound for the past 3 months, body mass index (BMI) ≥16 kg/m^2, serum albumin ≥3.0 g/dL, ability to swallow pills, and willingness to receive influenza vaccine and provide informed consent. Exclusion criteria included active neoplastic disease, tube feeding, kidney dialysis, intravenous or urethral catheters for the last 30 days, tracheostomy or chronic ventilator use, chronic steroid treatment >10 mg/d, use of immunosuppressive drugs, use of antibiotics within the prior 2 weeks, and >RDA level supplements of vitamins E, C, B_6, selenium, zinc, β-carotene, or fish oil.

The current analyses include all enrolled subjects with baseline (N=578) or end of study zinc measurements (N=420, including 7 subjects with only end of study zinc values). For the purposes of this study, subjects were categorized by serum zinc concentrations using cutoffs of <70 μg/dL to indicate low serum zinc concentrations and ≥70 μg/dL to indicate normal serum zinc concentrations (23).

Outcomes

Pneumonia-related outcomes included incidence of and number of days with pneumonia, new antibiotic prescriptions for pneumonia, days of antibiotic use for treatment of pneumonia, and death due to pneumonia. We also examined all-cause mortality.

Data collection

Information regarding subject characteristics, baseline diseases and medications, and vaccination history was obtained from medical records. Fasting blood was collected at baseline and at study completion for clinical chemistries, complete blood count, and nutritional status as previously described (19). Serum samples were collected using trace metal-free tubes and serum zinc concentrations were measured using the Perkin Elmer flame atomic absorption spectrometer (24) at the Nutrition Evaluation Laboratory, Human Nutrition Research Center on Aging at Tufts University.

Study nurses were trained by a study physician to identify relevant respiratory symptoms and to perform a focused physical examination of the respiratory tract. Supervised practice evaluations were repeated throughout the study to reinforce the nurses' clinical skills and to ensure consistency of the pneumonia data collection. The study nurses collected information weekly relating to infection, including symptoms of respiratory infections, temperature, respiratory and heart rate, and a physical examination focused on the respiratory system. The nurses reviewed each participant's chart for documentation of laboratory analyses, radiography, medications, micronutrient supplementation, weight, and nursing or physician descriptions of symptoms and signs relating to pneumonia and other respiratory infections. At the end of the study, data collected from the subjects were randomly assigned, by nursing home, to the two study physicians for diagnosis of infections. Infection data from any one subject were evaluated by only one physician, except for 18 subjects whose records were used to determine the concurrence of diagnoses between physicians.

Diagnosis of pneumonia

Details on how the study physicians evaluated the data to determine incidence and duration of pneumonia have been described previously (19). Briefly, clinical definitions of pneumonia were developed based on accepted definitions (25). In order to increase the specificity of the definitions, a diagnosis of pneumonia had to include at least one physical sign and thus could not be made on symptoms alone. An episode was considered resolved when all symptoms ceased. A new infection was defined as one occurring after 7 symptom-free days. Pneumonia symptoms could include cough with or without sputum production, chest pain, dyspnea, and fever. Signs of infection included elevated temperature (≥38°C), tachycardia, tachypnea, abnormal breath sounds, and dullness to percussion of the chest. The diagnosis required radiological findings of 1 or more new pulmonary infiltrates.

Statistical analysis

The demographic and clinical characteristics of participants in the low and normal serum zinc groups were compared by using Student's t-test for independent samples (continuous measures) and Fisher's exact test (categorical measures).

As noted above, all subjects received a capsule containing 50% of the RDA for essential micronutrients, including zinc. Because of this supplementation, the baseline zinc concentrations might not reflect the usual zinc status during the entire study period. Therefore, we also used zinc concentrations measured at the final study visit as a marker of zinc status. However, analyses based on final zinc concentrations were necessarily limited to those who survived or completed the trial.

Rate ratios and their confidence intervals for incidence of pneumonia and number of antibiotic prescriptions per year were modeled using Poisson regression with the natural logarithm of time as an offset (26). None of the deviance statistics from the Poisson regressions exceeded 1, which suggests that there was no overdispersion. Multiple linear regression analyses were used to determine the association between serum zinc and duration of pneumonia and antibiotic use due to pneumonia. Cox-proportional hazards models using baseline zinc concentrations were fitted to determine the hazards ratio for deaths due to pneumonia or overall deaths using baseline zinc concentrations. Except for the proportional hazards analyses, these analyses were performed by using both baseline and final zinc concentrations as predictors. Although the original study did not show a significant difference in the rate of pneumonia between the vitamin E and placebo groups (19), we nevertheless controlled for allocation to treatment and placebo groups in these analyses. We also adjusted for year of enrollment, as well as age, sex, baseline BMI, current smoking, diabetes mellitus, and chronic obstructive pulmonary disease (including bronchial asthma), which have been shown to be associated with increased risk of pneumonia and/or pneumonia-associated death (1,27,28). Analyses done comparing those with low compared to normal final serum zinc concentrations were also controlled for change in BMI between baseline and follow-up values. Additionally, in separate analyses, we also controlled for baseline serum albumin and change in serum albumin concentrations between baseline and follow-up in these models. Two-sided observed significance concentrations (*p* values) <0.050 were considered to be statistically significant. All calculations were performed by using SAS for Windows, version 9.1.2 (SAS Institute Inc, Cary, NC, USA).

RESULTS

The demographic and clinical characteristics of participants with baseline zinc (N=578) and those with final study zinc concentrations (N=420) were similar (Table 1). These characteristics were also similar in distribution to those of our original overall study population (N=617) (19).

FOI 26-3132 - Document 5

NIH-PA Author Manuscript
NIH-PA Author Manuscript
NIH-PA Author Manuscript

Of the characteristics listed in Table 1, only the difference in age between those with low and normal baseline serum zinc concentrations was statistically significant (mean ± SD were 86 ± 8 and 84 ± 7 years, respectively; $p<0.001$). Elderly with low final serum zinc concentrations were older at baseline (86 ± 8 versus 84 ± 7 years; $p=0.014$), and were more likely to have had coronary artery disease (39% versus 28%; $p=0.042$) at baseline compared to those with normal final zinc concentrations. All subjects received influenza vaccine and there was no difference between the two groups in the proportion of subjects who had pneumococcal immunization.

When participants with low and normal baseline zinc concentrations were compared, differences in the incidence and duration of pneumonia, and total amount and duration of antibiotic use due to pneumonia (Table 2) were not statistically significant. Deaths due to pneumonia were 53% lower in those with normal compared to low baseline serum concentrations of zinc, but this association was not statistically significant ($p=0.198$). All-cause mortality rate was 39% lower in those with normal versus lower baseline zinc concentrations ($p=0.049$) (Table 2).

End of study serum zinc concentrations were strongly associated with the incidence and duration of pneumonia as well as antibiotic use and duration of antimicrobial therapy (Table 3; $p\leq0.004$ in all cases). The incidence of pneumonia and the total number of antibiotics used for treatment of pneumonia were about 50% lower in those with end serum zinc concentrations ≥70 μg/dL compared to those with concentrations <70 μg/dL. In addition, the duration of pneumonia was lower by 3.9 days and the duration of antibiotic use by 2.6 days in those with end serum zinc in the normal range compared to those with low concentrations (Table 3). Controlling for coronary artery disease in our multiple regression analyses model did not change the statistical significance of the differences observed. In addition, differences remained statistically significant after controlling for baseline serum albumin and change in serum albumin concentrations between baseline and follow-up. The 310 subjects with normal end zinc concentrations at completion suffered 78 cases of pneumonia while the 110 with low end zinc concentrations suffered 51. The fraction of pneumonias occurring in the final 2 months of the study was similar in those subjects with normal (14 cases out of 78) and low (8 cases out of 51) end serum zinc concentrations, i.e., 18% vs 16%, respectively.

Our findings were specific to zinc. We did not observe similar associations in our outcome variables of interest with other micronutrients that might influence immune function such as vitamins A, B6, D, E, β-carotene, and iron (data not shown). In addition, the mean changes in weight and BMI from baseline to follow-up between subjects with low and normal zinc concentrations were not significantly different; mean weight changes were −0.80 and −0.01 kg, respectively, and BMI, −0.35 and −0.01 kg/m^2, respectively.

DISCUSSION

We observed that elderly nursing home residents with low serum zinc concentrations at the end of one year of 50% RDA micronutrient daily supplementation, including zinc, had a higher risk of pneumonia and longer duration of pneumonia episodes as well as increased antibiotic use and longer duration of antibiotic use for treatment of pneumonia episodes. In addition, low baseline concentrations of serum zinc in our elderly nursing home population were associated with increased all-cause mortality.

Our finding of a significantly lower all-cause mortality rate (by 39%) between those with normal versus low baseline serum zinc concentrations among elderly in this study suggest that zinc may play a crucial role in influencing mortality in the elderly. Severe zinc deficiency can impair immunity and increase susceptibility to infectious diseases, a major cause of mortality in the elderly (1,3,29,30). Indeed, the risk of mortality was reduced by 27% in participants of

FOI 26-3132 - Document 5

NIH-PA Author Manuscript

NIH-PA Author Manuscript

the Age-related Eye-Disease Study (aged 55 to 81 years) who received zinc supplements (RR: 0.73; 95% CI, 0.61−0.89) (31). In addition, zinc supplementation has been shown to reduce overall mortality by as much as 51% in children with diarrhea and 68% in infants born full-term and small for gestational age (32,33).

When baseline serum zinc status was used as a measure of zinc to determine if low serum zinc affects susceptibility to pneumonia, differences failed to reach statistical significance. It may be that findings using baseline zinc concentrations were attenuated due to the higher risk of death among subjects with low baseline zinc concentrations or due to loss of subjects from serious illnesses and/or hospitalizations. In addition, because all study participants were provided with ½ RDA supplement that included zinc, the baseline concentrations may not reflect zinc status during much of the study period.

Because of the potential bias introduced by zinc supplementation, we performed similar analyses using final zinc concentrations, as this measure may better reflect the zinc status of subjects during the course of the study. We observe a strong association between low final zinc concentrations with increased incidence and duration of pneumonia, as well as total and duration of antibiotic use for pneumonia treatment. As described in the results, the effects observed were specific to zinc and were not observed with other micronutrients. Furthermore, the lower incidence and morbidity of pneumonia observed in subjects with normal final zinc concentrations compared to those with low final zinc concentrations were not due to differences between the two groups in changes in weight, BMI, or other micronutrients (19) during the study period.

Zinc deficiency has been suggested to be a risk factor for immune deficiency and subsequent infection relapses in the elderly (12,29,34). Zinc is essential for membrane integrity, DNA synthesis and cell proliferation, in addition to being a cofactor to more than 300 enzymes (5, 35).

It is essential for all highly proliferating cells in the human body, especially the immune system (36). Thymus atrophy and lymphopenia, as well as other defects in T cell function have been observed in both zinc deficiency and in the elderly (2,5,8).

Low zinc consumption has been reported in the elderly (10,37). Bogden et al. reported that zinc ingestion was below the RDA in more than 90% of their 100 study subjects aged 60−89 years (37). In addition, as mentioned above, we found below normal serum zinc concentrations in approximately 30% of the nursing home elderly enrolled in our vitamin E supplementation study. This level of deficiency persisted during the study period despite giving the participants supplements with ½ RDA of zinc (19). Thus, our finding of a significant association between low serum zinc level and pneumonia could be of major importance to the health of elderly, as poor zinc status would lead to impaired immune response, which could in turn result in increased susceptibility to infections in the elderly (9,29,34). Supplementing with ½ RDA of zinc appeared to benefit many of the subjects with inadequate baseline zinc concentrations, but the results also showed that this supplementation was not adequate to maintain serum zinc concentrations in a significant proportion of subjects.

Plasma or serum zinc concentrations are also known to decrease sharply in many infections (35,38,39). The decline is part of a set of metabolic reactions to infection known as the acute phase response (40). Although one could argue that lower serum zinc concentrations might be due to a higher incidence of pneumonia, this is unlikely to be the case here as the acute effect of pneumonia on zinc is likely to be transient--approximately 2 weeks if effective therapy is provided (41). Given the similar incidence of pneumonia in our participants in the last months of the study, transient suppression of serum zinc by the acute phase response is unlikely to be responsible for the low end study zinc concentrations.

Zinc supplementation may play an important role in the prevention and/or modulation of infectious diseases in the elderly (3,9,14,29). Various studies on zinc supplementation in the elderly have observed increased circulating zinc concentrations (13,14), as well as enhanced immune status including improved cell-mediated immune response, serum thymulin activity, and IL-2 production, and increased response to skin-test antigens (12,15,42). Also, when cultures of white blood cells from elderly subjects were supplemented with 15 μM zinc (the physiologic concentration), they produced interferon-alpha in amounts comparable to those from the younger subjects (43). In a randomized, double-blind, placebo-controlled clinical trial (N=81), institutionalized elderly had a significant decrease in the mean number of respiratory infections 2 years following supplementation with micronutrients containing zinc and selenium, but not vitamins (44). In another, larger (N=725), randomized, double-blind, placebo-controlled intervention study, low-dose supplementation of zinc and selenium significantly increased the humoral response in institutionalized elderly after vaccination (45). The number without respiratory tract infections during the study was also found to be higher in elderly that received trace elements over a 2-year period (45). While these studies suggest a protective effect of zinc against respiratory infections, contribution from other nutrients present in the mixture cannot be ruled out.

The results from our current study, in addition to these earlier findings, suggest that elderly with low serum zinc concentrations might benefit from zinc supplementation. Such a measure has the potential to reduce not only the number of episodes and duration of pneumonia and the total and duration of antibiotic use due to pneumonia, but also overall deaths in the elderly. Randomized, double blind, controlled studies are needed to determine the efficacy of zinc supplementation as a potential low cost intervention to reduce morbidity and mortality due to pneumonia in this vulnerable population.

Identification of 3-chymotrypsin like protease (3CLPro) inhibitors as potential anti-SARS-CoV-2 agents

Vicky Mody[1,3], Joanna Ho[1], Savannah Wills[1], Ahmed Mawri[1], Latasha Lawson[1], Maximilian C. C. J. C. Ebert[2], Guillaume M. Fortin[2], Srujana Rayalam[1] & Shashidharamurthy Taval[1,3]✉

Emerging outbreak of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection is a major threat to public health. The morbidity is increasing due to lack of SARS-CoV-2 specific drugs. Herein, we have identified potential drugs that target the 3-chymotrypsin like protease (3CLpro), the main protease that is pivotal for the replication of SARS-CoV-2. Computational molecular modeling was used to screen 3987 FDA approved drugs, and 47 drugs were selected to study their inhibitory effects on SARS-CoV-2 specific 3CLpro enzyme in vitro. Our results indicate that boceprevir, ombitasvir, paritaprevir, tipranavir, ivermectin, and micafungin exhibited inhibitory effect towards 3CLpro enzymatic activity. The 100 ns molecular dynamics simulation studies showed that ivermectin may require homodimeric form of 3CLpro enzyme for its inhibitory activity. In summary, these molecules could be useful to develop highly specific therapeutically viable drugs to inhibit the SARS-CoV-2 replication either alone or in combination with drugs specific for other SARS-CoV-2 viral targets.

FOI 26-3132 - Document 5

The major pandemic outbreak of the 21st century due to severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) has become a global threat to public health because of its high rate of infection leading to mortality. As of 24 December 2020, there are a total of 13,881,620 COVID-19 positive cases and 272,820 deaths in the United States alone and 64,326,880 confirmed cases and 1,488,992 deaths globally (https://coronavirus.jhu.edu/). The death toll is increasing at an alarming rate because of the lack of COVID-19 specific drugs or vaccines. Development, validation, and approval of COVID-19 specific drugs takes years[1]. Therefore, the idea of drug repositioning, also known as repurposing, is an important strategy to control the sudden outbreak of life-threatening infectious agents that spread rapidly. FDA approved anti-viral drugs are known to be safe for use in humans[2], but their effectiveness against SARS-CoV-2 needs to be experimentally validated. Several FDA approved anti-viral drugs such as favipiravir, danoprevir, darunavir, lopinavir, oseltamivir, ritonavir, remdesivir, and umifenovir are in clinical trials to study anti-COVID-19 activity[3]. However, the effectiveness of these drugs for preventing or reducing the severity of symptoms of COVID-19 has not yet been completely established. Therefore, there is an urgent need to identify additional drug candidates to target different SARS-CoV-2 proteins for enhanced efficacy in the treatment of COVID-19.

Recently, Wu et al.[4] sequenced and compared SARS-CoV-2 genome with other coronaviruses (CoVs) and confirmed that novel SARS-CoV-2 belongs to β-CoVs, which were originally found in bats and have now adapted to infect humans. CoVs are RNA viruses with positive-sense single stranded RNA (+ssRNA) as their genetic material[5] and recent studies have shown that SARS-CoV-2 shares ~89% sequence similarity with other SARS-CoVs[4]. Additionally, SARS-CoV-2 has similar genetic organization as other SARS-CoVs with a 5′-untranslated region followed by 16 non-structural proteins (open reading frame; ORF1a and ORF1b complex) also called as replicase complex, and the structural proteins such as spike (S), envelop (E), membrane (M), and nucleocaspid (N) protein along with other accessory proteins present towards the 3′ end[6]. The life cycle of the virus begins with the binding of the S protein of the virus to its receptor on the host cells, the ACE2. The binding is then followed by the fusion of the viral envelop with host cell membrane and the release of the viral genome into the cytoplasm[7]. The viral genome (+ssRNA) hijacks the host ribosomes and gets translated into ~ 800KDa large polypeptide (PP) chain. The newly generated PP chain is auto-proteolytically cleaved by two proteases such as papain like proteases (PLpro) and 3-chyomotrypsin like protease (3CLpro), encoded by the viral genome, to generate several non-structural proteins (NSPs) required for the viral replication. 3CLpro is also called the main protease (Mpro) and plays a major role in the viral replication. PLpro and 3CLpro cleaves the PP chain into 16 NSPs and out of the 16 NSPs generated, 11 NSPs are generated by the 3CLpro, making this protease one of the major targets for developing anti-SARS-CoV drugs[8,9]. On the other hand, structural and other accessary proteins are generated through a unique mechanism called sub-genome (Sg) translation. Sg's are produced through discontinuous transcription from 5′ end of the anti-sense viral RNA[10–13]. After successful genome replication and translation, NSPs, structural proteins and accessory proteins assemble along with positive-sense viral RNA genome to form a new virion. The CoVs genome and proteolytic cleavages by PLpro and 3CLpro is illustrated in Fig. 1.

The genomic and protein sequences for SARS-CoV-2 are publicly available from the NIH gene data bank[4,6,14]. Herein, we have selected 3CLpro of SARS-CoV-2 as a target to identify potential inhibitors since this protease is indispensable for viral replication and hence an excellent drug target[9]. The structure of 3CLpro protein of SARS-CoV-2 in complex with an inhibitor N3 is available in the PDB database (ID: 6LU7). To identify the FDA approved drugs as inhibitors for 3CLpro, in silico drug screening studies were carried out. In all, 3987 FDA approved drugs (SuperDrugs2 database) were sorted as viral protease inhibitors (PIs), viral non-protease inhibitors (VNIs) and off-target drugs (OTDs), and screened for the anti-3CLpro activity using the Molecular Operating Environment (MOE) software. The protein structure-based drug design using computational methods is an alternative for screening of currently approved drugs to rapidly identify potential drug candidates for the treatment of emerging infectious diseases such as COVID-19[15–17]. However, the potential for false positives with computational modeling is one of the most common limitation of docking studies[18]. Therefore, we have established SARS-CoV-2 3CLpro enzymatic assays for selected drugs using commercially available 3CLpro protease inhibitor screening assay kits to evaluate the in vitro inhibitory activity of the drugs and investigated whether any correlation exist between the computational binding score and the in vitro inhibitory activity. In this report, we have selected 47 from the list of 3987 FDA approved drugs based on binding score, side effects, half-life, active form, immunosuppressant properties, autofluorescence, and availability for an in vitro 3CLpro enzymatic inhibitor-screening assay. We observed that, boceprevir, ombitasvir, paritaprevir, tipranavir, and micafungin exhibited partial inhibitory effect whereas, ivermectin blocked more than 85% of 3CLpro activity of SARS-CoV-2. Although the anti-viral activity of ivermectin mediated through the blocking of α/β1 importin[19–23] is established, herein we report the inhibitory effects of ivermectin on 3CLpro enzyme of SARS-CoV-2, suggesting additional anti-viral mechanism of ivermectin towards SARS-CoV-2.

Results

In silico screening of FDA approved drugs for potential binding to SARS-CoV-2 3CLpro enzyme. All the 3987 FDA approved drugs (downloaded from SuperDrugs2) were sorted as PIs, VNIs, and OTDs and docked with monomeric form of 3CLpro protein using the Molecular Operating Environment (MOE) software. Drugs were ranked according to the highest binding energy (S score). S score was calculated using the London dG score for placement and GBVI/WSA dG score for refinement of poses. A binding energy with ≤−6.5 kcal/mol (S score) was selected as a cutoff to rank the drugs with highest binding affinity[16]. The list was further narrowed down based on the criteria listed in the Methods section. We found that 56 drugs have a binding affinity of <−6.50 kcal/mol for the 3CLpro enzyme (Table 1). The computational study suggested that the list of drugs identified might inhibit the SARS-CoV-2 viral replication by targeting the viral 3CL protease. However, the potential for false positives with the predicted binding score is one of the most common limitation of docking studies[24,25]. Hence, to rule out any ambiguity in false prediction, we carried out the in vitro enzymatic assay to identify potential therapeutics and investigate correlation between the binding score and the in vitro activity. In the current study, we did not find any correlation between the in vitro results of selected drugs and their computational inhibition constants. Even though, computational studies are being widely used to predict the initial protein-drug interactions, in vitro screening of the drugs is necessary to confirm the inhibitory activities of the drugs.

Inhibition of SARS-CoV-2 3CLpro enzymatic activity by selected drug candidates. To further validate the SARS-CoV-2 3CLpro inhibitory activity of the selected drugs from computational studies, we performed an in vitro enzymatic inhibitory

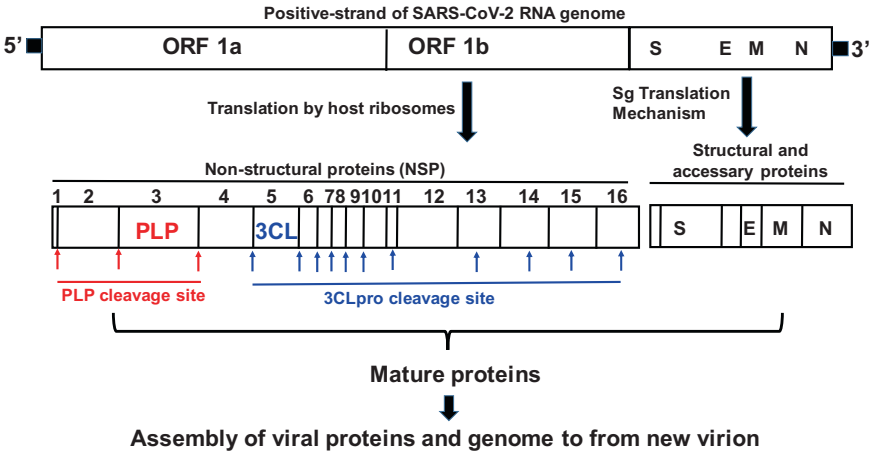

Fig. 1 Representation of SARS-CoV-2 genome arrangement and protease cleavage sites. Genetic material (RNA) of SARS-CoV-2 enters the host cell and borrows ribosome to translate into 16 nonstructural proteins upon auto-proteolytic cleavage by PLpro and 3CLpro enzymes. Structural proteins (S, E, M, and N) are translated by sg translation mechanism. All mature proteins assemble along with positive-sense single stranded RNA genome to form new virion. Arrows indicates the protease cleavage sites. ORF open reading frame, PLP papain like protease, 3CLP 3-chymotrypsin like protease, S spike protein, E envelop protein, M membrane protein, N nucleocaspid protein.

assay using commercially available assay kits. The background autofluorescence of the selected 56 compounds was measured by excitation/emission wavelength of 360/460 nm. Nine out of 56 drugs exhibited extremely high autofluorescence (Supplementary Fig. 2) and were therefore eliminated from the in vitro protease inhibitor enzymatic assay. The remaining 47 drugs were sorted as PI, VNIs, and OTDs. The specific mechanism of action and their clinical uses are listed in Supplementary Table 1. The 3CLpro inhibitory activity was screened at 50 μM concentration of the drugs. Among the 17 PIs screened, boceprevir, paritaprevir and tipranavir significantly inhibited the 3CLpro enzymatic activity by 45, 70, and 64%, respectively (Fig. 2). Out of the 17 VNIs, only ombitasvir was able to partially block (65%) the 3CLpro enzymatic activity (Fig. 3). Interestingly, as shown in Fig. 4, out of 13 OTDs only ivermectin completely blocked (>80%) the 3CLpro activity at 50 μM concentration. Additionally, micafungin exhibited partial inhibitory activity (57%) against 3CLpro of SARS-CoV-2.

The compounds that exhibited more than 50% inhibitory activity were subjected to subsequent dose-dependent studies to calculate the concentration required to inhibit 50% of the 3CLpro enzymatic activity (IC_{50}). Boceprevir, ivermectin, micafungin, ombitasvir, paritaprevir, and tipranavir were subjected to dose-dependent inhibitory activity studies. As shown in the Fig. 5, ivermectin inhibited more than 85% of the enzymatic activity at 50 μM concentration, whereas micafungin and paritaprevir inhibited around 80% of the enzymatic activity at 100 μM concentration. Both tipranavir and ombitasvir were able to inhibit only 50% of the enzymatic activity even at 100 μM concentration (Fig. 5). The percent enzymatic activity versus the log concentration of the inhibitors was used to calculate the IC_{50} values using non-linear curve fit model as described under Methods section. The calculated IC_{50} values for ivermectin, tipranavir, boceprevir, micafungin, paritaprevir, and ombitasvir were found to be 21.5, 27.7, 31.4, 47.6, 73.4, and 75.5 μM, respectively (Table 2). Taken together, these studies suggest that the molecules listed above exhibited inhibitory activity against 3CLpro enzyme of SARS-CoV-2.

Structural interaction of boceprevir, paritaprevir ombitasvir, tipranavir, ivermectin, and micafungin with the enzymatic active site of 3CLpro. The presence of an unconventional catalytic cysteine residue in 3CLpro makes it unique as compared to other chymotrypsine like enzymes and other Ser (or Cys) hydrolases[26]. In addition, the 3CLpro consist of a catalytic Cys^{145}-His^{41} dyad instead of a canonical Ser(Cys)-His-Asp(Glu) triad[27]. This catalytic dyad is activated in the presence of the substrate containing Leu-Gln↓Ser-Ala-Gly (↓ marks the cleavage site)[26]. Structurally the catalytic residues Cys^{145} and His^{41} in 3CLpro are buried in an active site cavity located on the surface of the protein (Supplementary Fig. 1) and both residues are at a distance of 3.8 Å[26,28]. This distance might be long enough to prevent formation of any intermolecular hydrogen bond between Cys^{145} and His^{41} at physiological pH. Additionally, the Cys^{145} is protonated at physiological pH and His^{41} is present in the neutral state. The substrate binding triggers the intramolecular proton transfer from Cys^{145} to His^{41} triggered via the attack of Cys^{145}-Sulfur onto the (C=O) of the substrate peptide bond[27]. During catalytic activity, the protonated His^{41} is stabilized by the presence of H_2O molecule close to His^{41}. Thus, the ability to form a hydrogen bond with both Cys^{145} and His^{41} residues or either with one of these residues might be a characteristic of a good inhibitor.

Using computational modeling, the structural interaction of boceprevir, paritaprevir ombitasvir, tipranavir, ivermectin, and micafungin with 3CLpro SARS-CoV-2 enzyme was studied. We found that carbonyl (C=O) group in ivermectin and boceprevir forms a hydrogen bond with Cys^{145} which might explain their inhibitory activity (Fig. 6a, e; panel I and II). Similar type of hydrogen bonding was also observed between carbonyl (C=O) group in paritaprevir next to the sulfonamide and Cys^{145} and also between sulfonamide group in tipranavir and Cys^{145} (Fig. 6b, c: panel I and II). In addition, same carbonyl (C=O) group in paritapavir also shows hydrogen bonding interaction with His^{41} (Fig. 6b; panel I and II). However, ombitasvir and micafungin show a hydrogen bonding interaction with Glu^{166} (Fig. 6d, f; panel I and II). The hydrogen bonding interaction of Glu^{166} with ombitsavir and micafungin is very important, as the Glu^{166} is responsible for the formation of the homodimer of 3CLpro in SARS-CoV-2[28]. This dimer form is important for its enzymatic activity and any interaction with Glu^{166} can result in the formation of an inactive monomer which interferes with the enzyme activity of 3CLpro[28]. Computational modeling illustrations are presented in Fig. 6a–f; panel-III shows the interaction of the drugs with the lipophilic pocket of the 3CLpro enzymatic site.

9	Candicidin	−9.05496
10	Chloroquine	−6.7514
11	Daclatasvir	−8.47852
12	Danoprevir	−9.26908
13	Darunavir	−8.59002
14	Delavirdine (mesylate)	−7.3092
15	Elbasvir	−8.77218
16	Elvitegravir	−7.48581
17	Etravirine	−6.91494
18	Favipiravir	−4.23592
19	Fumagillin	−7.25118
20	Gabexate	−7.24702
21	Glecaprevir	−8.70897
22	Grazoprevir	−8.85946
23	Hydroxychloroquine	−7.03572
24	Indinavir	−8.39968
25	Itraconazole	−7.99098
26	Ivermectin	−7.74053
27	Ledipasvir	−9.52825
28	Lopinavir	−9.10074
29	Maraviroc	−8.19033
30	Methylprednisolone	−6.42667
31	Micafungin	−9.60339
32	Nelfinavir	−8.55575
33	Ombitasvir	−8.96571
34	Oseltamvir Phosphate	−7.04549
35	Paritaprevir	−7.43470
36	Peramivir	−6.7811
37	Pibrentasvir	−9.87502
38	Pimodivir	−6.79098
39	Pleconaril	−7.16664
40	Posaconazole	−7.95234
41	Quinine	−6.67637
42	Raltegravir	−7.76854
43	Remdesivir	−5.9488
44	Ribavirin	−6.3251
45	Ribostamycin	−7.28802
46	Rilpivirine	−7.09415
47	Ritonavir	−9.94965
48	Saquinavir	−9.25575
49	Simeprevir	−9.50916
50	Sofosbuvir	−8.4513
51	Telaprevir	−8.96481
52	Temsavir	−8.33862
53	Tenofovir Diphosphate	−6.557
54	Tipranavir	−7.47819
55	Umifenovir	−7.23012
56	Velpatasvir	−9.33025

100 nanosecond (ns) Molecular Dynamics simulations for micafungin and ivermectin. To investigate the stability of these docking poses, 100 ns molecular dynamics (MD) simulation studies were performed for two compounds, ivermectin and micafungin. Figure 7a panel I–III shows the MD simulations of micafungin with the monomer form of 3CLpro. The MD simulation data suggests that micafungin was stable and remained bound in the active site pocket throughout the 100ns simulated time (compare Fig. 7a I–III). The analysis of protein-ligand interaction fingerprints between the monomeric 3CLpro enzyme and micafungin (Fig. 7a, panel-IV) shows that micafungin has a predominant interaction with Glu^{166}. It is possible that the micafungin remained bound in the pocket of the monomeric form of 3CLpro for the entire length of the 100-ns trajectory via a hydrogen bonding with Glu^{166}. As noted earlier, interaction with Glu^{166} suggests interference with the dimerization of the 3CLpro in SARS-CoV-2, which is required for its activity[28] thus explaining the inhibitory activity of micafungin against 3CLpro enzyme. Supplementary Movie 1 presents the real-time interaction of micafungin with the active site of monomeric 3CLpro indicating the stability of micafungin in the catalytic pocket of monomer.

The MD simulations for ivermectin are shown in Fig. 7b (panel II–III), where ivermectin diffuses out of the catalytic pocket of 3CLpro monomer after 85 ns. It is evident from the protein-ligand fingerprint map that ivermectin interacts with both Cys^{145} and His^{41} of the 3CLpro monomer for about 14 ns (Fig. 7b, panel-IV). Later, ivermectin loses its interaction with His^{41} and does not show interaction with any amino acids of interest (Cys^{145}, His^{41}, and Glu^{166}) and eventually diffuses out of the pocket at 85 ns (Fig. 7b, panel-II). Supplementary Movie 2 shows the instability of the ivermectin in the catalytic pocket of the monomeric form of 3CLpro. Since the homodimer is the active form of 3CLpro enzyme[28], we hypothesized that the homodimeric form of 3CLpro is required to stabilize ivermectin in the catalytic pocket and hence is responsible for the inhibitory activity of ivermectin. To test our hypothesis, MD simulations of ivermectin with the homodimer form of 3CLpro was performed. Interestingly, we observed that ivermectin remained bound in the catalytic pocket of the homodimer (compare Fig. 7c, panel I–III) throughout the period of the simulation. The detailed analysis of the homodimer 3CLpro-ivermectin fingerprint region (Fig. 7c, panel-IV) shows that ivermectin interacts with both Cys^{145} and His^{41} for 2 ns, then with His^{41}. After 85 ns, ivermectin contacts with Ser^{1} of the neighboring monomer, suggesting that this amino acid residue assists in the stabilization of ivermectin in the catalytic binding pocket (Fig. 7c, panel IV). Supplementary Movie 3 exhibits the real-time MD simulation interaction and the stability of ivermectin in the catalytic pocket with homodimer of 3CLpro from 0–100ns.

Further, Supplementary Fig. 3 shows the binding affinity (S-score) over the course of the MD simulation for ivermectin with the monomer and homodimer form of 3CLpro, and micafungin with monomer form of 3CLpro. We observed that the S-score for micafungin was stable over the period of computation whereas, ivermectin with monomer form of 3CLpro fluctuated from −9.64 to −2.2 kcal/mol. As shown in the Supplementary Fig. 3, upon leaving the active site ~85 ns ivermectin exhibited an increase in S-score after (~−2.0 kcal/mol). This is in stark contrast to the S-score of ivermectin in complex with the homodimer form of 3CLpro, which remained stable throughout the simulation with an average of −5.64 kcal/mol. Taken together, this computational model provides a framework for the possible interaction between these inhibitors and 3CLpro. However, the structural interaction of these drugs with SARS-CoV-2 3CLpro needs to be validated by X-ray crystallographic studies.

Discussion

COVID-19 is a disease caused by the SARS-CoV-2 and is a major threat to public health globally because of the high rates of infection and mortality. Morbidity and mortality continue to rise

FOI 26-3132 - Document 5

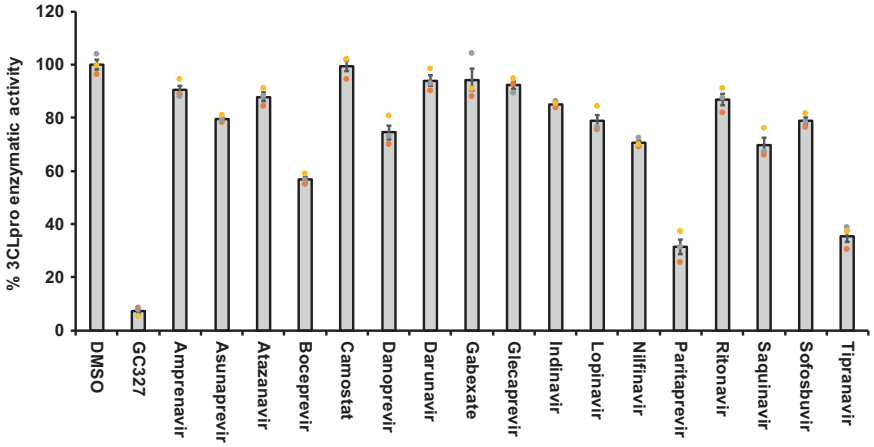

Fig. 2 Protease inhibitors boceprevir, paritapravir, and tipranavir exhibited partial inhibitory activity against SARS-CoV-2 3CLpro enzyme. The selected FDA approved viral-protease inhibitors were screened for their inhibitory activity against SARS-CoV-2 3CLpro enzyme as described under Methods section. The fluorescence units were converted to percent enzymatic activity considering DMSO treated control as 100% activity. Blank values were subtracted from all the readings before calculating the percent activity. Representative of three individual experiments with triplicate values were presented graphically ($n = 3$). P value < 0.001 considered as statistically significant. One-way ANOVA with Dunnett's Multiple Comparison post-hoc test was used to calculate the statistical significance.

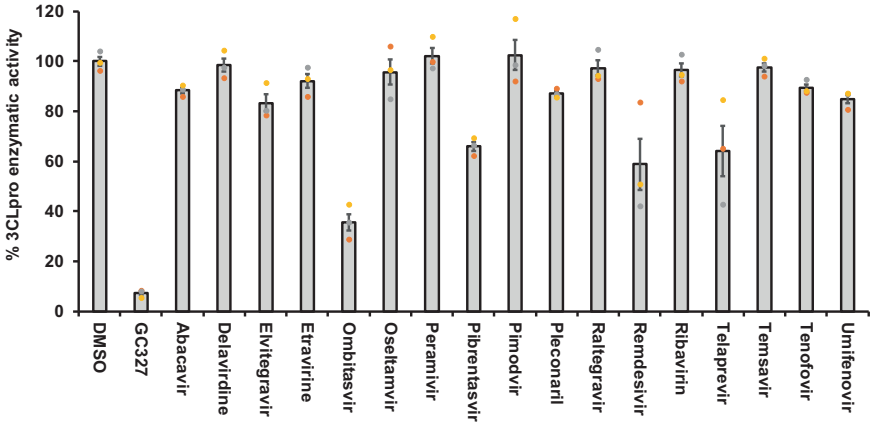

Fig. 3 Non protease inhibitor ombitasvir inhibited SARS-CoV-2 3CLpro activity partially. The non-protease anti-viral drugs selected by computational studies were screened for their inhibitory activity against SARS-CoV-2 3CLpro enzyme as described under Methods section. The percent enzymatic activity was calculated as described in Fig. 1 legend. Blank values were subtracted from all the readings before calculating the percent activity. Representative of three individual experiments with triplicate values were presented graphically ($n = 3$). P value < 0.001 considered as statistically significant. One-way ANOVA with Dunnett's Multiple Comparison post-hoc test used to calculate the statistical significance.

due to the lack of a specific vaccine and drugs that prevent COVID-19 disease progression. There is an urgent need to identify and test potential therapeutics for this disease. One approach that may lead to a more rapid increase in treatment options is to repurpose currently approved FDA drugs for their ability to prevent or reduce the spread of virus and severity of COVID-19 pathogenesis. Many of the FDA approved drugs are being repurposed in clinics to treat COVID-19. However, the effectiveness of these drugs and their specific targets for preventing or reducing the severity of symptoms of COVID-19 has not yet been completely established[2,29–31]. Therefore, several laboratories are identifying specific drugs for many targets of SARS-CoV-2. Herein, we have investigated 47 FDA approved drugs that inhibit the SARS-COV-2 3CLpro enzymatic activity, the main enzyme for viral replication and the preferred drug target for COVID- 19[32]. We used MOE computational studies for the initial screening to select the drugs that have high affinity for 3CLpro and further functional inhibitory activity of the 47 selected drugs was confirmed using in vitro enzymatic assay. As noted in the previous studies[24,25], our data suggests that inhibitory effects of drugs predicted from the computational screening as defined by the S-score do not agree with our experimental in vitro studies. Thus, additional in vitro screening for all the drugs is warranted.

Among 17 PIs tested here, boceprevir, paritaprevir, and tipranavir were able to partially inhibit the 3CLpro enzymatic activity at 50 µM drug concentration (Fig. 2). It has been shown that boceprevir and paritaprevir inhibit the hepatitis-C virus by inhibiting protease activity of nonstructural protein 3 and 4A (NS3/4A)[33,34]. Tipranavir is a retroviral protease inhibitor that binds to active site of HIV protease and prevents proteolytic cleaving of precursor polyproteins into mature functional proteins thereby inhibiting the viral replication[35]. Apart from these drugs, known PIs lopinavir and ritonavir did not exhibit any 3CLpro inhibitory activity (Fig. 2); thus explaining the ineffectiveness of these drugs in clinical trials of COVID-19 treatment[31]. Our observation with lopinavir and ritonavir are in agreement with Ma et al.[34]. Further, the VNI agent such as ombitasvir which targets the nonstructural proteins (NS5A) of hepatitis-C virus to inhibit the viral replication and assembly[36] was also able to

FOI 26-3132 - Document 5

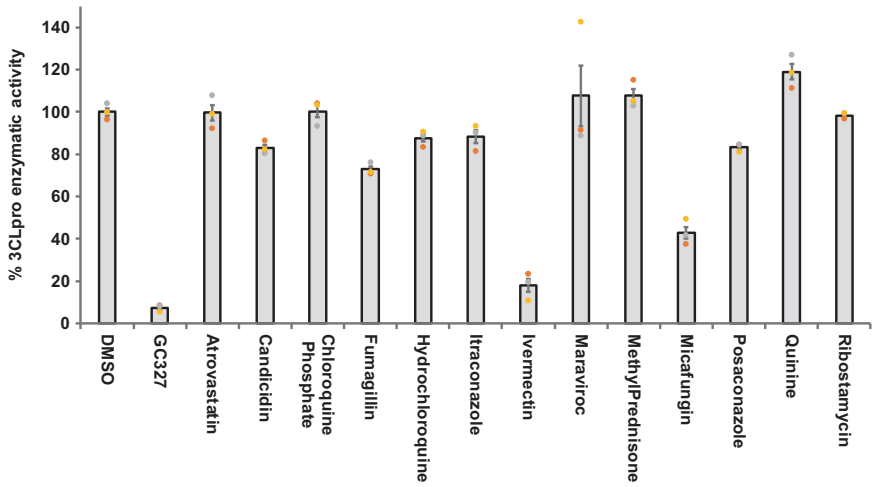

Fig. 4 Ivermectin exhibited complete inhibition of SARS-CoV-2 3CLpro enzymatic activity whereas micafungin partially inhibited the enzyme. The off-target drugs that are being used to treat non-viral ailments selected by in silico studies were screened for their inhibitory activity against SARS-CoV-2 3CLpro enzyme as described under Methods section. The percent enzymatic activity was calculated as described in Fig. 1 legend. Blank values were subtracted from all the readings before calculating the percent activity. Representative of three individual experiments with triplicate values were presented graphically ($n = 3$). P value < 0.001 considered as statistically significant. One-way ANOVA with Dunnett's Multiple Comparison post-hoc test used to calculate the statistical significance.

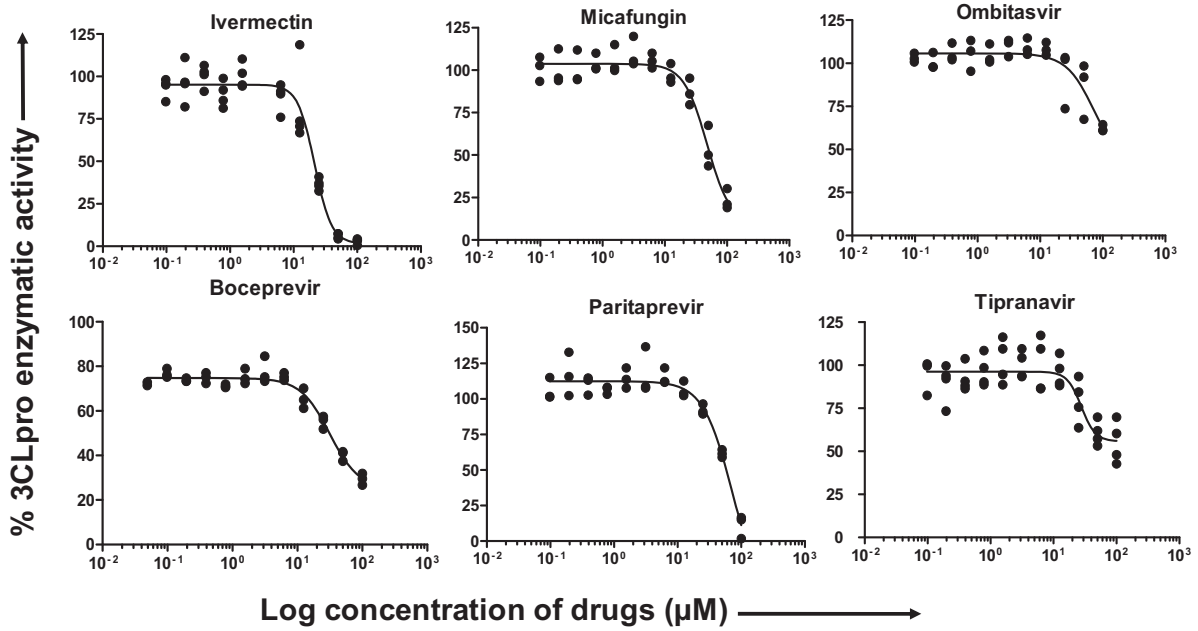

Fig. 5 Dose-dependent inhibition of SARS-CoV-2 3CLpro activity by selected PIs, VNIs, and OTDs. The drug candidates that exhibited more than 50% of inhibitory activity at 50 μM concentration were selected for dose-dependent and IC_{50} calculation studies. A serial dilution of drugs ranging from 0 to 100 μM in assay buffer was used. The percent activity was calculated as described in Fig. 1 legend. Representative of three individual experiments with triplicate values were presented graphically ($n = 3$). Non-linear regression (curve fit) with four variable dose vs inhibition was used to calculate the IC_{50} values using GraphPad Prism.

Table 2 IC_{50} values of non-viral protease inhibitor drugs for SARS-CoV-2 3CL protease.

SL. No.	Drug name	IC_{50} values
1	Ivermectin	21.53
2	Tipranavir	27.66
3	Boceprevir	31.36
4	Micafungin	47.63
5	Paritaprevir	73.38
6	Ombitasvir	75.49

partially inhibit the 3CLpro enzymatic activity in vitro. In addition to the anti-viral drugs, micafungin, one of the OTDs tested, also inhibited 66% of 3CLpro activity. Micafungin is a broad spectrum anti-fungal drug which belongs to the class of echinocandin and acts by targeting fungal β-1–3 glucan synthase[37].

While the reason for the partial inhibitory effect of the agents boceprevir, ombitasvir, paritaprevir, tipranavir, and micafungin towards 3CLpro is not clearly understood, it is possible that the strength of the hydrogen bonding interactions between these agents and Cys^{145}/His^{41}/Glu^{166} of 3CLpro may explain differential inhibitory effect. Nonetheless, our studies provide avenues

FOI 26-3132 - Document 5

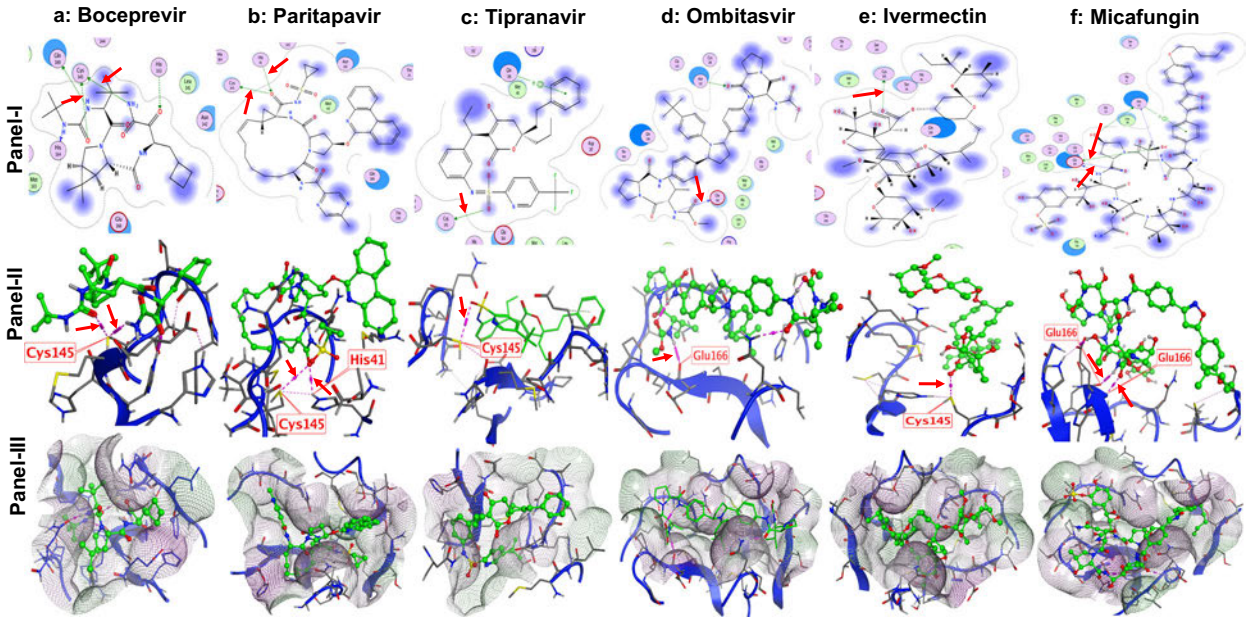

Fig. 6 Structural analysis and interaction of the potential inhibitors with SARS-CoV-2 3CLpro enzyme. Inhibitors were docked with active site of 3CLpro protein. Panel-I: ligand interaction map. Panel-II: interaction of inhibitors specific amino acids of 3CLpro at active site. Panel-III: lipophilic cavity of active site with drugs interacting with specific amino acids. Boceprevir (**a**), partapravir (**b**), tipranavir (**c**), ombitasvir (**d**), ivermectin (**e**), and micafungin (**f**) are arranged in columns for comparison. Drugs are represented in green color with ball and stick model. Arrows indicate the C–H, N–H, and C–O bonds between drugs and with Cys^{145}, His^{41}, and Glu^{166} residues since they are essential for the enzymatic activity of 3CLpro enzyme. However, we also observed the drugs interacting with neighboring amino acid residues.

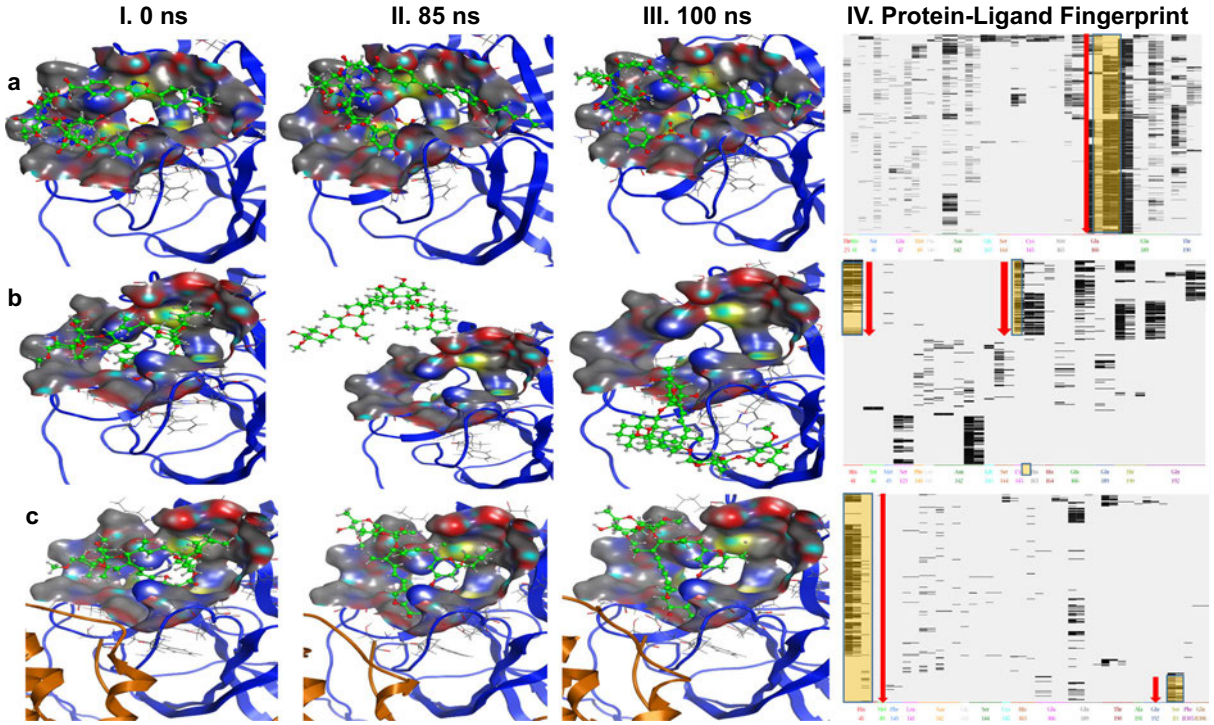

Fig. 7 MD 100 ns simulation studies for ivermectin and micafungin. MD simulation studies were carried as described under Methods section. Interaction of micafungin (**a**), and ivermectin (**b**) with monomeric form of 3 CLpro enzyme. **c** Interaction of ivermectin with active site of 3CLpro homodimer. Panel I–III represents the interaction of ligand at different time points in nano second (ns). Panel-IV represents the ligand-binding fingerprint of micafungin and ivermectin with specific amino acids of 3CLpro enzymes.

to use the scaffold of these molecules to design highly potent and specific inhibitors for SARS-CoV-2 3CLpro enzyme.

Interestingly, one of the OTD, ivermectin was able to inhibit more than 85% (almost completely) of 3CLpro activity in our in vitro enzymatic assay with an IC_{50} value of 21 μM. These findings suggest the potential of ivermectin to inhibit the SARS-CoV-2 replication. In support of this, a recent finding suggested that ivermectin (5 μM) inhibited the replication of live

FOI 26-3132 - Document 5

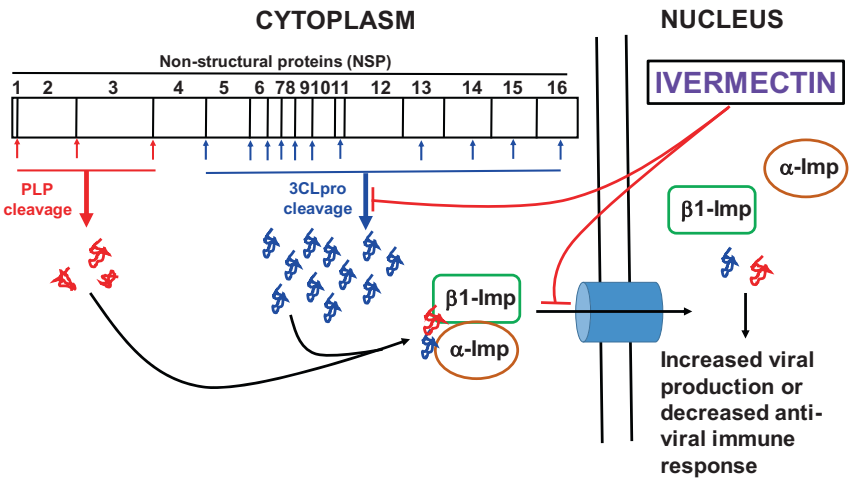

Fig. 8 Schematic representation of anti-viral mechanism of ivermectin. Hypothetical model illustrating the inhibition of SARS-CoV-2 replication by ivermectin mediated through the blocking of α/β1-importin (imp) as well as 3CLpro enzymatic activity.

SARS-CoV-2 isolated from Australia (VIo1/2020) in Vero/hSLAM cells[23]. They found that >5000-fold viral counts were reduced in 48 hr in both culture supernatant (release of new virion: 93%) as well as inside the cells (unreleased and unassembled virion: 99.8%) when compared to DMSO treated infected cells. Interestingly, this study reported the IC_{50} value of ivermectin as 2.5 μM[23], whereas, we observed an IC_{50} value of 21 μM (10-fold increase). The variability in the IC_{50} values reported could be attributed towards the differences in the assay conditions such as the use of live virus vs enzymatic assay with purified 3CLpro protein. Further, preclinical studies need to be established to validate the in vivo inhibitory activity and IC_{50} values of ivermectin.

Ivermectin is known to be effective against many positive-sense, single stranded RNA viruses such as Zika, Dengue, Yellow fever, West nile, Venezuelan equine encephalitis, Chikungunya, Semliki forest, Sindbis, Rorcine Reproductive and Respiratory Syndrome, and Human immunodeficiency-1 viruses[38]. The list of anti-viral effects of ivermectin against other RNA and DNA viruses were summarized in a recent review[38]. Earlier studies have demonstrated that the possible anti-viral mechanism of ivermectin was through the blockage of viral-protein transportation to the nucleus by inhibiting the interaction between viral protein and α/β1 importin heterodimer, a known transporter of viral proteins to the nucleus especially for RNA viruses[19–23]. However, in this study, we have reported that ivermectin inhibits the enzymatic activity of SARS-CoV-2 3CLpro and thus may potentially inhibit the replication of RNA viruses including SARS-CoV-2. These studies suggest that ivermectin could be a potential drug candidate to inhibit the SARS-CoV-2 replication and the proposed anti-viral mechanism of ivermectin presented in Fig. 8 and in vivo efficacy of ivermectin towards COVID-19 is currently been evaluated in clinical trials (ClinicalTrials.gov Identifier: NCT04438850).

In conclusion, the SARS-CoV-2 specific 3CLpro enzyme was used as a target to screen the potential drugs that have high binding affinity for 3CLpro since it plays a major role during viral replication. We have identified that boceprevir, micafungin, ombitasvir, paritaprevir, and tipranavir exhibited partial inhibitory effect, whereas ivermectin was able to completely inhibit the SARS-COV-2 3CLpro enzymatic activity in vitro at the tested doses. The 100 ns MD simulation studies suggest that the ivermectin may require homodimeric form of 3CLpro enzyme for its inhibitory activity. This could be due to the interaction of the amino acid residue, Ser[1], from the neighboring monomer. On the other hand, micafungin remained bound in the catalytic pocket of the monomeric from of 3CLpro throughout the period of simulation. The list of drugs that are reported in this study provides a rationale to prioritize these potential drugs to be tested preclinically followed by clinical studies to target the SARS-Cov-2 pathogenesis.

Methods

Reagents and drugs. Molecular biology grade DMSO was purchased from Sigma Aldrich (St. Louis, MO, USA), Sterile PBS was from ThermoFisher Scientific (Waltham, MA, USA). 3CLpro inhibitor screening enzymatic assay kits (Catalog #79955-1) were from BPS Biosciences (San Diego, CA, USA). Amprenavir, Atazanavir sulfate, Candicin, Chloroquine Phosphate, Hydroychloroquine Sulfate, and Lopinavir were purchased from Sigma Aldrich (Saint Louis, MO). Beclabuvir, Temsavir were from Medchem Express (Monmouth Junction, NJ). Abacavir (sulfate), Arbidol hydrochloride, Asunaprevir, Atrovastatin, Boceprevir, Daclatasvir, Danoprevir, Darunavir, Delavirdine (mesylate), Edoxudine, Elbasvir, Elvitegravir, Etravirine, Favipiravir, Fumagillin, Glecaprevir, Grazoprevir, Indinavir sulfate, Itraconazole, Ivermectin, Ledipasvir (G-5885), Maraviroc, Methylprednisolone, micafungin sodium, ombitasvir, Oseltamivir phosphate, Paritaprevir, Peramivir, Pibrentasvir, Pimodivir, Pleconaril, Posaconazole, Quinine, Raltegravir (potassium salt), Remdesivir, Ribavirin 5'-monophosphate (lithium salt), Ribostamycin sulfate, Rilpivirine, Saquinavir, Telaprevir, Tenofovir diphosphate (sodium salt), and Velpatasvir were purchased from Cayman Chemicals (Ann Arbor, MI).

Preparation of working solution of ligands. One mg of drug was used to prepare 8 mM stock solution using either DMSO or PBS as solvent. This stock solution was used to prepare the working solution of 250 μM and 500 μM of drugs in PBS.

3CLpro protein preparation. The crystal structure of COVID-19 main protease was retrieved from the protein data bank (www.rcsb.org) with PDB format (ID: 6LU7). Any structural issues if present in the protein were corrected using QuickPrep option in MOE. The QuickPrep option performs a protonation and calculates the minimum energy conformation of the protein. Default parameters of MOE software was used for QuickPrep function.

Preparation of ligands. The drug list of 3987 FDA approved drug molecules and active ingredients were downloaded from SUPERDRUGS2 database in sdf format. The database of these 3987 drugs were imported into Molecular Operating Environment MOE and were cleaned using wash function in MOE. This function rebalances protonation states and regenerate 3D coordinates to their minimum energy conformations. Default parameters of MOE software was used for wash function.

Protein:drug docking studies. Integrated Computer-Aided Molecular design computing method Molecular Operating Environment (MOE) software was used to dock the drugs with 3CLpro protein. Briefly, docking was performed on the ligand site of 6LU7 protease using washed dataset of 3987 drugs. 30 poses for London dG and 20 poses of GBVI/WSA dG were used for final docking. All docking results were sorted by the binding energy using S Score function and they were viewed for accuracy using the ligand interaction function in MOE. The drugs with a binding score (S-Score) of ≤−6.5 were considered for further studies. The

FOI 26-3132 - Document 5

list was further narrowed down based on the listed criteria (1) All peptidomimetic drugs were eliminated as they tend to elicit immune response in the body; (2) Drugs used as immunosuppressants or for the treatment of cardiovascular disorders were eliminated as they tend to be in high risk categories; (3) All prodrugs were eliminated unless the active form was readily available as our in vitro assay is specific for SARS-COV-2 3CLpro and does not provide an option to activate drugs in vitro; and (4) Drugs with a shorter half-life of <30 min were also eliminated. In addition, we also ensured that small molecules which are part of any current Phase I, II, or III clinical trials were included in this study irrespective of their S-Score. For e.g favipiravir has an S score of −4.23 and since it is under clinical trials for COVID-19, we have included favipiravir in the study. This screening led to the database of 56 drugs, which were selected to study their inhibitory effect on SARS-CoV-2 specific 3CLpro enzyme using an in vitro 3CLpro enzymatic assay.

3CLpro enzymatic assay. SARS-CoV-2 specific 3CLpro assay kits were purchased from BPS Biosciences (CA) and enzymatic assay was carried out as per the manufacturer's protocol using 96 well plates. Briefly, 4 ng 3CLpro-MBP tagged enzyme in 30 µl of assay buffer was pre-incubated with 10 µl of (250 µM) drugs for 1 h. The enzymatic reaction was initiated by adding 10 µl (250 µM) fluorescent substrate. The final volume of the assay samples was 50 µl. The final concentration of drugs and substrate in the reaction mixture was 50 µM. Incubation was continued at room temperature for 16–18 h. Fluorescence reading was taken at 360/40 excitation and 460/40 nm emission using Synergy HT fluorescent plate reader. For IC_{50} calculation, drugs were screened from 0 to 100 µM dose range. Wells with 1% DMSO with 4 ng of enzyme and 50 µM of substrate served as positive control with no enzyme inhibition. Wells with 50 µM of GC367 compound (provided by the BPS Biosciences) served as standard inhibitor and negative control. Wells with 1% DMSO with 50 µM of substrate without enzyme served as blank. All the values were subtracted from blank values.

Molecular dynamic simulation studies. The structure of COVID-19 main protease 6LU7 (PDB ID: 6LU7) was prepared in its monomeric and functional dimeric form using the QuickPrep application of MOE2019 with default parameters. This atomistic model was used for generating the input files for all MD simulations.

The best dock pose of micafungin was placed into the binding pocket of the prepared monomeric 3CLprotease structure. The best pose of ivermectin was placed into the monomeric and dimeric protease structure to test which form can stabilize the inhibitor. The simulation cell and NAMD 2.14[39] input files were generated using MOE2019. The crystallographic water molecules were removed prior to solvation. Next, the protein/ligand complexes were embedded in a TIP3P water box with cubic periodic boundary conditions, keeping a distance of 10 Å between the boundaries and the protein. The net charge of the protein was neutralized with 100 mM NaCl. For energy minimization and MD simulations, the AMBER10:EHT force field was used and the electrostatic interactions were evaluated by the particle-mesh Ewald method. Each system was energy-minimized for 5000 steps using the Steepest Descent and Conjugate Gradient method. For equilibration the system was subjected to a 100-ps simulation to gradually heating the system from 10 K to 300 K. Next, a 100-ps NVT ensemble was generated at 300 K followed by an NPT ensemble for 200 ps at 300 K and 1 bar. Then, for each complex, a 100-ns production trajectory was generated for further analysis. The trajectory analysis was done using scripts shared by the CCG support group.

Identification of ligand-binding mode. The protein ligand interaction fingerprint application in MOE2019 was used to study the average binding mode of each inhibitor bound to the monomer or dimer of 6LU7. The calculation used the default parameters on the recorded MD trajectories.

Statistics and reproducibility. One-way analysis of variance (ANOVA) with Dunnett's Multiple Comparison post-hoc test was performed with 99.9% confidence intervals to compare the statistical significance and represented as the mean ± SEM. P values < 0.001 considered statistically significant. Non-linear regression (curve fit) with four variable dose vs inhibition was used to calculate the IC_{50} values. Statistical analysis was performed using GraphPad Prism (version 6.07; La Jolla, CA, USA). All the experiments were carried out minimum three times with triplicates for reproducibility and the representative of three individual experiments is presented in this report. The data generated at different time points were combined to make the final graphs. Investigators performing the assay were blinded for the drugs being tested in the assay.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

Supplementary Data 1 provides the data set for Figs. 2–5, and Supplementary Figure 2 and 3. Supplementary Data 2 and 3 provides data set for 3CLpro-OTDs docking study and Supplementary Data 4 for PIs and VNIs (S score for Table 1 and structural analysis for Fig. 6). Supplementary Data 5 provides data set for MD simulation study of 3CLPro homodimer with ivermectin, Supplementary Data 6 for 3CLPro monomer with ivermectin and Supplementary Data 7 for 3CLPro monomer with micafungin (Fig. 7). Supplementary Data 5–7 provides data set for Supplementary Fig. 3 (S score comparison from MD simulation study). Any remaining information can be obtained from the corresponding author upon reasonable request.

Abstract

Background: It appears that ivermectin can potentially act against COVID-19 infection. Today, it is an urgent need to evaluate the efficacy and safety of ivermectin. The effect of ivermectin therapy on mild to severe COVID-19 patients was investigated.

Methods: A 45-days randomized, double-blind, placebo-controlled, multicenter, phase 2 clinical trial was designed at five hospitals. A total number of 180 mild to severe hospitalized patients with confirmed PCR and chest image tests were enrolled. The radiographic findings, hospitalization and low O_2 saturation duration, and clinical outcomes such as mortality and variables of blood samples were analyzed using standard statistical analyses in SPSS (V20).

Results: Average age of the participants was 56 years (45-67) and 50% were women. The primary and secondary results showed significant changes between day zero and day five of admission (Δ 0/5) in terms of ΔALC5/0, ΔPLT5/0, ΔESR5/0, ΔCRP5/0, duration of low O_2 saturation, and duration of hospitalization (CI = 95%). Risk of mortality was also decreased significantly in the study groups.

Conclusion: Ivermectin as an adjunct reduced the rate of mortality, low O_2 duration, and duration of hospitalization in adult COVID 19 patients. The improvement of other clinical parameters showed that the ivermectin, with a wide margin of safety, had a high therapeutic effect on COVID-19.

Trial Registration: This trial was registered with the Iranian Registry of Clinical Trials website (registration ID IRCT20200408046987N1).

Introduction

The COVID-19 infection has become a pandemic since its first outbreak in Wuhan, China in 2019. This infection is caused by the novel COVID-19 and has created a difficult condition around the world. Thus, there is an important and urgent need to find proper treatments for an effective cure, decrease the virus carriage duration, and thus limit its transmission in society [1-3]. So far, different drugs such as Hydroxychloroquine (HCQ) [4,5], Azithromycin [6], and combination of them have been used against COVID-19. Several studies have demonstrated that chloroquine phosphate and chloroquine sulfate inhibit COVID-19 *in-vitro* [7-9]. In addition, Gautret et al. evaluated a combination of HCQ and azithromycin on COVID-19 infected cells *in-vitro*, and concluded that there was a considerable synergetic effect when the combination was used at doses which imitates the concentrations likely to be taken in humans [8]. Chloroquine, illustrated positive results in Chinese COVID-19 patients in clinical trials by alleviating fever, delaying disease progression, and management of COVID-19 disease (500mg twice per day for ten days) [8,10,11]. However, among the candidate treatments, only three main drugs including Remdesivir, Oseltamivir, and HCQ have been tested in large comparative studies [8,10-15]. Some of studies have shown that Lopinavir, Ritonavir, and Remdesivir have no clear influence on COVID-19 infection and they are associated with many adverse effects [13,16,17]. In addition, HCQ has demonstrated its efficacy in

reducing viral shedding durability [11], and improving patients' clinical status in observational or randomized clinical trials [12,18,19]. Ivermectin is an unexpensive FDA-approved anti-parasitic drug, known to have a wide-spectrum antiviral activity against a variety of viruses in *in-vitro* conditions. It inhibits the proliferation of COVID-19 in cell culture as well [6,20,21]. Moreover, ivermectin shows antiviral activity against some RNA viruses including Zika, dengue, yellow fever, West Nile, Hendra, Newcastle, Venezuelan equine encephalitis, chikungunya, Semliki Forest, Sindbis, Avian influenza A, Porcine Reproductive and Respiratory Syndrome, and HIV-1. Furthermore, there are some studies showing the antiviral effects of ivermectin against DNA viruses such as Equine herpes type 1, BK polyomavirus, pseudorabies, porcine circovirus 2, and bovine herpesvirus 1 [22]. Ivermectin may also act on the COVID-19 virus through three proposed mechanisms that result in reducing the load of the virus. These mechanisms includes: inhibition of nuclear import of host [23], interfering with the attachment of the spike to the human cell membrane [24,25], and inhibition of helicase activity [26]. Based on elementary data from Caly et al., Monash University in Australia, a strategy was designed including early PCR test or chest image to detect positive patients and adding ivermectin to the treatment regimen at different doses, to investigate its possible treatment efficacy on COVID-19 patient.

Materials And Methods

Study design

A randomized, double-blind, placebo-controlled, multicenter, phase 2 study was carried out to examine the effectiveness of oral ivermectin in hospitalized adults (age >18 years) with COVID-19. The trial was conducted at five hospitals (Velayat, Bu Ali, Taleghani, Razi, and Sina) in Qazvin and Khuzestan provinces of Iran. Ethical approval was in accordance with the ethical standards of the Helsinki Declaration (1964, amendment of 2008). The study protocol was approved by the medical ethics committee of Qazvin University of Medical Sciences (registration ID IR.QUMS.REC.1399.017).

Patient selection

Eligible patients with COVID-19 who met the following criteria were admitted: a) Age >18 years; b) signed the informed consent; c) clinical symptoms of suggestive of COVID-19 pneumonia: cough (with or without sputum), fever, pleuritic chest pain or dyspnea; d) mild to severe COVID-19 disease confirmed by chest computed tomography (CT) scan findings compatible with COVID-19 or positive real-time reverse transcription polymerase chain reaction (RT-PCR). Exclusion criteria included presence of severe immunosuppression (e.g., use of immune-suppressants and HIV positive), pregnant women, chronic kidney disease, malignancy, and indications that the patients were unable and/or unlikely to comprehend and/or follow the protocol. The primary endpoint of this trial was clinical recovery within 45 days of enrolment. Clinical recovery was defined as normal fever, respiratory rate, and oxygen saturation (>94) without oxygen therapy sustained for 24h. The patients would be discharged if this trend continued. During the process the criteria for discharge was changed over the course of study. Initially, patients with two successive negative nasopharyngeal samples based on PCR assay (CT value≥35) were separated.

The study sample size was estimated based on a test of equivalence[27]. Using a two-sided test level of 0.05 and a desired statistical power of 90% and under the assumption that each treatment arm would yield a 75 % success rate, the number of patients in the study was obtained equal to 163 patients. Assuming an availability rate of 35%, 30 patients were enrolled per treatment arm.

Interventions

The participants were randomly allocated to six arms including common regimen based on Iran health ministry (Hydroxychloroquine 200mg/kg twice per day), placebo plus common regime, single dose ivermectin (200mcg/Kg, 1 pill per day), three low interval doses of ivermectin (200, 200, 200 mcg/Kg , 3 pills in 1, 3 and 5 interval days), single dose ivermectin (400mcg/Kg, 2 pills per day), and three high interval doses of ivermectin (400, 200, 200 mcg/Kg, 4 pills in 1, 3 and 5 interval days).

Randomization and masking

Eligible patients were randomly allocated to either the standard, Placebo and the ivermectin arms. Randomization according to the severity of the disease was as follows: mild, moderate, and sever. The transposed block randomization sequence, including stratification, was prepared by a statistician not involved in the trial using Random Allocation Software. The patients in six treatment arms enrolment were randomized after calling the central randomization telephone number and receiving randomization information and confirmation. Each patient received the unique patient numbers that were to be used on all study medication containers, case report forms, and to identify all specimens. Pharmacia generated the randomization list and provided the list to the central randomization service.

Laboratory and radiographic tests

The patients systematically underwent an unenhanced chest low-dose computed tomography (LDCT) at reception or soon after, using a single CT machine (16 slice Model Neusof, China). All images were analyzed by expert chest radiologists and classified as compatible or not compatible with pneumonia. Images were considered as compatible with circumferential multifocal ground-glass opacities, vesicular consolidation, or crazy paving template. Novel Coronavirus RNA was recognized by real-time reverse transcription PCR [28]. Negative results for viral RNA detection were defined as a cycle threshold (CT) value≥35.

Treatment

All patients were treated according to “Iranian guideline of hospitalized COVID-19 patients’ management (version 5)”. This comprised oral hydroxychloroquine (HCQ) 200mg/kg twice per day as standard regimen and a heparin prophylaxis in combination with supplemental oxygen. Tablet of ivermectin (14 mg) and placebo were formulated in Alborz Darou pharmaceutical Co., Tehran, Iran. The Participants received drug after signing the consent letter. For all arms, radiographic findings, hospitalization time, clinical outcomes such as mortality, and clinical parameters such as account oxygen saturation testing

and blood sampling absolute lymphocyte count (ALC), C-reactive protein (CRP), white blood cells (WBC), lactate dehydrogenase (LDH), thrombocyte count (PLT), erythrocyte sedimentation rate (ESR), blood urea nitrogen (BUN), and creatinine (Cr) were examined on days zero and five. Assessment of gas exchange requires knowledge of fractional inspired oxygen tension (FiO_2); unless the patient is breathing room air. Hence, all peripheral capillary oxygen saturation was measured in breathing room air at rest.

Statistical methods

The SPSS version 20 (SPSS®, Armonk, NY, USA) software was used for statistical analyses. Shapiro-Wilk test was used to evaluate normality of numerical variables. The quantitative variables were expressed as mean ± SD (standard deviation) or Median ± IQR (Inter Quartile Range). The difference values for each quantitative variable on days zero and five (Δ 0/5) were calculated to check recovery process of patients between groups. Pair T-test / Wilcoxon signed-rank test were used on inter-group comparison. The analysis of variance (ANOVA) was used to compare the mean scores of the groups. To compare the proportions, Pearson chi-square or Fisher's exact test was used. Analyses were based on non-missing data. P-value less than 0.05 was considered statistically significant.

Results

A clinical trial was started to determine the efficient dose of ivermectin for 45 days. A total of 180 patients with mild to severe infection, with positive PCR and chest image tests, hospitalized at Qazvin and Khuzestan provinces hospitals (five hospitals) were selected. The hospitalization term was from 1st of June to 15th of July 2020 (45 days) (Fig 1). Demographics (sex, age), Obesity, Severity on CT, PCR, Respiratory Rate (RR/min), Fever **(°C)**, Systolic and Diastolic Blood pressure (Bp;mmHg), Pulmonary Rate (PR /min) and Oxygen saturation (%) of the patients are reported in Table 1. The majority of patients had favorable outcomes and Mann-Whitney U Test and χ^2 test were used to analyze and compare the variables at the day one and five of admission (Δ 0/5). As reported in Table 2, complete blood count (CBC) evaluation of the patients among the standard and placebo and ivermectin treated (arms 3 to 6) showed that ivermectin had a good effect on blood biomarkers and improved other clinical parameters such as ALC, CRP, PLT , ESR , LDH, BUN, and Cr.

Patient care:

The majority of patients had desired consequence and were discharged from the hospitals. The results of preclinical consequences in Table 3 indicate a reduction in mortality rate in patients receiving ivermectin treatment to 0, 10, 0 and 3.3% for arms 1- 4 respectively, compared to the standard and placebo plus standard arms which was 16.7% and 20% respectively. Moreover, the decrease in hospitalization and low O_2 saturating terms was significant in ivermectin treated 1-4 arms compared to the two untreated controls (P=0.006 and P=0.025 respectively). The lowest mortality rate (0%), hospitalization duration (5days), and duration of low O_2 saturatin (2days) was observed arm 3 with single dose of 400mcg/kg

ivermectin. Table 4 lists the risk of mortality for comparison between ivermectin treated and untreated groups with CI: 95%. The estimation confirmed 15% reduction of the mortality with risk ratio of 0.18.

Discussion

Totally, 180 patients infected by COVID-19 virus were allocated to six arms and received single or interval doses of ivermectin. The positive effect of ivermectin therapy in patients receiving this drug was a reduction in mortality rate compared to the standard (16.7%) and placebo (20%) arms. The improvement of clinical manifestations of the patients was observed in all ivermectin groups in comparison with standard and placebo arms. From the beginning of the outbreak, various antiviral drugs such as Acyclovir, Ganciclovir, Oseltamivir and ribavirin have been tested. Unfortunately however, these drugs have not been effective in curing or alleviating the symptoms of COVID-19 [29]. Studies have shown that among the FDA-approved antiviral drugs, like ribavirin, Penciclovir, Nitazoxanide, Nafamostat and Remdesivir, the last two drugs are highly effective against novel coronavirus infection *in-vitro*[30]. Recently, ivermectin, another FDA-approved drug, was reported by Caly et al. to inhibit the *in-vitro* replication of novel Coronavirus. The results of this study showed that a single treatment of ivermectin was able to induce a 5000-folds reduction in the viral RNA 48hrs in cell culture[6]. As illustrated in Figure 2, the main *in vitro* proposed mechanism of activity of ivermectin hinders the viral load through inhibition of the interaction of importin α and β_1 proteins. Recently, a clinical trial reported lower mortality rates in hospitalized patients with COVID-19 who received ivermectin therapy [31]. Our clinical trial was designed with features such as double-blind, placebo-controlled, multicenter, open-label, phase 2/3, and randomized controlled trial. It is suggested by previous studies that the initial disease intensity assessment cannot rely only on clinical examination[11]. In this clinical trial, single and multiple oral doses (200mcg/Kg and 400 mcg/Kg) of ivermectin were added to the standard regimen of patients (treatment protocols of Iranian health ministry for COVID-19). At the time of writing the manuscript, the HCQ is stopped by world health organization (WHO) from all trials. As illustrated in Tables 2 and 3, the cure effect of ivermectin in different doses was confirmed by both laboratory and preclinical parameters. The results of ivermectin treated subgroups with the standard and placebo groups showed a difference between each subgroup and s,p groups. The combined effects of different-doses of ivermectin on patients' medication regimens shortened the duration hospitalization and low O_2 saturation. Promotion of other clinical parameters such as ALC, CRP, PLT, ESR, LDH, BUN and Cr showed that the ivermectin with a wide margin of safety had a higher therapeutic index and efficacy against COVID-19. One of the limitations of ivermectin in clinical utility is its potential to cause toxicity. Studies have shown that this defect can be eliminated by changing the formulation and pharmacokinetic properties. Therefore, a systematic design based on concentration of ivermectin is essential [32]. Schmith et al. showed in a study based on the pharmacokinetic simulations that ivermectin may have limited therapeutic utility on control COVID- 19. The reason is that the concentration of inhibitor required to act on the COVID-19 virus is much higher than the maximum plasma concentration by managing the approved dose [20,33]. Based on this limitation, they proposed ivermectin inhalation therapy; however, didn’t consider the host immune

response in human. In addition, Caly et al. did not clarify if lower doses were effective or not. However, the antiviral properties of ivermectin have been demonstrated by targeting critical cellular process of the mammalian cell. Therefore, in line with our study, it is speculated that ivermectin administration, even at low doses, can reduce the loading of the virus in the early stages [34]. In addition to above explanations, sustainability of ivermectin in different tissues of animals and humans has been reported by various studies [35-37]. As mentioned in the introduction, it seems that the mechanisms of antiviral activity of ivermectin against various viruses is mediated via targeting importin α/β-mediated nuclear transport of HIV-1 integrase and NS5 polymerase; NS3 helicase; nuclear import of UL42; and nuclear localization signal-mediated nuclear import of Cap [38-41]. Although, at the time of the writing of this paper the HCQ was eliminated from the clinical care protocols of our clinical centers, we did the dose finding of ivermectin based on the standard care (HCQ) of Iranian ministry protocols at start. Based on findings, combined designs of ivermectin with other antiviral drugs appeared to have desirable results. In an unpublished study, the combination of ivermectin with HCQ was investigated [42]. As to the safety of using the high doses of ivermectin through this study, the flow-ups showed that there were no side effects such as nausea or skin rash during the trial. In a three arms phase 3 clinical trial, ivermectin was administered in two doses of 200 and 400 mcg/kg in patients with dengue fever. The main purpose of this trial was to evaluate safety of ivermectin in children and adult patients and the results showed that one daily dose of ivermectin treatment for three days was safe [43]. There have been several reports about drug treatments that have significantly affected viral load in COVID-19 patients. The novel coronavirus has several evolutionary phases, so that in the first clinical phase, including lower respiratory tract infection (LRTI) and upper respiratory tract infection (URTI) symptoms are associated with a high viral load and the incidence of early lung lesions on LDCT [44,45]. Here the focus of this study was to emphasize on the proper dose of ivermectin (single dose of 400mcg/Kg) that may reduce the viral load and affect both LRTI and URTI symptoms. However, for more efficacy of drug especially on URTI symptoms further studies are needed to experiment different combinations of immunological triggering agents such as corticosteroids on the mild to severe patients. Moreover, because of the direct impact of ivermectin on virus and as mentioned above and its sustainability in different organs specially the pulmonary tissue, further researched should be implemented to investigate the possible prophylactic effect of this drug against the first entrance of virus or after observation LRTI symptoms. Moreover, as listed in Tables 3 and 4, the lowest mortality rate was observed in arms 1-4 in comparison with 16.7% and 20% rates in the standard and placebo plus standard arms respectively. The risk base estimation with CI: 95% in Table 4 confirm 15% reduction of mortality or about 5.5 folds increase of the mortality rate in control groups. These results are in line with Rajter et al. [31] who reported a 40% drop in mortality of critical COVID-19 patients after oral administration of ivermectin at least in one dose (200mcg/Kg).

Limitations

The sample size was not large and the study was limited to the selected hospitals. Studies in areas with a maximum prevalence of COVID 19 and on patients with more diverse conditions such as body mass index over 40, different underlying diseases, or younger patients are needed. Without these limitations, a

stronger trial study could be carried out. Ongoing studies with larger sample sizes, using strategies to enhance the antiviral potency of ivermectin and its combination with other antivirals or higher-dose regimens, and focus on severe COVID-19 cases are recommended.

Declarations

Acknowledgements

The supports of deputy of research and technology of Qazvin University of Medical Sciences and Qazvin Science and Technology Park are appreciated. We thank Cellular and Molecular Research Center and Infection Prevention Center of Qazvin University of Medical Sciences and all the clinical, technical, and paramedical staff of the wards and laboratories for their support and cooperative attitudes.

Abstract

Coronavirus disease-2019 (COVID-19) pandemic continues to threaten patients, societies, and economic and healthcare systems around the world. Like many other diseases, the host immune system determines the progress of COVID-19 and fatality. Modulation of inflammatory response and cytokine production using immunonutrition is a novel concept that has been applied to other diseases as well. Zinc, one of the anti-inflammatory and antioxidant micronutrient found in food with well-established role in immunity, is currently being used in some clinical trials against COVID-19. This review integrates the contemporary studies of role of zinc in antiviral immunity along with discussing its potential role against COVID-19, and ongoing COVID-19 clinical trials using zinc.

Keywords COVID-19 · Clinical trials · Immunity · Zinc

Introduction

As the whole world is grappling with coronavirus disease-2019 (COVID-19) pandemic caused by the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), there is a frantic race for finding treatment regimens based on current knowledge until effective vaccine and ad hoc drugs are developed. Indeed, therapeutic approaches against COVID-19, mostly centered on the management of its immunopathology and/or tailored to directly control viral replication, are for now based on off-label prescription. Several human trials are currently in progress to assess the therapeutic indexes of drugs already approved for other diseases (i.e., drug repurposing), and in combination with dietary supplements like vitamin C, vitamin D, vitamin B_{12}, probiotics, and zinc (Zn). Zn is a common theme in both prophylactic and curative COVID-19 clinical studies using nutritional supplements.

Zn, the second most abundant trace metal in the human body after iron, is essential for multiple cellular functions including maintenance of immune health. Notably, "Zn proteome" is estimated to encompass around 3000 proteins [1] including ~ 750 Zn finger transcription factors, a number of which are deeply implicated in homeostasis and inflammation. Ever since Zn deficiency was demonstrated as a human disease more than 56 years ago, it has been implicated in immune dysfunction, growth retardation, hypogonadism, and cognitive impairment [2, 3]. Importantly, Zn also plays a critical role in antiviral immunity [4, 5]. Readers are referred to specialized reviews on essential role of Zn in human health (including Zn homeostasis and transporters) and other non-viral/viral diseases [5–16].

With so many clinical trials going on against the COVID-19 pandemic, there is scientific curiosity about the nature and basis of these trials [17]. In this review, we will discuss the basis of clinical trials using adjunct Zn therapy for COVID-19 through the prism of its indispensable role in antiviral immunity along with briefly discussing immunopathology of COVID-19.

COVID-19 Immunopathology

As already shown for SARS and Middle East respiratory syndrome (MERS), the host immune response plays a central role also in the pathology associated to SARS-CoV-2 infection, as the fatalities occurring among COVID-19 patients are often preceded by the so-called cytokine storm, a massive systemic release of proinflammatory cytokines such as interleukin (IL)-1b, IL-6, and tumor necrosis factor-α (TNF-α). These events ultimately contribute to acute respiratory distress syndrome (ARDS) and lead to vascular hyperpermeability, diffuse coagulopathy, multi-organ failure, and eventually death [18, 19]. These cytokines are mainly secreted by innate immune cells such as monocytes, macrophages, and dendritic cells (DC), which are supposed to act mainly in the early phases of infections. However, cytokine storm occurs at late stages of SARS-CoV-2 infection, when the adaptive, instead of the innate immune response, is known to become prominent.

A series of timely coordinated actions are required for an effective immune response against viral infections, and the agenda in which these actions move may be outlined by opposing early/innate versus late/adaptive immune response waves. Firstly, innate immune and infected tissue cells initiate primitive and unspecific reactions in an attempt to restrain viral replication by producing type-I interferons (IFN), IFN-α and IFN-β, and to attract blood cells to the site of infection by producing chemokine and TNF-α, which activates endothelial cells enhancing vascular adhesion and diapedesis of leukocytes, and by secreting other proinflammatory cytokines to activate leukocytes. It is peculiar that, while SARS-CoV-2 replication in permissive cells may be effectively inhibited by exogenously added type-I IFN, endogenous production of IFN-α and IFN-β upon infection is inhibited by proteins encoded by SARS-CoV-related viruses, whereas chemokines and inflammatory cytokines are highly produced contributing to an unbalanced response [20, 21].

During this first phase of the immune response, DC migrate to lymph nodes and initiate a complex and slower intercellular cascade, ultimately culminating in the expansion and maturation of adaptive, virus-specific T and B lymphocytes. Seroconversion—i.e., the appearance in the blood of antibodies against immunogenic viral proteins—and probably the clonal expansion of virus-specific T cells, occurs in most COVID-19 patients 10 days after symptom onset [22] and severe disease and cytokine storm are associated in time and magnitude with the immunoglobulin response in SARS-CoV-1 [23] and SARS-CoV-2 infection [24, 25].

Strikingly, a similar cytokine storm is also the most notable side effect of chimeric antigen receptor T (CAR-T) cell therapy, and its severity is forecasted by the extent of tumor burden [26], leading to the hypothesis that a high antigen (i.e., viral) load at the time of the (late) adaptive immune cell activity against SARS-CoV-2, when antibodies and virus-specific T cells arise, may favor a massive second wave of cytokine release by innate cells in a positive feedback loop. Much effort is now trying to decipher, in the immunotherapy setting, the exact mechanisms pushing this positive feedback from adaptive to innate cells, which may deserve our attention to anticipate plausible pathways to interfere with COVID-19 immunopathology. One line of evidence points to cytokines produced by T cells upon antigenic stimulation, namely to TNF-α [27] and granulocyte-macrophage colony-stimulating factor (GM-CSF) [28], as triggers of the secondary systemic toxic cytokine release by innate cells. Importantly, these two cytokines are unnecessary (both) or detrimental (GM-CSF) for on-target effects of CAR-T cells [28], which suggests that they may be dispensable also for the antiviral response to SARS-CoV-2.

There is a clear sex- and age-dependent bias in COVID-19-related mortality. Better outcomes in women, for instance, may be the result of a more pronounced IFN-α production by plasmacytoid DC [29] during initial phases of infection. The more effective viral containment operated by such a response could be assumed to lower the antigen load at the onset of the adaptive wave and prevent the cytokine storm. In studies from patients during the 2003 SARS-CoV-1 outbreak, treatment with synthetic type-I IFN in conjunction with steroids has proven useful to ameliorate pneumonia course [30], and early, in contrast to delayed, type-I IFN treatment rescued mice from death after SARS-CoV-1 infection [31]. On the other hand, aging of the immune system, which is associated to chronic low-level activation of innate cells, also entails a delayed and inflated response upon pathogen encountering [32]. Lastly, with age, adaptive cells become slow in mounting antigen-specific responses to novel pathogens secondary to the loss of the naive B and T cell repertoire due to thymic involution [33].

Immunological Functions of Zn

Data gleaned from seminal animal model studies have added considerable knowledge about the principal roles of Zn in the immune system. Zn is an essential micronutrient, which plays an important role in the physiology of the immune system by acting as signaling molecule. Zn not only acts as an anti-inflammatory agent but also functions as an antioxidant stabilizing membrane [34]. Zn deficiency impinges on survival of immune cells and adversely affects important functions such as phagocytosis, target cell killing, and cytokine production (Fig. 1). It is clearly evident from studies on preclinical models that Zn deficiency plays a role in thymus and lymphoid tissue atrophy [35] and declines in the mechanisms of activation of both helper T cell [36] and cytotoxic $CD8^+$ T cell responses [37]. Specifically, Zn deficiency leads to compromised immune system, as evidenced by degeneration of thymus,

FOI 26-3132 - Document 5

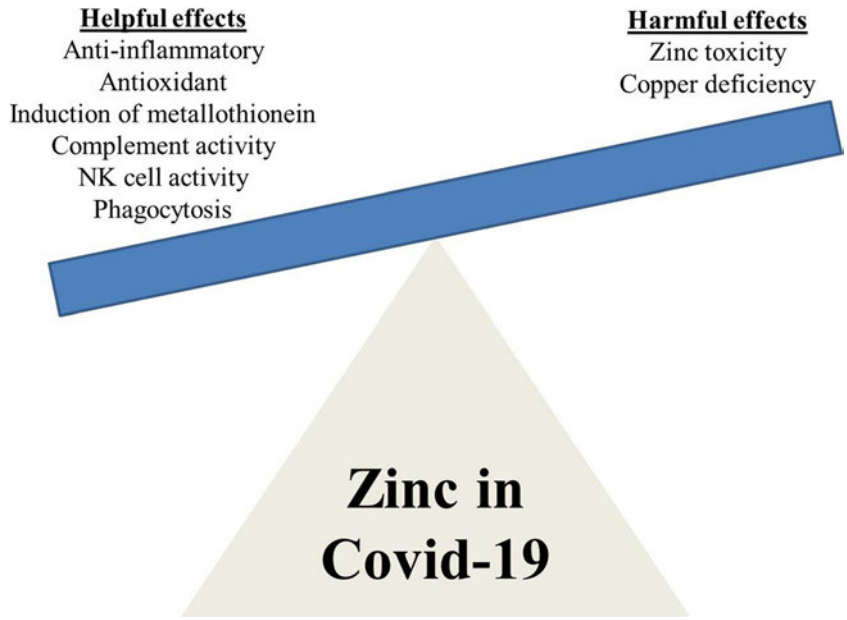

Fig. 1 Balance between helpful and harmful effects of zinc for COVID-19

lymphopenia, and defective lymphocyte responses [3, 5, 34]. Zn deficiency causes immunodeficiency with severe lymphopenia that is characterized in part by a considerable decrease in developing B cell compartments in the bone marrow [3, 38]. Moreover, Zn potentiates IFN-α effect by an order of magnitude [39] which can be used to counteract IFN antagonism by SARS-CoV-2 proteins.

A marked neutrophilia is observed in severe COVID-19 patients [40]. Zn gluconate supplementation is able to reduce airway neutrophil infiltration and TNF-α release by inhibiting NF-kB-dependent transcription of inflammatory genes [41]. The Zn finger CCHC-type containing 3 (ZCCHC3) potentiates TLR3 signaling induced by double-strand RNA [42], which is produced during intracellular replication of coronaviruses.

In vitro, Zn deficiency induced enhanced IL-6 and IL-1β production, as well as higher expression of intercellular adhesion molecule 1 (ICAM-1), important for leukocytes' extravasation, of CD86, a co-stimulatory molecule involved in T cell activation, and of HLA-DR, a MHC-II molecule, in cultured human monocytic cells [43]. Moreover, aged mice have lower plasma Zn concentration, and this was associated to higher IL-6 and ICAM-1 gene expression in splenocytes [43]. Thus, Zn supplementation may be instrumental to reduce inflammatory cytokines, particularly IL-6 and IL-1β, and at the same time to enhance the protective, though inhibited, type-I IFN response in SARS-CoV-2 infection. Zn deficiency indicates towards the decreased interferon-γ (IFN-γ) production, a major component of Th1 cytokine panel [44]. Since Th1 and Th2 responses are mutually inhibited by the effect of their respective signature cytokines IFN-γ and IL-4, such imbalance between Th1 and Th2 might lead to dysfunctions in cell-mediated immune response [34].

There can be a whole lot of factors for the development of Zn deficiency, whether geographic, socioeconomic, nutritional, or as a result of disease pathologies such as chronic viral infections. Notably, during infection, Zn levels decrease significantly and a person's requirement for Zn may increase with the severity of the infection. Aged individuals, infants, and chronic alcoholics are particularly more susceptible to Zn deficiency, increasing their chances of acquiring life-threatening viral infections [45–48]. As Zn is indispensable for a strong immune response, Zn deficiency (persistent hypozincemia [serum Zn < 70 μg/dL]) can considerably dampen innate as well as adaptive antiviral immunity [4, 5].

The Role of Zn in Antiviral Immunity

There is very scant information available on the role and effect of Zn in SARS and coronavirus disease, even though literature is rapidly increasing [17, 49]. Much of the current knowledge about the use of Zn as an antiviral therapy and immunomodulatory agent has originated from studies done with other viral diseases (Readers are referred to these specialized articles for role of Zn in viral diseases [4, 5]). Zn is an essential constituent of thymulin hormone, which is involved in maturation and differentiation of T cells in thymus gland. Zn not only plays an important role in IL-2 and IFN-γ production but also stimulates macrophages to produce IL-12. IL-12 activates the natural killer cells and T cytotoxic cells. Both IFN-γ and IL-12 play a crucial role in destruction of various pathogens. Among anti-inflammatory cytokines, only IL-10 production is affected by Zn deficiency, whose enhanced levels adversely affect the functioning of macrophages and Th1 response [50].

FOI 26-3132 - Document 5

The rationale behind the use of Zn in COVID-19 studies aroused from the observation that Zn ions and Zn ionophores, such as pyrithione (PT), have previously been described as potent inhibitors of various RNA viruses [51]. Also, targeting of RNA-dependent RNA polymerase (RdRps) of RNA viruses like SARS-CoV-2 is more suitable for antiviral drug development as RdRp activity is strictly virus-specific and may be blocked without severely affecting key cellular functions. The basis of Zn therapy in coronavirus infection is shown in Fig. 2. It is known previously that Zn ions are involved in many different cellular processes, proper folding, and activity of various cellular enzymes and transcription factors. On the other hand, Zn^{2+} is probably an important cofactor for numerous viral proteins as well. Zn^{2+} can serve as intracellular second messenger and may trigger apoptosis or a decrease in protein synthesis at elevated concentrations [52–54]. Metallothioneins, a family of metal-binding proteins, regulate homeostasis of Zn and copper, alleviate heavy metal poisoning, and lessen the superoxide stress. Various evidence indicates that metallothionein expression is increased in response to bacterial and viral infections, and it is anticipated that upregulated biosynthesis of human metallothionein might play a significant role in nutritional immunity at the time of active infection [55].

In cell culture studies, inhibition of the replication of various RNA viruses was reported using high Zn^{2+} concentrations and addition of compounds that stimulate cellular import of Zn^{2+}, such as hinokitiol, pyrrolidine dithiocarbamate, and PT as mentioned above (reviewed in) [5]. Around 10 years ago, an in vitro study demonstrated that the Zn ionophore PT in combination with Zn^{2+} is a potent inhibitor of the replication of SARS-CoV-1 [51]. In addition, authors also studied the effect of Zn ions on the RdRp of SARS-CoV-1 and demonstrated that Zn^{2+} directly inhibited the in vitro activity of RdRp (Fig. 2). More specifically, Zn^{2+} was found to block the SARS-CoV-1 RdRp elongation step along with reduced template binding. Further strengthening their claim, authors also showed that the Zn^{2+}-mediated RdRp inhibition of SARS-CoV-1 could be reversed through the addition of a Zn^{2+} chelator [51].

Recently, Finzi (2020) has reported that treatment of four COVID-19 cases with high dose of zinc salts initiated the reduction of disease symptoms within 24 h after initiation of high dose zinc salt lozenges [56]. As adjuvant therapy, Zn (in appropriate dose) may provide protection through decreasing lung inflammation, enhancing mucociliary clearance, inhibiting the ventilator-induced lung injury, and immunomodulation in COVID-19 patients [49].

COVID-19: Interventional Clinical Trials of Drugs/Nutritional Supplements with Zn

As of 4 August 2020, 22 studies were found after searching for Zn and COVID-19 at the clinical trial website https://clinicaltrials.gov/ct2/home. However, upon narrowing down the search criteria, 19 studies were clinical trials and the remaining 3 were observational studies (NCT04326725, NCT04407572, NCT04412746). Furthermore, among the remaining 19 studies, one study (NCT04371952 entitled DYNAMIC Study [DoxycYcliNe AMbulatoIre COVID-19]) was based on the fact that doxycycline, a tetracycline antibiotic, is known to chelate Zn from matrix metalloproteinases, which may help in part to inhibit COVID-19 infection by limiting its ability to replicate in the

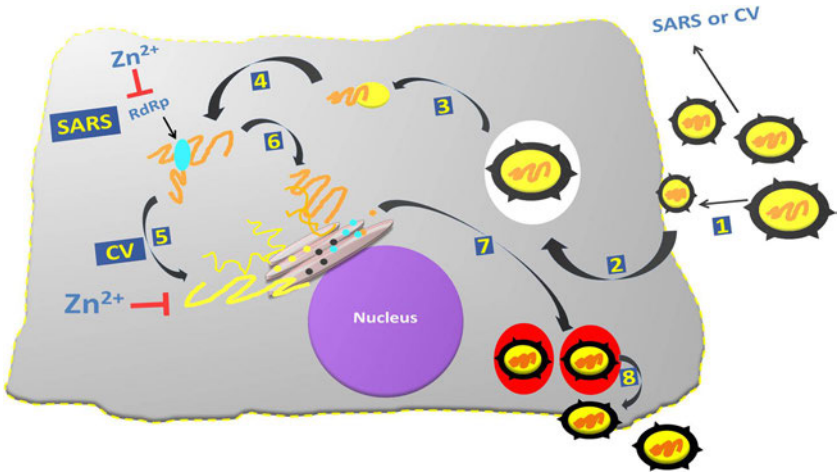

Fig. 2 Schematic representation of different stages of SARS-CoV-1 and coronavirus replication cycle. Viral attachment (1), entry (2), uncoating (3), transcription (4), viral protein translation (5), replication (6), assembly and maturation (7), and finally viral release (8). Data from in vitro studies has demonstrated two mechanisms by which zinc interferes with these viruses' replication cycle steps that include viral genome transcription for SARS-Cov-1 (5), and viral protein translation and polypeptide processing for CV (6). However, to date, no studies have shown zinc-mediated inhibition of SARS-CoV-1 or CV entry, receptor binding, uncoating, assembly, and/or viral particle release. CV, coronavirus; RdRp, RNA-dependent RNA polymerase; SARS, severe acute respiratory syndrome coronavirus; Zn, zinc

host. There is no intervention of Zn supplementation to the patient, so this study was ruled out for present review. Three more studies (NCT04485130, NCT04491994, NCT04485169) also did not use zinc in the experimental arm, so similarly left out from the present article.

Among the remaining 15 studies (Table 1), 4 studies are exclusively using different combinations of dietary supplement including Zn as an intervention against COVID-19 (NCT04351490, NCT04342728, NCT04323228, NCT04468139 at serial nos. 1, 2, 3, and 4 of Table 1, respectively). None of the four studies is completed yet at the time of writing this review. The NCT04351490 trial is using combination of vitamin D_3 with Zn gluconate with the rationale that these two micronutrients are able to modulate the immune response by reducing the inflammatory storm. Vitamin D, a steroid hormone synthesized from cholesterol, has recently been reported to have anti-fibrotic, anti-inflammatory, and immunomodulatory properties on the basis of various studies done with hepatitis C virus infection. Vitamin D impedes T cell proliferation, expression of IFN-γ, expression of IL-2, and CD8 T lymphocyte–mediated cytotoxicity [57].

The NCT04342728 trial is primarily studying whether ascorbic acid and Zn gluconate either alone or in combination can decrease the duration of symptoms in newly diagnosed COVID-19 patients. Ascorbic acid, also known as vitamin C which has potent antioxidant properties, has a very long history (>45 years) in combating or relieving the symptoms of rhinoviruses or common cold [58], and having immune booster properties [59]. Interestingly, various in vitro animal and clinical trials have shown that vitamin C may affect susceptibility to lower respiratory tract infections during the 2003 SARS epidemic [59]. Taking a holistic approach, clinical trial NCT04323228 is using an anti-inflammatory and antioxidant oral nutrition supplement against COVID-19 with rationale that n-3 fatty acids, vitamin A, vitamin C, vitamin E, selenium, and Zn in extraordinary doses may modulate the immune system response and improve the cytokine storm–associated COVID-19 (Readers are referred to specialized articles on antioxidant and/or antiviral properties of various nutrients [4]).

Four clinical studies (NCT04377646, NCT04335084, NCT04384458, NCT04446104 at serial nos. 5, 6, 7, and 8 in Table 1, respectively) are preventive studies, which are studying whether hydroxychloroquine and/or vitamin supplements in combination with Zn are effective as a prophylaxis for asymptomatic healthcare workers/general public. Hydroxychloroquine, derivative of chloroquine having anti-inflammatory, immunosuppressive, and anti-autophagy activities, is an anti-malarial drug and anti-rheumatologic agent. Besides, both hydroxychloroquine and chloroquine constrain pH-dependent steps of SARS-CoV-2 replication by increasing pH in intracellular vesicles [60]. Due to these properties, hydroxychloroquine with Zn and/or azithromycin has been touted as the medicine and as a prophylactic drug for COVID-19 [61–63]. More importantly, chloroquine and hydroxychloroquine work as Zn ionophore, thereby increasing the intracellular Zn concentration [64]. This increase of intracellular Zn concentration will in turn may help in the inhibition of RdRp of SARS-CoV-2 (reviewed in) [51, 61].

The rest of 5 clinical trials (serial nos. 10–15 of Table 1) are aimed at finding better treatment option for COVID-19 by using various combinations of antiviral drugs/dietary supplements with Zn. The results of these studies are still awaited. The common denominator among the above mentioned trials is the use of Zn by virtue of its antioxidant, anti-inflammatory, and antiviral properties [4, 5]. Based on its antioxidant properties, Zn can protect against age-associated macular degeneration, induced by oxidative stress [65]. In general, these properties are the therapeutic basis of the indication of Zn for the treatment of wounds, burns, and acne vulgaris. In addition, Zn is very effective in controlling toxic levels of non-ceruloplasmin copper in Wilson's disease and other copper-related diseases [7]. Acting synergistically, various antioxidants and anti-inflammatory nutrients/drugs combined with antiviral drugs may be beneficial at least in alleviating the COVID-19 symptoms or halting the progression to more severe form of COVID-19. For a clear picture, results of these randomized control trials will be eagerly awaited.

Word of Caution: Zn Toxicity

The recommended dietary allowance (RDA) for Zn is 11 mg/day for men and 8 mg/day for women [66]. Zn absorption is influenced by some foods; e.g., animal proteins result in greater Zn absorption, while phytates reduce its absorption (reviewed in [67]). Zn elimination half-life is in the range of 0.9–1.2 h.

Zn deficiency is far more widespread in population than Zn toxicity (Zn toxicity is very sporadic and occurs very rarely). In comparison to several other metal ions with similar chemical properties, Zn is relatively harmless. Having said that, caution should be practiced against indiscriminate self-medication and chronic use of Zn supplements without proper medical prescription/monitoring as Zn toxicity has also been reported in the literature [68–70]. Acute Zn intoxication is a rare event though exposure to high doses leads to toxic effects. However, it is well established that copper deficiency is associated with taking up large doses of supplemental Zn over extended periods of time [71–73]. In addition, chronic use of Zn as supplements [68] or as a medication [74] can block intestinal absorption of copper [75]. The finely tuned and synchronized systemic homeostasis and efficient regulatory mechanisms keep a check on the cytotoxic doses of exogenous Zn. It is the endogenous Zn that plays a pivotal role in

Table 1 Interventional clinical trials with zinc ± other drugs/dietary supplements for COVID-19

S. no.	Clinical trial study title	ClinicalTrial.Org identifier	Intervention (drug/s)	Zinc dose and duration	Types of intervention/allocation	No. of subjects/age/sex
Clinical trials using zinc with dietary supplements						
1	Impact of zinc and vitamin D_3 supplementation on the survival of aged patients infected with COVID-19	NCT04351490	• Dietary supplement: zinc gluconate • Dietary supplement: 25-OH cholecalciferol	Zinc gluconate 15 mg × 2 per day during 2 months	Treatment/randomized-open label	3140/60 years and older/all sex
2	Coronavirus 2019 (COVID-19)—using ascorbic acid and zinc supplementation	NCT04342728	• Dietary supplement: ascorbic acid • Dietary supplement: zinc gluconate • Dietary supplement: ascorbic acid and zinc gluconate • Other: standard of care	Zinc gluconate 50 mg ± ascorbic acid to be taken daily at bedtime for 10 days	Supportive care/randomized-open label	520/18 years and older/all sex
3	Anti-inflammatory/antioxidant oral nutrition supplementation in COVID-19	NCT04323228	• Dietary supplement: oral nutrition supplement (ONS) enriched in eicosapentaenoic acid, gammalinolenic acid, antioxidants including zinc • Dietary supplement: isocaloric/isonitrogenous ONS	ONS containing 5.7 mg zinc for 14 days	Supportive care/randomized-double masking (participant, care provider)	30/18 years to 65/all sex
4	The study of quadruple therapy zinc, quercetin, bromelain and vitamin C on the clinical outcomes of patients infected with COVID-19	NCT04468139	Drug: quercetin Dietary supplement: bromelain Drug: zinc Drug: vitamin C	Zinc 50 mg orally daily dose	Treatment/single group assignment/masking: none (open label)	60/18 years and older (adult, older adult)/all sex
Preventive clinical trials using zinc with hydroxychloroquine						
5	A study of hydroxychloroquine and zinc in the prevention of COVID-19 infection in military healthcare workers	NCT04377646	• Drug: hydroxychloroquine • Drug: hydroxychloroquine (placebo) • Drug: zinc • Drug: zinc (placebo)	Hydroxychloroquine ± zinc (15 mg) at daily dose up to 2 months	Prevention/randomized/double blind randomized clinical trial with 3 arms-triple masking (participant, care provider, investigator)—random blind allocation	660/18 years to 65 years/all sex
6	A study of hydroxychloroquine, vitamin C, vitamin D, and zinc for the prevention of COVID-19 infection	NCT04335084	• Drug: hydroxychloroquine • Dietary supplement: vitamin C • Dietary supplement: vitamin D • Dietary supplement: zinc	No information available on zinc dose	Prevention/randomized-double masking (participant, investigator)	600/18 years and older/all sex
7	COVID-19 prophylaxis with hydroxychloroquine associated with zinc for high-risk healthcare workers	NCT04384458	• Drug: hydroxychloroquine • Drug: zinc sulfate	Hydroxychloroquine with zinc sulfate (66 mg) daily for 50 days	Prevention/randomized-open label	400/18 years to 70 years/all sex
8	A preventive treatment for migrant workers at high-risk of Covid-19	NCT04446104	• Drug: hydroxychloroquine sulfate • Drug: ivermectin 3 mg tab • Drug: zinc • Drug: povidone-iodine • Dietary supplement: vitamin C	Zinc tablet 80 mg/vitamin C 500 mg daily for 42 days	Prevention/randomized intervention/parallel assignment/open label	5000/21 years to 60 years/all sex
9		NCT04447534	• Drug: chloroquine		Treatment/randomized	

Table 1 (continued)

S. no.	Clinical trial study title	ClinicalTrial.Org identifier	Intervention (drug/s)	Zinc dose and duration	Types of intervention/allocation	No. of subjects/age/ sex
	Zinc with chloroquine/-hydroxychloroquine in treatment of COVID-19		• Drug: zinc	No information available on zinc dose	•Intervention model: parallel assignment •Masking: double (participant, care provider)	200/18 years and older/all sex
Treatment clinical trials using zinc with antiviral drugs/dietary supplements						
10	Hydroxychloroquine and zinc with either azithromycin or doxycycline for treatment of COVID-19 in outpatient setting	NCT04370782	• Drug: hydroxychloroquine • Drug: azithromycin • Drug: zinc sulfate • Drug: doxycycline	Zinc sulfate 220 mg once daily for 5 days	Treatment/randomized-open label	750/30 years and older/all sex
11	A study of quintuple therapy to treat COVID-19 infection	NCT04334512	• Drug: hydroxychloroquine • Drug: azithromycin • Dietary supplement: vitamin C • Dietary supplement: vitamin D • Dietary supplement: zinc	No information available on zinc dose	Treatment/randomized-double masking (participant, investigator)	600/18 years and older/all sex
12	International ALLIANCE study of therapies to prevent progression of COVID-19	NCT04395768	• Dietary supplement: vitamin C • Drug: hydroxychloroquine • Drug: azithromycin • Dietary supplement: zinc citrate • Dietary supplement: vitamin D_3 • Dietary supplement: vitamin B_{12}	Zinc citrate (30 mg) daily	Treatment/randomized-double masking (investigator, outcomes assessor)	200/18 years and older
13	New antiviral drugs for treatment of COVID-19	NCT04392427	• Drug: treatment group: will receive a combination of nitazoxanide, ribavirin, ivermectin, and zinc	No information available on zinc dose	Treatment/randomized-single masking (outcomes assessor)	100/12 years and older/all sex
14	Efficacy of subcutaneous ivermectin with or without zinc and *Nigella sativa* in COVID-19 patients	NCT04472585	• Drug: *Nigella sativa*/black cumin • Drug: ivermectin injectable solution • Other: placebo • Drug: zinc	Zinc sulfate 20 mg 3 times a day	Treatment/randomized, controlled, multi-armed, open-label, interventional study Masking: quadruple (participant, care provider, investigator, outcomes assessor)	40/18 years and older/all sex
15	Trial of combination therapy to treat COVID-19 infection	NCT04482686	• Drug: ivermectin • Drug: doxycycline Hcl • Dietary supplement: zinc • Dietary supplement: vitamin D_3 • Dietary supplement: vitamin C	No information available on zinc dose	Treatment/randomized intervention model/parallel assignment/masking: triple (participant, care provider, investigator)	300/18 years to 75 years/all sex

HCQ, hydroxychloroquine; *ONS*, oral nutrition supplement

Zn-induced cytotoxic events in single cells. Brain, in particular, is very sensitive to Zn toxicity.

Zinc as a Two-Edged Sword

Using Zn as a supplement or treatment adjuvant is a two-edged sword. Large doses of Zn (300 mg/day) over 6 weeks can affect the immune response, impairing lymphocyte, and neutrophil function [76]. On this basis, a concern had arisen that long-term Zn treatment can cause suppression of the immune system. On the similar lines, using excess Zn supplementation as an antiviral therapy can also do harm to the immune system. Maywald et al. have shown in an in vitro study that excess Zn supplementation can in fact reduce the expression of IFN-γ (a key cytokine for T-helper-1 immune reactions) by reducing interferon regulatory factor 1 expression in regulatory T cells [77]. However, it has been shown for elderly persons that zinc supplementation increased interferon-alpha (IFN-α) production by leukocytes in vitro as compared to younger subjects [78]. This observation necessitates the need to continuously monitor the levels of Zn to obtain maximum therapeutic efficacy. Cellular Zn intake can be improved by ionophores including chloroquine and some of its derivatives such as hydroxychloroquine [64]. Alternatively, natural ionophores of potential use with a good tolerability profile are quercetin and epigallocatechin gallate [79].

Summary and Future Directions

With no slowing down of COVID-19 pandemic as indicated by 18 million confirmed cases including 0.69 million deaths worldwide as of August 4, 2020 (https://covid19.who.int/), researchers are seeking ways in which to potentially protect people from the SARS-CoV-2 or to alleviate its effects once caught. One such means is Zn therapy in addition to other antiviral drugs. Zn is well tolerated and it is best known for its antioxidant, anti-inflammatory, immunomodulatory, and antiviral activities, the latter possibly mediated by its ability to inhibit RNA virus RdRp [51], thus protecting the body's cells and tissues from viral infection, oxidative damage, and dysfunction. Based on the current knowledge of beneficial and harmful effects of Zn (Fig. 1), it can be safely concluded that risk to reward ratio is in favor of Zn supplementation in COVID-19. However, the clinical and preclinical data on this aspect is very scanty now and results of current clinical trials employing Zn in COVID-19 can somehow shed more light on the efficacy of Zn against viral infections in vivo. The investigators of the different studies hope to complete the trials in the near future.

Basic and experimental research is still at infancy stage with regard to antiviral mechanisms, clinical benefits, and optimal dose of Zn supplementation as a therapeutic treatment as well as a preventative measure for viral infections including SARS-CoV-2. Generous funding is the need of hour to rigorously pursue this aspect of basic research and provide conclusive evidence to the clinical trials and assumptions based on current knowledge. Although the findings of these trials will be too late for the many thousands of people currently infected with COVID-19, these studies will offer valued data as to the potential alleviation of symptoms by adjunct Zn during future viral/COVID-19 outbreaks and provide platform for future research avenues.

ABSTRACT -- The current management of COVID-19 is mostly limited to general supportive care and symptomatic treatment. Ivermectin is a broad-spectrum anti-parasitic drug used widely for the treatment of onchocerciasis and lymphatic filariasis. Apart from its anti-parasitic effect it also exhibits antiviral activity against a number of viruses both in vitro and in vivo. Hence, we conducted this systematic review and meta-analysis to assess the currently available data on the therapeutic potential of ivermectin for the treatment of COVID-19 as add on therapy. A total of 629 patients were included in the 4 studies and all were COVID-19 RT-PCR positive. Among them, 397 patients received ivermectin along with usual therapy. The random effect model showed the overall pooled OR to be 0.53 (95%CI: 0.29 to0.96) for the primary outcome (all-cause mortality) which was statistically significant (P=0.04). Similarly, the random effect model revealed that adding ivermectin led to significant clinical improvement compared to usual therapy (OR=1.98, 95% CI: 1.11 to 3.53, P=0.02). However, this should be inferred cautiously as the quality of evidence is very low. Currently, many clinical trials are on-going, and definitive evidence for repurposing this drug for COVID-19 patients will emerge only in the future.

INTRODUCTION:

Since the beginning of the outbreak in December 2019, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has become a cause of global concern (1,2). Remdesivir, favipiravir, chloroquine, hydroxychloroquine, and azithromycin are some of the drugs commonly being used for the treatment of COVID-19 infection but with variable success (3-6). The current management is mostly limited to general supportive care and symptomatic treatment.

Recent reviews have discussed theeffectiveness of multiple classes of drugs including antimalarials, antivirals, antibiotics, corticosteroids and monoclonal antibodies in COVID-19 (7,8). However, the utility of ivermectin, a broad-spectrum anti-parasitic drug used widely for the treatment of onchocerciasis and lymphatic filariasis has largely been overlooked (9,10). Apart from its anti-parasitic effect it also exhibits antiviral activity against a number of viruses both *in vitro* and *in vivo* (11-13). The antiviral activity is purportedly due to the inhibition of importin (IMP) α/β Integrase which helps in the nuclear import and propagation of infection of RNA viruses (14,15). Based on this, researchers have proposed the use of ivermectin as an add on therapy for COVID-19 treatment (16). Few observational studies have been performed to evaluate the effectiveness of ivermectin in the treatment of COVID-19 and have shown favourable result (17-20). However, there is a wide disparity regarding the clinical benefit accrued from this drug. Hence, we conducted this systematic review and meta-analysis to assess the currently available data on the therapeutic potential of ivermectin for the treatment of COVID-19 as add on therapy. This review may provide clinicians an overview of contemporary scientific evidence regarding the therapeutic potential of ivermectin in the clinical management of COVID-19 patients.

review (PROSPERO) registration number for the study is CRD42020207299.

Types of studies: All randomized controlled trials (RCTs) and observational studies reporting the use of ivermectin as an add-on therapy in COVID 19 patients in the English language were included. All the included articles reported all-cause mortality as an outcome measure. The study inclusion was not restricted by year of publication, site of study, dose of the drug, and the control arm.

Types of Participants: RT-PCR confirmed COVID-19 adult patients of both genders treated with ivermectin as an add-on therapy were included in the study.

Types of intervention: The intervention in all included studies was the administration of ivermectin in COVID 19 patients along with standard treatment protocol irrespective of the dose, timing, and frequency of administration of ivermectin.

Types of comparator: The comparison was between standard treatment protocol with and without ivermectin.

Outcome measures: Primary outcome were all-cause mortality and any death during the available period of follow up in the studies. Secondary outcomes were 1) time to discharge from the hospital, 2) time to viral clearance by RT-PCR, 3) clinical improvement assessed by the need for respiratory support.

Information source:

PubMed, EMBASE, the Cochrane Library, SCOPUS, and Web of Science were searched for articles on ivermectin as an add-on therapy in COVID 19 from inception till August 31, 2020. The reference lists of retrieved articles were checked for additional studies. For unpublished data, we checked the International Clinical Trials Registry Platform (ICTRP), which is a central database containing trial registration datasets provided by the different international trial registries including ClinicalTrials.gov.Pre-print servers medRxiv and bioRxiv were also searched for pre-print data.

Search strategy: A combination of subject terms and keywords were used and appropriate adjustments of vocabulary and grammar between different databases were done using PICO method. The search used both Medical Subject Headings (MeSH), as well as keyword variants of all relevant terms. A combination of keywords and Boolean operators like "Ivermectin" OR "Anthelminthic" AND "COVID-19" OR "Severe acute respiratory syndrome coronavirus 2" was used for designing the search algorithm.

Data extraction and management: The data were extracted and assessed for quality using the predesigned eligibility criteria following Cochrane Collaboration's guidelines by 3 review authors (RRM, BRM, SD) independently. Any disagreement between them was resolved by the fourth author (BMP). A pre-designed data extraction format was used for the recording of data which included study design, basic information, treatment details, and outcome measures.

Assessment of risk of bias in included studies: Risk of Bias in Non-Randomized Studies - of Interventions (ROBINS-I) for observational studies was used to assess the risk of bias in the included studies.

Data analysis: Cochrane Program Review Manager 5.3 software was used for the Meta-analysis. For dichotomous values, odd's ratio (OR) and 95% confidence interval was expressed in accordance with Cochrane Handbook for Systematic Reviews of Interventions. I^2 statistic was used to check heterogeneity among eligible studies. The random-effect model was used for data synthesis.

Assessment of publication bias: A funnel plot was used to assess the presence of publication bias.

Grade of evidence: GRADE profiler software (V 3.6.1) was used for quality assessment of the evidence.

RESULTS:

Description of studies: A total of 119 studies were found from all database searches. Out of those 91 were from PubMed and 28 from preprint server medRxiv. Search in clinicaltrials.gov resulted in 37 registered studies, among those 2 were completed studies with results. A total of 5 studies were selected for full-text review after screening and removal of duplicates. Other studies were excluded as those were letters to the editor, commentaries, and review articles. Finally, 4 observational studies were included for systematic review and meta-analysis, 3 with the control arm and 1 without control arm. One

of the studies evaluating the prophylactic effect of ivermectin for COVID-19 was excluded from the review. We did not find any published RCT evaluating the effect of ivermectin on COVID-19. Three of the included studies are not peer-reviewed as they were published in preprint server medRxiv.

A total of 629 patients were included in the 4 studies and all were RT-PCR positive. Among them, 397 patients received ivermectin along with usual therapy. Ivermectin treated group had 233 mild cases and 104 moderate to severe cases. Similarly, the usual treatment group had 121 mild and 57 moderate to severe cases. The study by Choudhury *et al* with 60 patients in the ivermectin group and 56 patients in the usual therapy group had not mentioned the severity of the disease. Most of the patients had one or more comorbidities like diabetes, hypertension, and bronchial asthma. The dose of ivermectin varied from 150 to 200 µg/kg body weight administered as a single dose. In the study by Rajtor *et al*, 13 patients also received the 2nd dose of ivermectin. The characteristics of studies included for systematic review and meta-analysis are depicted in Table 1.

Risk of bias in the included studies:

The risk of bias assessment of all studies included in the meta-analysis was carried out for the primary outcome (all-cause mortality) using the risk of bias in non-randomized studies - of interventions (ROBINS-I). The result of the risk of bias assessment of observational studies is depicted in table 2.

Effects of intervention:

The study by Bhattacharya *et al* did not have a control arm for comparison. Therefore, 3 studies were included for measuring the pooled effect of add on ivermectin to usual therapy on the primary and secondary outcomes. The forest plots for the pooled effect are depicted in Figure 1.

Primary outcome (all-cause mortality)

All-cause mortality was reportedly reduced in 2 of the 3 included studies. Test for heterogeneity for the pooled studies was not significant (Chi^2 =0.09, df=1, (P=0.77), I^2=0%) and the random effect model showed the overall pooled OR to be 0.53 (95%CI: 0.29 to 0.96). Sensitivity analysis was not carried out as the test of heterogeneity across the included studies was not significant. The overall result suggests that there was a statistically significant reduction in all-cause mortality with the additional use of ivermectin compared to usual therapy only (P=0.04).

Since the search period mentioned in our protocol registered on PROSPERO was from inception till August 31, 2020, data from the study by Hashim *et al* has not included in the primary meta-analysis as this trial was published in the preprint server in October 2020 (21). In this study, out of 140 COVID-19 patients, 70 were randomized to receive ivermectin plus standard treatment and the rest 70 received standard treatment only. In the ivermectin plus standard treatment arm, the mortality was 2 compared to 6 in the standard treatment only arm. As a secondary analysis, when this study was included, the test for heterogeneity for the pooled studies was not significant (Chi^2 =0.45, df=2, (P=0.80), I^2=0%) and pooled OR was 0.50 (95%CI: 0.29 to 0.88). This suggested that addition of ivermectin significantly reduced the mortality (P= 0.02).

Secondary outcomes:

Clinical improvement assessed by the need for respiratory support:

All the 3 studies included in the meta-analysis reported clinical improvement as assessed by the need for respiratory support until the available follow-up period. The test of heterogeneity was not significant (Chi^2=0.56, df=2, (P=0.76), I^2 =0%). The random effect model revealed that adding ivermectin led to significant clinical improvement compared to usual therapy (OR=1.95, 95% CI: 1.09 to 3.49, P=0.02).

Time to discharge from the hospital:

In the study by Gorial *et al*, the meantime of hospital stay was significantly lower in the ivermectin group than the non-ivermectin group (7.62± 2.75 versus 13.22± 5.90 days, p= 0.00005). But in other studies, there was no significant difference in time to discharge from the hospital between the 2 groups. As the exact data for time to discharge from the hospital within a specified time period was not available in all the studies, the data were not pooled for meta-analysis.

Time to viral clearance by RT-PCR:

The median time to viral clearance was lower in the ivermectin group (7 days) in the study by Gorial *et al*, which was statistically significant (p=0.001)

compared to the non-ivermectin group (12 days). But the study by Choudhury *et al* did not find any significant difference between the 2 groups. The other 2 studies by Rajter *et al* and Bhattacharya *et al* did not report about time to viral clearance.

Publication bias:

Although we created a Funnel plot for publication bias, it could not be assessed as there were only 2 studies where mortality was reported. However, due to the small sample size and large effect we expect that publication bias would be present.

Grade of evidence:

The evidence was assessed using GRADE profiler for all-cause mortality and clinical improvement. There were 54 lower deaths per 1000 population on the addition of ivermectin to usual therapy. Similarly, clinical improvement was achieved in 61 more cases per 1000 population when ivermectin was used as an add-on therapy. However, the grade of evidence was very low for both the outcomes. The detailed analysis of the summary of evidence is depicted in table 3.

DISCUSSION

In this systematic review and meta-analysis, we have synthesized the available evidence on the use of add on ivermectin in COVID-19 patients. We included 3 observational studies for estimating the pooled effect. It is important to note that at the time of analysis, 2 of the included studies were not peer-reviewed and were retrieved from the preprint server. However, one of these, the ICON study by Rajter *et al* has been recently published (18). To the best of our knowledge, this is the first systematic review and meta-analysis on the effectiveness of add-on ivermectin in COVID-19 patients. The pooled estimate suggested a statistically significant reduction in all-cause mortality when ivermectin was added to usual therapy with OR of 0.53 (P= 0.04). Even on secondary analysis after inclusion of the study by Hashim *et al*, the pooled OR did not change meaningfully and was 0.50 (P=0.02). Ivermectin has been hypothesized to exert its effect by inhibiting importin (IMP) α/β Integrase and thereby preventing the propagation of viruses. However, the exact mechanism is still not established.

The OR of 1.98 indicates significant clinical improvement as assessed by the need for respiratory support by using ivermectin as add-on therapy in the management of COVID-19 patients (p= 0.02). However, this should be inferred cautiously as the sample sizes of included studies were relatively small and showing large effect.

Most of the included studies involved mild to moderate cases that might have not required respiratory support. All the included studies were observational in nature and suffered from various biases inherent to such study design. The study by Gorial *et al* used a synthetic matched control group for comparison. Similarly, one of the included studies was a retrospective case-control study. All these factors, therefore, contribute to the overall very low quality of evidence. Additionally, the complication rate and mortality amongst patients with severe disease have been reported to be very high (22). In such patients the effectiveness of add on ivermectin has not yet been explored.

Although add-on ivermectin was associated with a significant reduction in all-cause mortality and clinical improvement it did not translate into early discharge from the hospital or viral clearance. Only the study by Gorial et *al* reported a significant decrease in a hospital stay and viral clearance. This might have been due to differences in the management protocol followed in different countries.

In a recent study whose data has been made publicly available on www.clinical trials.gov , [NCT04422561] prophylactic use of ivermectin has reduced the development of COVID-19 symptoms during 14 days follow up period (7.4% in ivermectin group compared to 58.4% in the control group). This drug has traditionally been used in the mass prophylaxis programs of filariasis, onchocerciasis and is generally safe and well-tolerated. In all the studies included in this review, the safety profile of ivermectin was reported to be favourable.

STRENGTH AND LIMITATIONS:

This is the first meta-analysis on the effectiveness of ivermectin as an add-on therapy in COVID-19 using a comprehensive search strategy and assessing the strength of evidence using GRADE profiler. Limitations include small observational studies with confounders and possible publication bias thus providing very low-quality evidence.

Table III: Grade of evidence for included studies

Ivermectin for COVID-19, Bibliography: Meta-analysis

Outcomes	No of Participants (studies) Follow up	Quality of the evidence(GRADE)	Relative effect (95% CI)	Anticipated absolute effects	
				Risk with control	Risk difference with Ivermectin (95% CI)
All-cause mortality	483 (3 studies)	⨁⊖⊖⊖ VERY LOW[1,2,3,4,5] due to risk of bias, inconsistency, indirectness, publication bias, large effect	OR 0.53 (0.29 to 0.97)	Study population 125 per 1000 moderate effect	54 fewer per 1000 (from 3 fewer to 85 fewer)
Secondary outcomes	No of Participants (studies) Follow up	Quality of the evidence (GRADE)	Relative effect (95% CI)	Anticipated absolute effects,	
				Risk with control	Risk difference with Ivermectin (95% CI)
Clinical improvement	483 (3 studies)	⨁⊖⊖⊖ VERY LOW[1,2,3,4,5] due to risk of bias, inconsistency, indirectness, publication bias, large effect	OR 1.98 (1.11 to 3.53)	Study population 868 per 1000 moderate effect	61 more per 1000 (from 12 more to 91 more)

*The basis for the assumed risk (e.g. the median control group risk across studies) is provided in footnotes. The corresponding risk its 95% confidence interval) is based on the assumed risk in the comparison group and the relative effect of the intervention (and it CI). CI: Confidence interval; OR: Odds ratio;

GRADE Working Group grades of evidence; High quality: Further research is very unlikely to change our confidence in the estim effect; Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and ma change the estimate; Low quality: Further research is very likely to have an important impact on our confidence in the estimate of and is likely to change the estimate; Very low quality: We are very uncertain about the estimate.

[1] Bias due to confounding: [2] Due to study types,[3] Due to retrospective study, [4] Due to small number of studies' [5] due to less numb study and small sample size

CONCLUSION

Ivermectin is an established drug with a long history of clinical use and with minimal safety concern. Recent observational studies have reported the effectiveness of this drug as add-on therapy in patients with COVID-19. Our meta-analysis also supports this finding and suggests the modest utility of ivermectin in reducing all-cause mortality and improving clinical outcomes. Currently, many clinical trials are on-going, and definitive evidence for repurposing this drug for COVID-19 patients will emerge only in the future.

AUTHOR CONTRIBUTION: The concept was developed by RRM and BMP. BRM, SD, and RRM carried out the search, data extraction, and quality assessment. Any disagreement was resolved by BMP. Statistical analysis and inference was done by BMP and BRM. The manuscript was written by RRM, BRM, BMP, and SD. All authors approved the final version for publication.

CONFLICTS OF INTEREST: There are no conflicts of interest.

Abstract:

Zinc deficiency is linked to poor prognosis in COVID-19 patients while clinical trials with Zinc demonstrate better clinical outcome. The molecular target and mechanistic details of anti-coronaviral (SARS-CoV2) activity of Zinc remain obscure. We show that ionic Zinc not only inhibits SARS-CoV-2 main protease (Mpro) with nanomolar affinity, but also viral replication. We present the first crystal structure of Mpro-$Zinc^{2+}$ complex at 1.9 Å and provide the structural basis of viral replication inhibition.

COVID-19 pandemic caused by SARS-CoV-2 is a major clinical challenge[1,2,3]. Lower serum Zinc concentration at the time of admission of COVID-19 patients correlates with severe clinical presentations; an extended duration to recovery, higher morbidity, and a higher mortality in elderly[4,5]. However, clinical trials with Zinc and ionophore show positive clinical outcome with a decreased rate of mortality, and transfer to hospice[6,7,8].

Zinc plays several key roles in biological systems viz. structural, catalytic, regulatory and signalling events[9,10,11]. Further, Zinc exhibits anti-viral properties[12], including anti-SARS-CoV. SARS-CoV Main protease (Mpro)[13] and RNA dependent RNA polymerase (RDRP)[14] are potential key molecular targets of Zinc. However, the structure of SARS-CoV-2 RDRP[15] suggests a structural role for Zinc rather than an inhibitory one. Notably, detailed kinetics and mechanism of ionic Zinc targeting SARS-CoV-2 Mpro is lacking.

We first studied one on one binding kinetics of Zinc acetate with purified SARS-CoV-2 Mpro using Surface Plasmon Resonance (SPR). Zinc binds to SARS-CoV-2 Mpro with an association rate constant (ka) of 8,930±30 $M^{-1}s^{-1}$ and the dissociation rate constant (kd) of 0.01755±10 s^{-1}, and an equilibrium dissociation constant (KD) of 1.965E-06 M. (**Fig. 1a**) The half-life (t1/2=ln [0.5]/kd) of Zinc-Mpro complex is computed to be ~10s. We then assessed the inhibitory effects of $Zinc^{2+}$ binding on the proteolytic activity of SARS-COV-2 Mpro in the presence of Zinc acetate. We obtained an IC_{50} value of 325.1 ± 5.1 nM with complete inhibition at 6.25 µM and

FOI 26-3132 - Document 5

above (**Fig. 1b**). We also tested Zinc glycinate and Zinc gluconate complexes, which are available as Zinc supplements in the market and are also investigated in COVID-19 clinical trials[16], and obtained IC_{50} values of 279.35±17.95 nM and 405.25±0.45 nM, respectively (**Supplementary Figure 1, a and b**). Reversibility of $Zinc^{2+}$-mediated inhibition was tested by first inhibiting the enzyme with 500 nM Zinc acetate, and then initiating the reaction with a substrate peptide, followed by addition of EDTA to regain the enzyme activity by chelating $Zinc^{2+}$ ions. We find that Zinc inhibition is completely reversible by EDTA (**Supplementary Figure 1, c**), suggesting that inhibition by the metal ion is not because of oxidation of catalytic cysteine (Cys145).

To further understand the structural basis of SARS-CoV-2 Mpro inhibition by $Zinc^{2+}$ ion, we solved the crystal structure of $Zinc^{2+}$ bound complex at 1.9 Å (**Supplementary Table 2**). The asymmetric unit contains a dimer of Mpro in space group $P2_12_12_1$ (**Fig. 1c**). An unambiguous electron density for $Zinc^{2+}$ (**Fig. 1d, e**) shows that the metal ion is coordinated by the catalytic dyad His41 and Cys145, which is absent in the control datasets collected for apo-enzyme crystals grown in the same condition. $Zinc^{2+}$-bound complex shows a tetrahedral coordination geometry at the Mpro active site by coordinating with two water molecules that are absent in the apo-enzyme structure (**Fig. 1c**). Distortion in the tetrahedral geometry observed is attributed to the presence of heterogeneous atoms; sulphur (Cys145-SG) and nitrogen (His41-NE2) in the inhibited complex. A 180º flip of the imidazole ring of His41 brings NE2 closer to $Zinc^{2+}$ with an inter-atomic distance of 1.94 Å to form a coordinate bond. The interatomic distance between catalytic Cys145 and Zinc is 2.36 Å consistent with observed bound complexes. Two structural water molecules W1 and W2 (PDB: 7DK1; HETATM 5028 and 5031, respectively) coordinate $Zinc^{2+}$ at an inter-atomic distance of 2.23 Å and 1.98 Å, respectively, to satisfy the tetrahedral geometry (**Fig. 1c**). The coordination of $Zinc^{2+}$ with the catalytic dyad is expected to prevent a nucleophilic attack on the carbonyl moiety of the amide bond in polyprotein substrate. We hypothesize that the two strongly coordinated water molecules impart stability to the $Zinc^{2+}$ inhibited complex.

FOI 26-3132 - Document 5

To gain deeper insights into the stability of Mpro- $Zinc^{2+}$ complex, we simulated the complex for 1 µs at 300K, keeping the coordinating waters, W1 and W2. During the simulation, $Zinc^{2+}$ remains strongly bound to the active site via metal coordination bonds with His41 (NE2) and Cys145 (SG) with an interatomic distance of 1.951±0.031 and 2.518±0.031 Å, respectively, throughout the 1µs time frame. The mobility of $Zinc^{2+}$ ion is restricted with a mean RMSD of 0.920 Å (**Fig. 1f**) in accordance with the dynamics of side chains of coordinating catalytic dyad. Visualization of MD simulation trajectory shows (**Supplementary Movie**) that coordinating water molecules W1 and W2 remain bound to $Zinc^{2+}$ throughout the simulation, and help maintain the tetrahedral geometry observed in complex crystal structure (**Fig. 1g**).

We further assessed the inhibitory potential of Zinc acetate, Zinc glycinate and Zinc gluconate against SARS-COV-2. Infected Vero E6 cells were treated with all the three Zinc salts at their respective maximum non-toxic concentrations (MNTD) for 48 hours. The MNTDs used for the three compounds were 100 µM for Zinc acetate and Zinc gluconate and 70 µM for Zinc glycinate. We observed that Zinc acetate treatment resulted in more than 50% reduction of viral titre, as compared to the untreated infected cells (**Fig. 2a**). Based on these results, we determined the IC_{50} of Zinc acetate to be 3.227 µM (**Fig 2b**). Surprisingly, Zinc glycinate and Zinc gluconate failed to inhibit viral replication in standard antiviral assays at non-toxic concentrations albeit showing effective enzyme inhibition *in vitro*. Quercetin, a natural Zinc ionophore, increases the bioavailability of Zinc in treated cells[17], which prompted us to ask whether an increased bioavailability of $Zinc^{2+}$ results in enhanced inhibition of viral replication. To test this, we mixed Zinc acetate with Quercetin at 1:2 molar ratio[18] at non-toxic concentrations (**Supplementary Figure 2**) and tested the antiviral activity against SARS-CoV-2. We observed >2-fold viral inhibition in the presence of Quercetin (**Fig. 2c**).

Taken together, our data strongly suggest an inhibitory role for ionic Zinc[10], wherein it inhibits SARS-CoV-2 Mpro enzyme activity, supported by complex crystal structure and subsequent inhibition of viral replication *in vitro.* Known crystal structures of Zinc conjugates such as N-ethyl-n-phenyl-dithiocarbamic acid (EPDTC), JMF1600, and Zinc-pyrithione in complex with 3C-like (Mpro) proteases from coronaviruses[19], including SARS-CoV[20] and SARS-CoV-2[21],

FOI 26-3132 - Document 5

show a similar mode of metal ion coordination with the catalytic dyad (**Supplementary Figure 3**). However, the $Zinc^{2+}$ inhibited SARS-CoV-2 Mpro enzyme structure presented in this study clearly suggests that ionic form of Zinc alone is capable of inhibiting the enzyme, by forming a stable complex at the active site with the help of two water molecules, previously unknown. We further show Zinc complexes; Zinc glycinate and Zinc gluconate failed to produce any antiviral effects in our cell culture experiments, in agreement with a recent clinical trial data[16] that show no significant effect of Zinc gluconate in clinical outcome in COVID-19 patients. Most notably, we show that Zinc ionophore Quercetin aids in inhibition of SARS-CoV-2 replication as it increases the intracellular concentration of Zinc[17]. Our data support the findings that a combination of Zinc salt, which provides ionic Zinc, with ionophores[6-8], may have a better clinical outcome in COVID-19 therapy. As the $Zinc^{2+}$ coordinating catalytic dyad; Cysteine and Histidine, is present across all coronaviral 3C-like protease (Mpro) active sites, including the ones coded by virulent strains of SARS-CoV-2, the mode of $Zinc^{2+}$ inhibition is expected to be conserved. Short half-life (~10s) of Mpro-$Zinc^{2+}$ complex, fast association and dissociation rates, and water-soluble nature of Zinc acetate suggest that constant doses of Zinc-ionophore combination may be required for effective inhibition of SARS-CoV-2 Mpro.

Data accessibility: Mpro-$Zinc^{2+}$ complex coordinates are available at PDB: 7DK1. X-ray raw data is available from Integrated Resource for Reproducibility in Macromolecular Crystallography (IRRMC) repository (https://proteindiffraction.org/).

Zinc in Human Health: Effect of Zinc on Immune Cells

Ananda S Prasad

Wayne State University School of Medicine, Detroit, Michigan, United States of America

Although the essentiality of zinc for plants and animals has been known for many decades, the essentiality of zinc for humans was recognized only 40 years ago in the Middle East. The zinc-deficient patients had severe immune dysfunctions, inasmuch as they died of intercurrent infections by the time they were 25 years of age. In our studies in an experimental human model of zinc deficiency, we documented decreased serum testosterone level, oligospermia, severe immune dysfunctions mainly affecting T helper cells, hyperammonemia, neurosensory disorders, and decreased lean body mass. It appears that zinc deficiency is prevalent in the developing world and as many as two billion subjects may be growth retarded due to zinc deficiency. Besides growth retardation and immune dysfunctions, cognitive impairment due to zinc deficiency also has been reported recently. Our studies in the cell culture models showed that the activation of many zinc-dependent enzymes and transcription factors were adversely affected due to zinc deficiency. In HUT-78 (T helper 0 (Th_0) cell line), we showed that a decrease in gene expression of interleukin-2 (IL-2) and IL-2 receptor α (IL-2Rα) were due to decreased activation of nuclear factor-κB (NF-κB) in zinc deficient cells. Decreased NF-κB activation in HUT-78 due to zinc deficiency was due to decreased binding of NF-κB to DNA, decreased level of NF-κB p105 (the precursor of NF-κB p50) mRNA, decreased κB inhibitory protein (IκB) phosphorylation, and decreased Iκκ. These effects of zinc were cell specific. Zinc also is an antioxidant and has anti-inflammatory actions. The therapeutic roles of zinc in acute infantile diarrhea, acrodermatitis enteropathica, prevention of blindness in patients with age-related macular degeneration, and treatment of common cold with zinc have been reported. In HL-60 cells (promyelocytic leukemia cell line), zinc enhances the upregulation of A20 mRNA, which, via TRAF pathway, decreases NF-κB activation, leading to decreased gene expression and generation of tumor necrosis factor-α (TNF-α), IL-1β, and IL-8. We have reported recently that in both young adults and elderly subjects, zinc supplementation decreased oxidative stress markers and generation of inflammatory cytokines.

INTRODUCTION

In 1869, Raulin (1) first showed that zinc was required for the growth of Aspergillus niger. In 1934, Todd *et al*. (2) reported that zinc was essential for the growth of rats. Although the essentiality of zinc for animals was established, its ubiquity made it seem improbable that zinc deficiency in humans could lead to any significant clinical problem. During the past 40 years, however, it has become apparent that deficiency of zinc in humans is quite prevalent and may affect over two billion subjects in the developing world (3–5). Here, we review some of the clinical manifestations of zinc deficiency in humans, with particular emphasis on our observations in experimental human models of this syndrome.

CLINICAL MANIFESTATIONS OF ZINC DEFICIENCY

During the past four decades, a spectrum of clinical deficiency of zinc in human subjects has emerged (6). On the one hand, the manifestations of zinc deficiency may be severe; and, on the other end of the spectrum, zinc deficiency may be mild or marginal. A severe deficiency of zinc has been reported to occur in patients with acrodermatitis enteropathica (a genetic disorder), following total parenteral nutrition (TPN) without zinc, following excessive use of alcohol, and following penicillamine therapy. The manifestations of severe zinc deficiency in humans include bullous pustular dermatitis, alopecia, diarrhea, emotional disorder, weight loss, intercurrent infections due to cell-mediated immune dysfunctions, hypogonadism in males, neurosensory disorders, and problems with healing of ulcers. If this condition is unrecognized and untreated, it becomes fatal.

The manifestations of a moderate deficiency of zinc include growth retardation and male hypogonadism in adolescents, rough skin, poor appetite, mental lethargy, delayed wound healing, cell-mediated immune dysfunctions, and abnormal neurosensory changes.

In our studies in the experimental human model in whom only a mild deficiency of zinc in males was induced by dietary means, decreased serum testosterone level, oligospermia, decreased natural killer (NK) cell activity, decreased interleukin-2 (IL-2) production, decreased thymulin activity, hyperammonemia, hypogeusia, de-

Abstract

Zinc inhibits replication of the SARS-CoV virus. We aimed to evaluate the safety, feasibility, and biological effect of administering high-dose intravenous zinc (HDIVZn) to patients with COVID-19. We performed a Phase IIa double-blind, randomized controlled trial to compare HDIVZn to placebo in hospitalized patients with COVID-19. We administered trial treatment per day for a maximum of 7 days until either death or hospital discharge. We measured zinc concentration at baseline and during treatment and observed patients for any significant side effects. For eligible patients, we randomized and administered treatment to 33 adult participants to either HDIVZn (n = 15) or placebo (n = 18). We observed no serious adverse events throughout the study for a total of 94 HDIVZn administrations. However, three participants in the HDIVZn group reported infusion site irritation. Mean serum zinc on Day 1 in the placebo, and the HDIVZn group was 6.9 ± 1.1 and 7.7 ± 1.6 μmol/l, respectively, consistent with zinc deficiency. HDIVZn, but not placebo, increased serum zinc levels above the deficiency cutoff of 10.7 μmol/l (p < .001) on Day 6. Our study did not reach its target enrollment because stringent public health measures markedly reduced patient hospitalizations. Hospitalized COVID-19 patients demonstrated zinc deficiency. This can be corrected with HDIVZn. Such treatment appears safe, feasible, and only associated with minimal peripheral infusion site irritation. This pilot study justifies further investigation of this treatment in COVID-19 patients.

1 | INTRODUCTION

Cheap, safe, and easily administered interventions to improve outcomes associated with COVID-19 infection remain an important goal. Zinc and Zn-salts inhibit viral infections in clinical and experimental settings,[1–10] including replication of SARS-coronavirus (SARS-CoV).[8] Thus, zinc supplementation might be beneficial in patients with COVID-19.[11–17] Clinical trials have been registered to test the efficacy of zinc against COVID, mostly with oral zinc supplementation.[18] However, the bioavailability of enterally administered zinc is low.[15] Thus, logically, intravenous zinc at a high dose should be the preferred mode of administration.[15] Unfortunately, no studies have assessed the feasibility, safety, and impact on zinc levels of high-dose intravenous zinc (HDIVZn). We designed a Phase IIa pilot double-blind randomized controlled trial (RCT) to determine the feasibility, safety, and biological efficacy of HDIVZn in subjects with COVID-19.

2 | METHODS

2.1 | Human ethics

The Austin Health Human Research Ethics Committee approved this study (HREC/62996/Austin-2020-208572(v3) and the trial was prospectively registered (Australia New Zealand Clinical Trial Register Registration no. ACTRN12620000454976).

2.2 | Study protocol and drug

A detailed clinical trial protocol has been published previously.[19] Briefly, we randomized consenting COVID-19 confirmed hospitalized adults with oxygen saturation (SpO_2) of 94% or less while on ambient air to either daily HDIVZn or saline placebo. Colorless pharmaceutical grade Zinc Chloride ($ZnCl_2$) stock solution obtained from Phebra Pty Ltd was diluted in 250 ml of normal saline and infused via

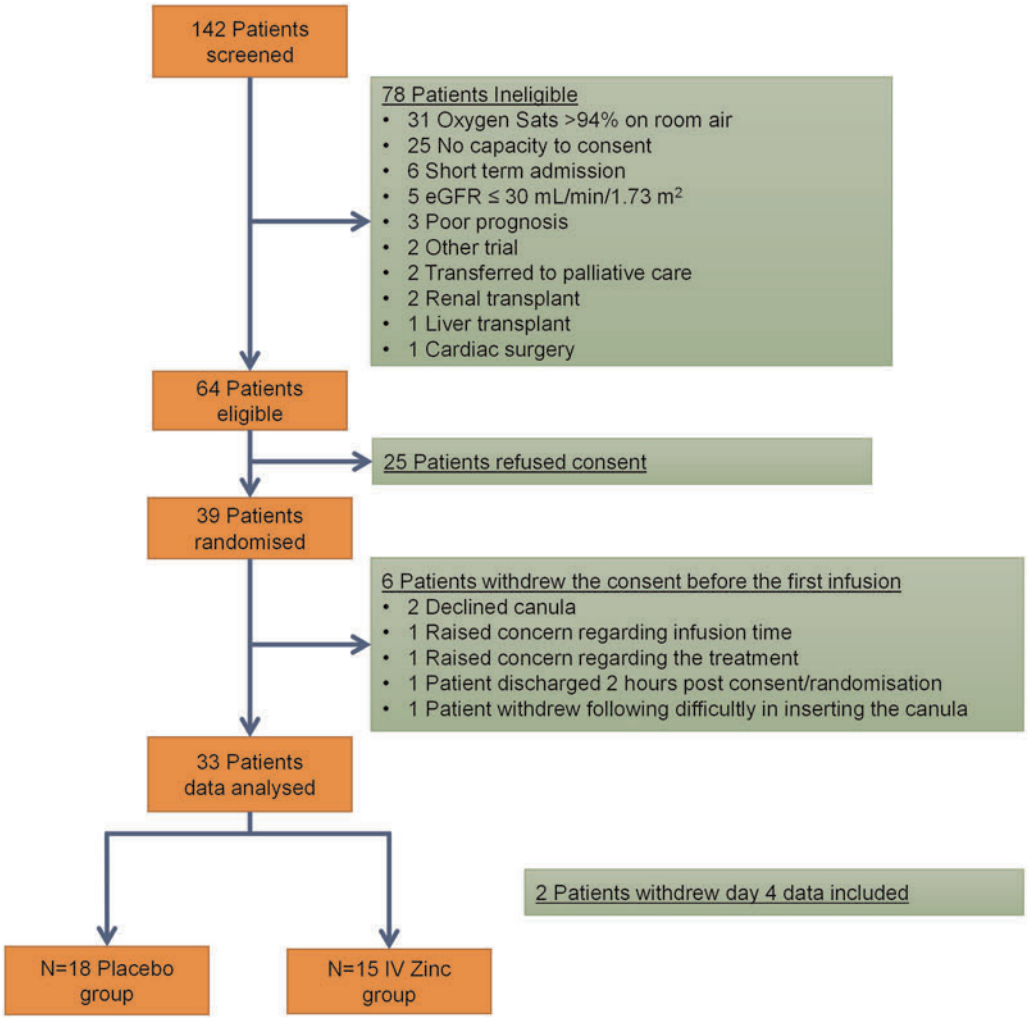

FIGURE 1 Flow chart showing patient recruitment and randomisation

peripheral intravenous access over 3 h at a dose of 0.5 mg/kg/day (elemental zinc concentration, 0.24 mg/kg/day) for a maximum of 7 days, or until hospital discharge or death. The investigators, study coordinators, treating physicians, bedside nurses, and patients/family remained blinded to the allocated study solution.

The serum trace metal analysis was carried out by Austin Pathology using inductively coupled plasma mass spectrometry (ICP-MS).

2.3 | Statistical analysis

Continuous variables are presented as means ± standard deviation and compared between groups with the Wilcoxon rank-sum test. Categorical variables are presented as numbers and percentages and compared with Fisher's exact tests. Variables are presented over time in line plots and compared between groups with a mixed-effect generalized linear model with Gaussian distribution, considering the patients as a random effect to account for repeated measurements, and with the time of measurement (as a continuous variable), group of randomization and an interaction between time x group as fixed effects. A two-sided value of $p < .05$ was taken to indicate statistical significance.

3 | RESULTS

We randomized 33 adults to either HDIVZn ($n = 15$) or placebo ($n = 18$; Figure 1 and Table 1). Hypertension, diabetes mellitus, and chronic cardiovascular disease were frequently present. We observed no drug-related severe adverse events during 94 administrations of HDIVZn However, three HDIVZn patients reported infusion site irritation, two on Day 4, and one on Day 6.

Mean serum zinc on Day 1 in the placebo and the HDIVZn group was 6.9 ± 1.1 and 7.7 ± 1.6 μmol/l, respectively, consistent with zinc deficiency. HDIVZn increased serum zinc levels above the deficiency cutoff of 10.7 μmol/l ($p < .001$) on Day 6. In contrast, serum zinc levels with placebo remained below this value (Figure 2A). In contrast, serum copper, calcium, and magnesium were within the normal range at baseline and were not affected by HDIVZn. As most of the patients enrolled in our study were donating blood across multiple trials, we had limited ability to collect enough blood samples to perform all the planned

TABLE 1 Demographics and baseline disease characteristics

Baseline Characteristics recorded on day 1 before receiving the first injection	HDIVZn ($n = 15$)	Control ($n = 18$)	p
Age, years (range)	59.8 ± 16.8 (25–84)	63.8 ± 16.9 (31–95)	.550
Male gender, *N* (%)	11 (73.3)	10 (55.5)	.711
Weight, kg (range)	86.6 ± 23.1 (50–128)	73.9 ± 16.8 (48 –100)	.073
Co-existing disorders, *N* (%)			
Hypertension	7 (46.7)	9 (50.0)	.999
Diabetes	3 (20.0)	3 (16.7)	.999
Chronic cardiovascular disease	4 (26.7)	3 (16.7)	.786
Chronic respiratory disease	0 (0.0)	2 (11.1)	.549
Cirrhosis	0 (0.0)	3 (16.7)	.294
Hepatic failure	0 (0.0)	1 (5.6)	.999
Drugs on Day 1, *N* (%)			
Dexamethasone	12 (80.0)	13 (72.2)	.911
Remdesivir	5 (33.3)	5 (27.8)	.999
Laboratory tests			
Zinc, μmol/l (range)	7.7 ± 1.6 (4.8–10.5)	6.9 ± 1.1 (4.6–8.5)	.122
Creatinine, μmol/l (range)	71.4 ± 24.9 (37–120)	80.4 ± 33.7 (37–156)	.718
C-reactive protein, mg/l (range)	123.7 ± 72.7 (10–223)	91.4 ± 75 (4–294)	.126
Troponin I, ng/l (range)	91.2 ± 223.2 (4–786)	18.1 ± 21.2 (2–71)	.981
Lactate, mmol/l (range)	0.661 ± 2.1 (0.8–2.9)	0.634 ± 2.4 (0.7–3.1)	.868
White blood cell count, $\times 10^3$ cells/mm^3 (range)	5.5 ± 2.7 (2.2–10.7)	6.6 ± 3.1 (2.4–12.7)	.193

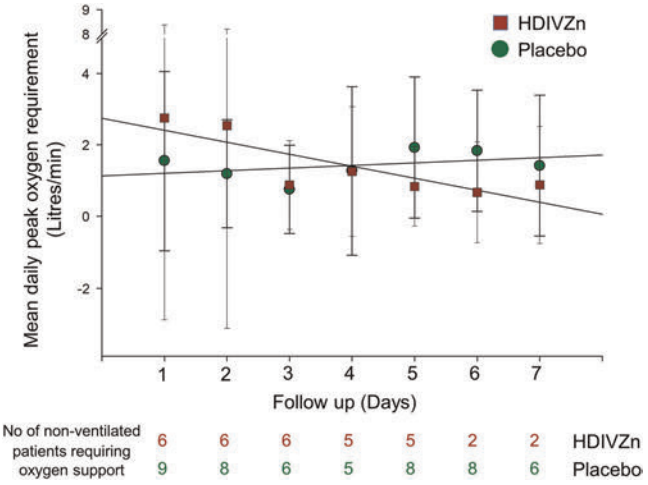

FIGURE 3 The effect of high dose intravenous zinc (HDIVZn) on mean daily peak oxygenation requirement in COVID-19 patients

biochemical tests daily, including the serum zinc levels. Figure 2B shows the serum zinc for eight patients who had their serum zinc determined at all the time points across the 7-day study period.

The primary outcome in non-ventilated patients was assessed as the level of oxygenation expressed as oxygen flow (in liters/min) required to maintain blood oxygen levels (SpO_2) above 94% and the worst (lowest) PaO_2/FiO_2 ratio in ventilated patients. Our study did not reach its target enrollment because stringent public health measures markedly reduced new patient presentations to zero. Consequently, we could not adequately assess the primary outcome of whether HDIVZn reduced the level of oxygenation in non-ventilated (Figure 3) or improved the PaO_2/FiO_2 ratio in the four ventilated patients (data not shown) and other clinical efficacy outcomes (Table 2).

4 | DISCUSSION

Zinc therapy is logical in COVID-19 because of the inhibitory effect of zinc on viral replication and because low zinc levels appear common in COVID-19 patients.[20,21] In a recently published study among a cohort of 47 COVID-19 patients, 27 (57.4%) were found to be zinc deficient.[20] In a Japanese study among a cohort of 29 COVID-19 patients, 9 (31%) were found to be zinc deficient.[21]

There is no globally accepted cutoff level for zinc deficiency. However, Hotz et al.[22] based on the data from the second National Health and Nutrition Examination Survey (NHANES II) suggested that for males greater than 10 years of age serum zinc levels below 61–74 µg/dl (9.3–11.3 µmol/l) depending on the fasting status can be considered as a cutoff value for zinc deficiency. Furthermore, the International Zinc Nutrition Consultative Group (IZiNCG)[23] has defined 10.7 µmol/l as a cutoff value for zinc deficiency, and this value was previously used in an Australian study.[24] Serum zinc levels less than 60 µg/dl (9.1 µmol/l) are defined as clinical zinc deficiency in Japan. However, in a recently published Japanese study, the zinc deficiency cutoff value was set at <70 µg/dl (10.7 µmol/l) to enable direct comparison with domestic and international information.[21]

A previous study has determined that the mean serum zinc in the Australian population is 13 ± 2.4 and 13 ± 2.5 µmol/l for men and women, respectively.[24] One of the leading causes of zinc deficiency is aging; however, in a well-characterized cohort of healthy Australians with an average age of 70.6 ± 7 years, the serum zinc levels were 12.7 ± 2.5 µmol/l.[25] In our study, 100% of patients (33/33) were zinc deficient as the mean serum zinc values in the placebo, and the HDIVZn group were 6.9 ± 1.1 and 7.7 ± 1.6 µmol/l, respectively, well below the zinc deficiency cutoff value of 10.7 µmol/l. Therefore, our results suggest that such zinc deficiency seen in COVID-19 patients may be an acute phase reaction, specifically due to COVID-19 infection.[26]

Zinc deficiency has been associated with a twofold increase in complication rates,[20] greater risk of acute respiratory distress syndrome, longer hospital stay, and increased mortality[20] with an independent relationship between low serum zinc level and disease severity.[21] A recent European study with 35 participants confirmed that most COVID-19 patients were zinc deficient with lower zinc

levels in non-survivors.[27] Given the above observations, various investigators have hypothesized that zinc therapy may be beneficial in COVID-19,[11–13] but zinc bioavailability from enteral administration is low, and the low dosage is inadequate.[15]

A recently published study with four participants suggested that oral administration of elemental zinc to a maximum amount not exceeding 200 mg (zinc salt lozenges) was well tolerated and may have been associated with positive recovery from COVID-19.[28] In contrast, a single-center retrospective study of hospitalized patients with COVID-19 ($n = 242$) determined a lack of association between zinc sulfate intake (100 mg elemental zinc daily) and survival. Hydroxychloroquine (HCQ) has been shown to act as a zinc ionophore, increasing zinc uptake and inducing apoptosis in malignant cells.[13,29] A recent trial by Boulware et al.[29] determined that zinc, in combination with HCQ, was ineffective as there was no evidence that HCQ, in combination with zinc, reduced the incidence of COVID-19 after a high-risk exposure. However, the authors conceded that the study could not be considered conclusive. It was limited by the small sample size of the zinc cohort exacerbated by the lack of details regarding zinc formulation, dose, and treatment duration.

In contrast, Derwand et al.[30] showed that oral supplementation with 50 mg elemental zinc (zinc sulfate), in combination with HCQ (200 mg twice a day), and azithromycin (500 mg per day) for five consecutive days was associated with significantly fewer hospitalizations. Similarly, Carlucci et al.,[31] using the same combination determined that 50 mg elemental zinc (zinc sulfate), when added to HCQ and azithromycin, decreased the mortality and hospitalization. Several shortcomings of these studies include the fact that interventions were not controlled nor blinded. Patients were not randomized or monitored for various other laboratory parameters. However, the most significant limitation of the studies mentioned above is the lack of data showing whether oral zinc supplementation on its own or in combination with HCQ indeed improved the serum zinc status among COVID-19 patients.

The upper daily oral intake limit for elemental zinc is 40 mg/day as defined by the National Institutes of Health and a lower 25 mg/day as defined by the European Food Safety Authority. A recent study noted that enteral delivery (via a nasogastric feeding tube) of 100–150 mg/day elemental zinc supplied as zinc acetate (brand name Nobelzin) takes between 14 and 24 days to correct zinc deficiency, defined as serum zinc less than 70 μg/dl (equivalent to 10.7 μmol/l) in hospitalized Japanese COVID-19 patients.[21] In comparison, our HDIVZn regimen using an elemental zinc dose ranging from a minimum daily dose of 12 mg (in a 50 kg patient) to a maximum of 30.7 mg (in a 128 kg patient) corrected zinc deficiency within a week without any toxicity or side effects. The need to use significantly higher doses of zinc than the recommended upper daily oral intake stems from an analysis by Hambidge et al.,[32] indicating that the maximal absorption (A_{max}) for zinc via oral delivery is only ≈7 mg Zn/day. This low A_{max} is due to the molecular complexities of oral zinc absorption into and across the enterocyte and basolateral membrane. Overall, our study suggests that intravenous zinc overcomes low A_{max} of oral zinc supplementation. Furthermore, intravenous zinc may be superior to oral zinc supplementation in rectifying the acute phase zinc deficiency seen in COVID-19 patients; however, a direct comparative study (intravenous vs. oral Zn) is warranted.

In summary, our study provides the first evidence showing the safety and feasibility of intravenous zinc treatment and the ability of HDIVZn to reverse the acute phase zinc deficiency associated with COVID-19. These findings support further investigation of this treatment in larger RCTs.

CONFLICT OF INTERESTS

The authors declare that there are no conflict of interests.

Hydroxychloroquine
Safety
Anti-viral mechanism

ABSTRACT

Recent global outbreak of the pandemic caused by coronavirus (COVID-19) emphasizes the urgent need for novel antiviral therapeutics. It can be supplemented by utilization of efficient and validated drug discovery approaches such as drug repurposing/repositioning. The well reported and clinically used anti-malarial aminoquinoline drugs (chloroquine and hydroxychloroquine) have shown potential to be repurposed to control the present pandemic by inhibition of COVID-19. The review elaborates the mechanism of action, safety (side effects, adverse effects, toxicity) and details of clinical trials for chloroquine and hydroxychloroquine to benefit the clinicians, medicinal chemist, pharmacologist actively involved in controlling the pandemic and to provide therapeutics for the treatment of COVID-19 infection.

1. Introduction

Coronavirus disease 2019 (COVID-19 or 2019-nCoV) continues to spread all over the world. The infection has spread over to 213 countries (23,14,621 confirmed cases and 157,847 confirmed deaths) since its outbreak in November 2019 in China (as on 20 April 2020) (Fig. 1) [1–5]. The worldwide pandemic and uncontrolled scenario demands use of efficient drug discovery approaches such as computational chemistry and biology, high throughput screening (HTS), artificial intelligence (AI), drug repurposing etc. for effective control [6–12]. Among these approaches, drug repurposing (or drug repositioning) has been implemented for anti-viral drug discovery (Fig. 2) [13–90]. It has helped to conduct in vitro studies and clinical trials for a dozen of chemical molecules and evaluate their anti-viral efficacy against COVID-19 (Table 1) [91–93].

One of the examples of successful application of drug discovery approaches is drug repurposing of the traditional anti-malarial drugs aminoquinolines namely, chloroquine (CQ) and hydroxychloroquine (HCQ) (Fig. 3). Both are synthetic anti-malarial drugs with rapid absorption. Chloroquine and hydroxychloroquine are water soluble; the latter is more soluble due to presence of hydroxyl group and possesses plasma half-life of 900 h and 1300 h, respectively [94]. During chronic treatment the drugs gets accumulated in tissues [95]. The selected anti-malarial drugs have been used for last 70 years. They are economic, have proven safety profile and are categorized as essential medicines by World Health Organization (WHO) [96]. Aminoquinolines have effectively reduced viral replication in Zika virus, Chikungunya virus, SARS-associated coronavirus (CoV) and MERS-CoV [97–100]. Chloroquine and hydroxychloroquine has shown inhibition of SARS-CoV-2 replication [101]. Clinical trials have demonstrated the effective role of chloroquine phosphate (dose 500 mg/day) against COVID-19 [102]. The N-hydroxyethyl substituted derivative of chloroquine, hydroxychloroquine is less toxic, more soluble and has similar activity towards COVID-19 inhibition. There is continuous requirement to explore the molecular mechanism towards underlying antiviral action and clinical benefits of aminoquinolines and the toxicity profile. The detailed outcomes will help to design the randomized clinical trials [95,103–107]. The present manuscript provides a systematic review of mechanism of action, efficacy, and safety of chloroquine and hydroxychloroquine which are being used as therapeutic measure to cure COVID-19 infection.

2. Mechanism of action

For viral replication, a stable acidic pH of endosomes, lysosomes, Golgi complex of host is required. The bioaccumulation properties of both the selected aimnoquinolines explain the antiviral mechanism of their action [108]. Chloroquine increases the pH of intracellular vacuoles. In lysosomes, it alters the catalysis of the protein degradation pathways through acidic hydrolases. It also alters endosomal

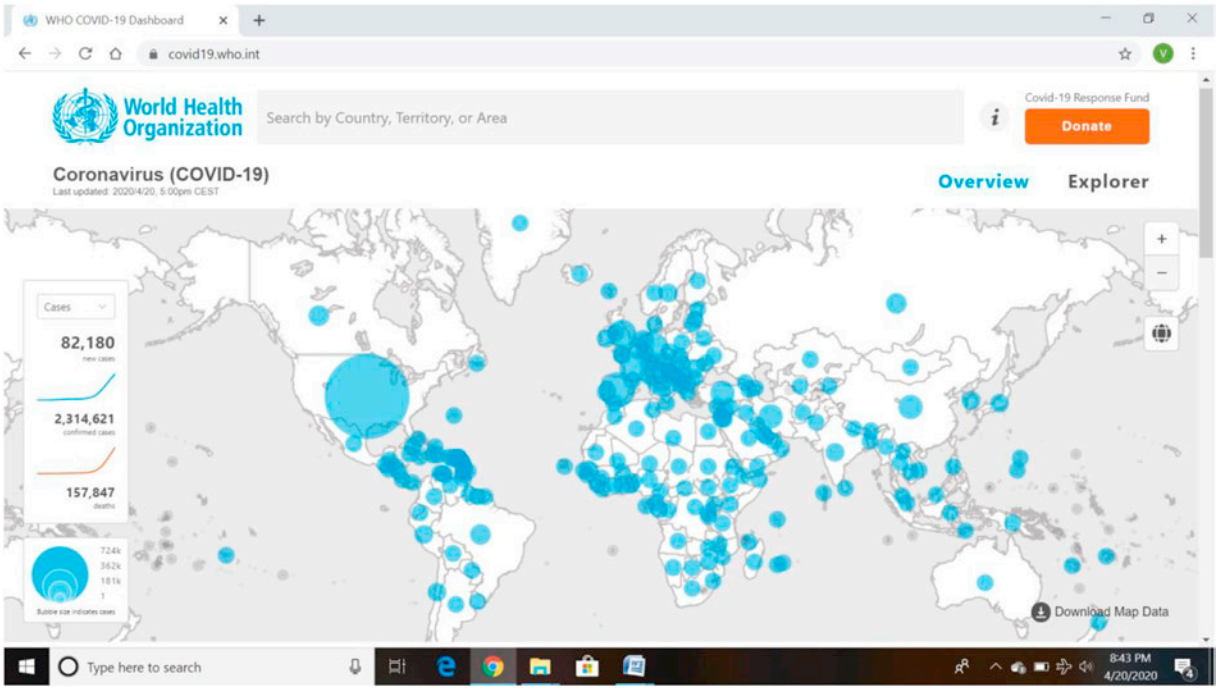

Fig. 1. Global COVID-19 spread showing number of confirmed cases (blue color) (as on 20 April 2020, 8:43 pm). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

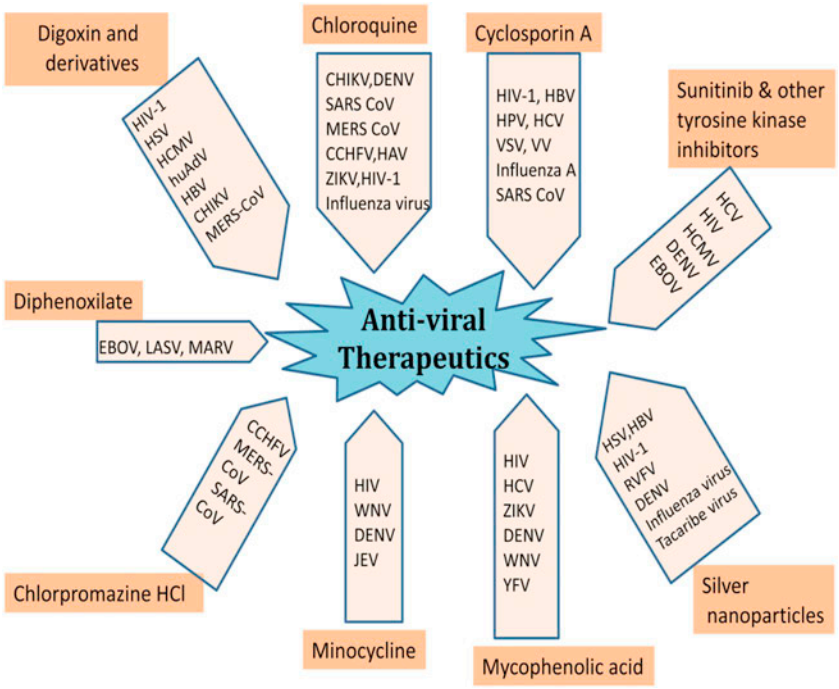

Fig. 2. Examples of drug repurposing for viral inhibition [13–90].

macromolecule synthesis and in Golgi apparatus it affects post-translational modifications. The antirheumatic response is produced by interfering with the immunological process which occurs in macrophages and antigen-presenting cells [109]. The mechanism involved for antiviral action is similar. It decreases the pH and interferes with the viral fusion process. In coronavirus, chloroquine binds to the cellular receptors and changes the glycosylation [110]. Chloroquine possesses selective and reversible immunomodulatory effect through its action on human $CD4^+$ T-cells which is mediated by inhibition of JNK catalytic activity [109].

Hydroxychloroquine exerts similar mechanism of antiviral action and some of the key features are – i) increases the pH, ii) modulation of activated immune cells, iii) downregulation of expression of Toll-like receptors (TLR), iv) downregulation of TLR-mediated signal transduction; v) interleukin-6 formation drops; vi) reduces the formation of pro-inflammatory cytokines and other mediators to control inflammation [105,110,111].

The recent literature review helps to propose the possible mechanism of action of chloroquine and hydroxychloroquine through three ways i.e. immunomodulatory effect, zinc ionophore effect and

binding with Sialic acid [112–114]. The three mechanisms are illustrated in Fig. 4.

3. Chloroquine vs. hydroxychloroquine

When compared for pharmacological profile, chloroquine and hydroxychloroquine possess equivalent anti-malarial activity. The latter is preferred due to lower ocular toxicity [115]. Theoretically, the antiviral activity for chloroqunie and hydroxychloroquine are similar but the reported clinical details for chloroquine are more in number [116]. Use of chloroquine is less due to some associated adverse effects and lack of availability in some countries. In patients with COVID-19 infection hydroxychloroquine is preferred as chloroquine when used in combination with lopinavir or ritonavir shows prolongation of the QT interval. Some of the other antiviral therapeutics that does not interfere with hydroxychloroquine is oseltamivir, lopinavir/ritonavir, robavirin, interferons, and immunoglobulins (intravenous) [117].

4. Safety and adverse effects

The toxicological properties reported with use of chloroquine and hydroxychloroquine are retinopathy, neuromyopathy and cardiomyopathy. Both these drugs possess affinity for melanin and affect the macular cones. The phagocytic activity of lysosomes is declined on the photoreceptors and they migrate towards central and peripheral regions as well as induces epithelial atrophy and irreversible alterations in photoreceptors [106]. In the lysosomes, hydroxychloroquine is protonated and accumulated due to its basic nature. It inhibits the activity of lysosomal phospholipases causing vacuolization of cardiac and skeletal muscle cells [118]. Prolong use of hydroxychloroquine produces – i) toxicity to retina tissue which may lead to unrepirable retinopathy [119,120]; ii) Cardiotoxicity and CNS toxicity with neuromyopathy symptoms and alterations in gastrointestinal tract [121]; toxicity to liver cells (genetic material) [122]; and genotoxicity [123,124]. Studies have shown substantial increase in retinal toxicity with chronic treatment based on the hypothesis of bioaccumulation [125]. Some investigators report $<2\%$ incidences of retinopathy and more common in Asian patients [126,127]. Some studies failed to report cardiac

complications and neuromyopathy and may be rare after long-term treatment [128,129]. The monitoring of side effects need to be continued even after discontinuation of treatment due to prolong half-life of chloroquine and hydroxychloroquine. The side effects (keratopathy, maculopathy) may be delayed. The current anti-COVID-19 therapeutic regimen suggests longer duration of treatment with chloroquine than that as anti-malarial drug. Thus close monitoring of the adverse reactions, pharmacological effects, poisoning and toxicological mechanisms to provide help to the worldwide clinical work [110].

Consideration of clinical outcomes is essential to be monitored to design safe and effective protocol with prevention of toxicological effects for therapeutic use of the antiviral aminoquinolines (chloroquine and hydroxychloroquine).

5. Outcomes of in vivo, in vitro studies and clinical trials

WHO has framed a collective protocol to conduct randomized clinical trials for investigating the clinical role and safety of therapeutics for the treatment of COVID-19 infection [130]. As on 14 April 2020, approximately 961 clinical trials which are carrying on worldwide have been reported to WHO. The essential ethical requirement is use of chloroquine in COVID-19 patients with ethical trial approval or off-label. Timely availability of the clinical outputs to the biomedical fraternity is important considering the evolving outbreak and growing number of COVID-19 infected patients with availability of any specific licensed drug. The use of chloroquine in the treatment of COVID-19 infection is considered by WHO as experimental. In this regard use of chloroquine is associated with various concerns such as patient safety, close monitoring of drug use, etc. The repurposing of the anti-malarial drugs need to follow ethical approaches and may raise concern about shortage of such drugs. The outcomes of some of the reported in vivo, in vitro and clinical studies carried globally have been documented here one by one. Approximately 100 clinical trials are in recruiting or pending approval and are ongoing at single or multiples centers with satisfactory primary outcomes but final outcomes/results are pending. These are summarized in Table 1 for ease of access to medical fraternity.

- In vitro study of chloroquine were performed in Vero E6 cells infected with SARS-CoV with a multiplicity of infection (0.05) demonstrated effective reduction of viral replication (EC_{90} = 6.90 μM). The antiviral effects are reproducible with standard dose with favorable tissue and lung penetration. The proposed mechanism of viral inhibition involves increased pH in endosomes, altered glycosylation of SARS-CoV cellular receptor and the synergistic action of immunomodulation properties [131].
- The Department of Science and Technology (Guangdong Province and Health Commission of Guangdong Province) reported a multicentric collaborative in vitro and clinical study, use of chloroquine phosphate (dose 500 mg twice a day for 10 days) in mild, moderate and severe SARS-CoV-2 pneumonia [132]. The study included some advisories to monitor for history of drug contraindication, blood testing for anemia, thrombocytopenia or leucopenia, serum electrolyte disturbances, tests for hepatic and renal functioning, routine electrocardiography and monitoring for visual and mental disturbances. Concurrent administration of some drugs should avoided including drugs which can prolong QT interval (examples: quinolones, macrolides, ondansetron), anti-arrhythmic, anti-depressant and antipsychotic drugs.
- The Italian Society of Infectious and Tropical disease, Lombardy section suggests administration of chloroquine (500 mg, twice a day) or hydroxychloroquine (200 mg per day for 10 days) (5 to 20 days treatment depending on clinical severity) [133].
- Another guideline as documented by the Dutch Center of Disease Control (CDC) recommended use of chloroquine to treat severe infections with requirement of oxygen therapy and optimal supportive care [134]. The recommended dose for chloroquine base is 600 mg followed by 300 mg after 12 h (on day 1) and 300 mg twice a day (for 2–5 days) and discontinuation of the treatment at day 5 to reduce the side effects (30 h half-life of chloroquine) (500 mg of chloroquine phosphate = 300 mg of chloroquine base).
- In China, more than two dozen clinical trials have been carried out for evaluating efficacy various anti-viral drugs in different disease severity to investigate dose and duration of treatment. The studies have been coordinated by the Chinese authorities through a prescribed regulating guideline [135]. These trials are the first to report the characteristics and management of COVID-19 infected patients but no details on use of chloroquine [136–140].

6. Conclusion

For therapeutic use of aminoquinolines (chloroquine and hydroxychoroquine) the important aspects are – i) it will be administered to millions of infected patients with COVID-19, ii) It will be administered to medical workers as preventive measure, iii) during acute approach against COVID-19 higher dose will be administered as compared to use during the treatment of chronic rheumatic diseases [141]. Following points can be concluded and to be considered during the use of aminoquinolines (chloroquine and hydroxychloroquine) for the treatment of COVID-19 infection –

i) History of previous or ongoing use of chloroquine and hydroxychloroquine in malaria, amebiasis, rheumatoid arthritis, and systemic lupus;
ii) Higher risk of development of retinopathy in Asian patients;
iii) Periodical monitoring of patients with vision problems, cardiovascular problems;
iv) To measure central and peripheral visual acuity;
v) Drug interaction with Kaolin clay and antacids reduces antiviral and anti-inflammatory action;
vi) Regular monitoring for symptoms like ocular pruritus and cardiac arrhythmias;
vii) Aminoquinolines decreases activity of immunosupressants and antibiotics;
viii) Other aminoquinoline analog, Mefloquine is associated with increased risk of convulsion;
ix) The toxicity is associated with the dose calculated by real weight and therefore dose should be suitable for patients with potential high risk of adverse effects. Cumulative dose >203 mg/kg body weight/day is under high risk category. [142].

In the absence of sufficient clinical data, detailed information on safety, adverse effects, dose of aminoquinolines (chloroquine and hydroxychloroquine), etc. should be made available among health professionals who will dissipate it among patients. The successful application of available resources needs to be grounded in practices to minimize risk of rigorous screening and dose calculation.

Effect of Zinc Sulphate on the Absorption of Tetracycline and Doxycycline in Man

O. Penttilä, H. Hurme and P. J. Neuvonen

Maria Hospital and Department of Clinical Pharmacology, University of Helsinki, Finland

Received: April 23, accepted: May 31, 1975

Summary. A possible interaction between zinc sulphate and tetracycline or doxycycline was examined in a cross-over study in seven volunteers. A single dose of zinc sulphate (45 mg Zn^{++}) was given simultaneously with tetracycline hydrochloride (500 mg) or doxycycline chloride (200 mg). The serum concentration of tetracycline, the area under the serum tetracycline concentration-time curve and the excretion of tetracycline in urine were reduced by about 30% ($p < 0.05$) from the respective control values. The absorption of doxycycline was not influenced significantly by zinc sulphate. The clinical significance of the zinc-tetracycline interaction seems to be of limited importance.

Key words: Drug interaction, drug absorption, zinc sulphate, tetracycline, doxycycline.

It is well documented that the gastrointestinal absorption of various tetracycline derivatives is affected by many di- and trivalent cations, e.g. simultaneous ingestion of aluminium, magnesium, calcium or iron may interfere with the absorption of tetracyclines (8, 10, 12). Similarly, absorption of the various cations may also be inhibited by the interaction (4, 9), which is based on formation of tetracycline-metal complexes in the gut. The ability of various tetracycline derivatives to form chelates *in vitro*, e.g. with calcium, varies considerably (11). Furthermore, the absorption of doxycycline is not significantly affected by milk in conditions when the absorption of tetracycline is markedly inhibited (6). On the contrary, the simultaneous intake of iron causes much more reduction of the absorption of doxycycline than of tetracycline (9).

Oral zinc sulphate has been introduced recently into the treatment of leg ulcers (3), acrodermatitis (7) and to hasten wound healing in situations of increased zinc loss or reduced intake (2). Because zinc sulphate and tetracycline derivatives may be used simultaneously in certain clinical situations and since zinc is able to form chelates with tetracyclines *in vitro* (1), a study has been made of the effect of therapeutic doses of zinc on the absorption of tetracycline and doxycycline.

PATIENTS AND METHODS

A cross-over study was performed in four healthy persons and in three long-stay patients who volunteered for the experiment. The ages of the subjects ranged from 29 to 85 years, and their weights from 44 to 75 kg. Two of the patients were on digoxin 0.25 mg daily. All the volunteers received the usual hospital diet during the study. The

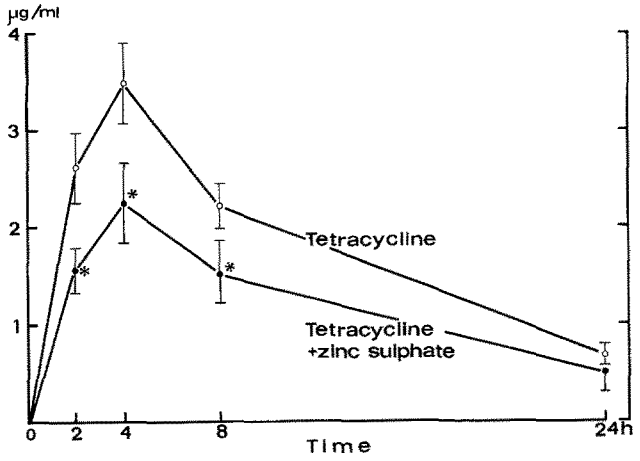

Fig. 1. Serum concentration of tetracycline after ingestion of tetracycline hydrochloride (500 mg) alone or simultaneously with zinc sulphate (200 mg, containing 45 mg Zn^{++}). Means (± S.E.) in a cross-over study in seven persons are shown. The asterisk indicates a significant difference ($p<0.05$) between the appropriate results

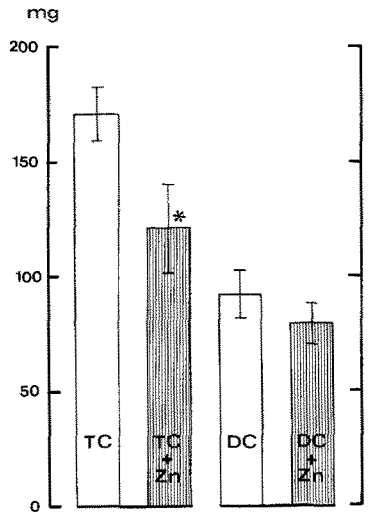

Fig. 2. Effect of simultaneous ingestion of zinc sulphate (containing 45 mg Zn^{++}) and tetracycline hydrochloride (500 mg) or doxycycline chloride (200 mg as a base) on 48 hour excretion of the antibiotics in urine (Mean ± S.E.; n = 7). The asterisk indicates a significant difference ($p<0.05$) between the appropriate results

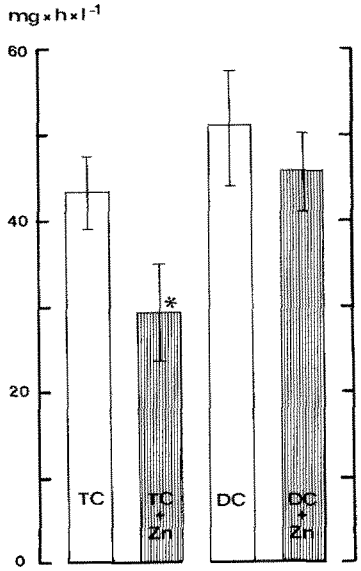

Fig. 3. Effect of simultaneous ingestion of zinc sulphate (containing 45 mg Zn^{++}) and tetracycline hydrochloride (500 mg) or doxycycline chloride (200 mg as a base) on the areas under individual serum antibiotic concentration-time curves (Mean ± S.E.; n = 7). The asterisk indicates a significant difference ($p<0.05$) between the appropriate areas

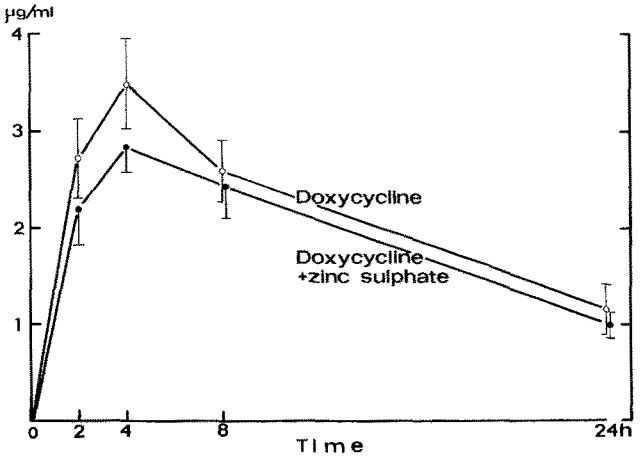

Fig. 4. Serum concentration of doxycycline after ingestion of doxycycline chloride (200 mg as a base) alone or simultaneously with zinc sulphate (containing 45 mg Zn^{++}). Means (± S.E.) in a cross-over study in seven persons are shown

FOI 26-3132 - Document 5

drugs were administered after an overnight fast. A light meal without any dairy products was served three hours after taking the drugs.

The experiment was carried out according to the following plan: according to a cross-over design the volunteers took in random order a single dose of two capsules of tetracycline hydrochloride 250 mg (caps. Medicyclin, Medica Ltd., Helsinki) simultaneously with either 200 ml water or 200 mg zinc sulphate (containing 45 mg Zn^{++}; Solvezink, Draco Ltd., Lund) in 200 ml of water. The interval between the two experiments was one week. After a further week the second cross-over study which was of identical design, was started using the other tetracycline derivative, doxycycline chloride (caps. Vibramycin, Pfizer Corp., Brussels).

Blood samples were taken 0, 2, 4, 8 and 24 h after ingestion of the drugs Urine was collected in 24 hour fractions for 2 days. The pH of the fresh morning urine was determined. Serum and urine samples were stored at -18°C until analysed by a fluorometric method (5). The relative areas under the individual serum tetracycline and doxycycline concentration-time curves during 24 h were estimated.

The means and standard errors (S.E.) were calculated and the results were analysed statistically by Student's t-test for paired values.

RESULTS

Simultaneous ingestion of zinc sulphate and tetracycline resulted in a 30-40 per cent reduction in the serum concentration of tetracycline, the difference from the control group being significant ($p < 0.05$) at 2, 4 and 8 hours after treatment (Fig. 1). The area under the serum tetracycline concentration-time curve and the 48 hour excretion of tetracycline in urine were significantly less ($p < 0.05$) when tetracycline was taken with zinc than without it (Figs. 2 and 3).

The absorption of doxycycline was not significantly affected by simultaneous ingestion of zinc sulphate 200 mg, as judged by the serum doxycycline concentration, by the area under the serum doxycycline concentration-time curve and by the excretion of doxycycline in urine (Figs. 2, 3 and 4).

The pH of fresh morning urine was not significantly different between various groups.

DISCUSSION

The present results demonstrate that absorption of tetracycline was inhibited to some degree whereas the absorption of doxycycline was not affected significantly by simultaneous treatment with zinc sulphate.

Recently oral zinc sulphate has been introduced into the therapy of certain surgical and dermatological situations including, for example, promotion of wound healing after operations and burns, venous leg ulcers and acrodermatitis enteropathica as well as certain other disorders of cutaneous healing in patients with zinc deficiency (2, 3, 7). In these conditions the use of tetracycline derivatives may sometimes be indicated and their absorption is likely to be inhibited if both drugs are taken together. It is reasonable to assume that they interact by formation of zinc-tetracycline complexes in the gut, as demonstrated *in vitro* by Albert (1). The absorption of zinc would also be decreased as a result of the mutual interaction, as in the reported iron-tetracycline interaction (4, 9).

It has been shown previously that the interaction between tetracycline and iron can be avoided by leaving a certain time interval between the doses (6). Zinc and tetracycline seem unlikely to affect each other if there is a 2-3 hour interval between the doses.

The affinity with which various tetracycline derivatives form chelates *in vitro* with different cations varies considerably (11). The absorption of doxycycline, a derivative with the lowest affinity for calcium is affected only to a small extent, or not at all (6), by milk in conditions where the absorption of tetracycline is significantly inhibited. On the other hand, simultaneous intake of iron causes much greater reduction of the absorption of doxycycline than of tetracycline (8). Thus, zinc resembles calcium more closely than iron in that it has very little effect on the absorption of doxycycline.

In conclusion, there is a statistically significant interaction between zinc sulphate and tetracycline when they are ingested simultaneously. However, the reduction of serum tetracycline or doxycycline concentration by zinc sulphate is so small that their interaction can only be of limited clinical significance.

Zinc in Human Health: Effect of Zinc on Immune Cells

Ananda S Prasad

Wayne State University School of Medicine, Detroit, Michigan, United States of America

Although the essentiality of zinc for plants and animals has been known for many decades, the essentiality of zinc for humans was recognized only 40 years ago in the Middle East. The zinc-deficient patients had severe immune dysfunctions, inasmuch as they died of intercurrent infections by the time they were 25 years of age. In our studies in an experimental human model of zinc deficiency, we documented decreased serum testosterone level, oligospermia, severe immune dysfunctions mainly affecting T helper cells, hyperammonemia, neurosensory disorders, and decreased lean body mass. It appears that zinc deficiency is prevalent in the developing world and as many as two billion subjects may be growth retarded due to zinc deficiency. Besides growth retardation and immune dysfunctions, cognitive impairment due to zinc deficiency also has been reported recently. Our studies in the cell culture models showed that the activation of many zinc-dependent enzymes and transcription factors were adversely affected due to zinc deficiency. In HUT-78 (T helper 0 (Th_0) cell line), we showed that a decrease in gene expression of interleukin-2 (IL-2) and IL-2 receptor α (IL-2Rα) were due to decreased activation of nuclear factor-κB (NF-κB) in zinc deficient cells. Decreased NF-κB activation in HUT-78 due to zinc deficiency was due to decreased binding of NF-κB to DNA, decreased level of NF-κB p105 (the precursor of NF-κB p50) mRNA, decreased κB inhibitory protein (IκB) phosphorylation, and decreased Iκκ. These effects of zinc were cell specific. Zinc also is an antioxidant and has anti-inflammatory actions. The therapeutic roles of zinc in acute infantile diarrhea, acrodermatitis enteropathica, prevention of blindness in patients with age-related macular degeneration, and treatment of common cold with zinc have been reported. In HL-60 cells (promyelocytic leukemia cell line), zinc enhances the upregulation of A20 mRNA, which, via TRAF pathway, decreases NF-κB activation, leading to decreased gene expression and generation of tumor necrosis factor-α (TNF-α), IL-1β, and IL-8. We have reported recently that in both young adults and elderly subjects, zinc supplementation decreased oxidative stress markers and generation of inflammatory cytokines.

INTRODUCTION

In 1869, Raulin (1) first showed that zinc was required for the growth of Aspergillus niger. In 1934, Todd *et al*. (2) reported that zinc was essential for the growth of rats. Although the essentiality of zinc for animals was established, its ubiquity made it seem improbable that zinc deficiency in humans could lead to any significant clinical problem. During the past 40 years, however, it has become apparent that deficiency of zinc in humans is quite prevalent and may affect over two billion subjects in the developing world (3–5). Here, we review some of the clinical manifestations of zinc deficiency in humans, with particular emphasis on our observations in experimental human models of this syndrome.

CLINICAL MANIFESTATIONS OF ZINC DEFICIENCY

During the past four decades, a spectrum of clinical deficiency of zinc in human subjects has emerged (6). On the one hand, the manifestations of zinc deficiency may be severe; and, on the other end of the spectrum, zinc deficiency may be mild or marginal. A severe deficiency of zinc has been reported to occur in patients with acrodermatitis enteropathica (a genetic disorder), following total parenteral nutrition (TPN) without zinc, following excessive use of alcohol, and following penicillamine therapy. The manifestations of severe zinc deficiency in humans include bullous pustular dermatitis, alopecia, diarrhea, emotional disorder, weight loss, intercurrent infections due to cell-mediated immune dysfunctions, hypogonadism in males, neurosensory disorders, and problems with healing of ulcers. If this condition is unrecognized and untreated, it becomes fatal.

The manifestations of a moderate deficiency of zinc include growth retardation and male hypogonadism in adolescents, rough skin, poor appetite, mental lethargy, delayed wound healing, cell-mediated immune dysfunctions, and abnormal neurosensory changes.

In our studies in the experimental human model in whom only a mild deficiency of zinc in males was induced by dietary means, decreased serum testosterone level, oligospermia, decreased natural killer (NK) cell activity, decreased interleukin-2 (IL-2) production, decreased thymulin activity, hyperammonemia, hypogeusia, de-

FOI 26-3132 - Document 5

creased dark adaptation, and decreased lean body mass were observed. It is, therefore, clear that even a mild deficiency of zinc in humans affects clinical, biochemical, and immunological functions adversely (7–9).

Nutritional deficiency of zinc in the developing countries is caused by ingestion of high cereal protein intake, rich in phytate (an organic phosphate compound), which makes zinc unavailable for absorption. Other causes of zinc deficiency include malabsorption syndrome, hyperzincuria as seen in cirrhosis of the liver and sickle cell disease, blood loss due to hookworm infection, and excessive sweating in hot tropical climates.

In 1974, a landmark decision to establish recommended dietary allowances (RDAs) for humans for zinc (15 mg elemental zinc daily for adult men and women) was made by the Food and Nutrition Board of the National Research Council of the United States of America National Academy of Sciences.

ZINC AND IMMUNITY

Zinc affects multiple aspects of the immune system (10). Zinc is crucial for normal development and function of cells mediating innate immunity, neutrophils, and NK cells. Macrophages also are affected by zinc deficiency. Phagocytosis, intracellular killing, and cytokine production all are affected by zinc deficiency. Zinc deficiency adversely affects the growth and function of T and B cells. The ability of zinc to function as an antioxidant and stabilize membranes suggests that it has a role in the prevention of free radical-induced injury during inflammatory processes.

STUDIES OF IMMUNE FUNCTIONS IN EXPERIMENTAL HUMAN MODEL

During our studies in the Middle East, we observed that most of the zinc deficient dwarfs did not live beyond the age of 25 years. The cause of death appeared to be infections. Parasitic infections were common. Viral and bacterial infections, although prevalent, remained undocumented, however. The possibility that zinc deficiency may have played a role in immune dysfunctions in the zinc-deficient dwarfs was considered, but lack of proper facilities prevented us from gathering meaningful data on immune functions in those patients in the Middle East.

In our experimental human model studies, when zinc deficiency was very mild (3 to 5.0 mg Zn intake during the zinc-restricted period), the plasma zinc concentration remained more or less within the normal range and it decreased only after 4–5 months of zinc restriction. On the other hand, zinc concentrations in lymphocytes, granulocytes, and platelets decreased within 8–12 weeks, suggesting that the assay of cellular zinc provided a more sensitive criterion for diagnosing mild deficiency of zinc (7–9).

We assayed serum thymulin activity in mildly zinc-deficient human subjects (8). Thymulin is a thymus-specific hormone and it requires the presence of zinc for its biological activity to be expressed. Thymulin binds to high-affinity receptors on T cells, induces several T-cell markers, and promotes T-cell function, including allogenic cytotoxicity, suppressor functions, and interleukin-2 (IL-2) production. As a result of mild deficiency of zinc, the activity of thymulin in serum was decreased significantly and was corrected by both *in vivo* and *in vitro* zinc supplementation (7). The *in vitro* supplementation studies indicated that the inactive thymulin peptide was present in the serum in zinc-deficient subjects and was activated by the addition of zinc.

For the quantification of T cells, beads coated with T_{101} Mab and, for B lymphocytes, beads coated with anti human immunoglobulin were used, (Quantigen, Bio-Rad laboratories, Richmond, CA, USA) 1×10^6 mononuclear cells (MNC) were incubated with 200 μL of one or two microbeads preparation. Cells with no beads were counted as T_{101}–, slg–. An increase in T_{101}–, slg- cells, a decrease in the ratio of $CD4^+$ to $CD8^+$, and decreased IL-2 activity (proliferation assay [7]) were observed in the experimental human model during the zinc-depletion phase, all of which were corrected after repletion with zinc. We previously had reported that NK cells' activity was also sensitive to zinc restriction, thus it appears that zinc may play a very important and critical role in the functions of T cells in humans (6,10). Our studies in the experimental human model showed for the first time that the production of IFN-γ was decreased, whereas the production of IL-4, IL-6 and IL-10 was not affected due to zinc deficiency (8,9). IFN-γ is known to downregulate the T helper 2 (Th_2) clone, and IL-10 may downregulate the T helper 1 (Th_1) clone. An imbalance between Th_1 and Th_2 responses in patients with human immunodeficiency virus infection has been implicated in the immune dysregulation in these patients, and it has been proposed that resistance to infection and/or progression to acquired immunodeficiency syndrome is dependent on a $Th_1 > Th_2$ dominance. Our data in experimental human models suggest that cell-mediated immune dysfunctions in human zinc deficiency may be due to an imbalance between Th_1 and Th_2 cell functions.

Th_1 cells are known to promote macrophage activation and production of complement fixing and opsonizing antibodies. IFN-γ is the major component of the Th_1 response panel, and it upregulates major histocompatibility complex class I antigen expression. Inasmuch as we have observed that IFN-γ production is decreased as a result of zinc deficiency, our studies provide a possible mechanism by which zinc deficiency may affect cell-mediated immunity adversely.

Several studies have shown the benefits of zinc supplementation on infectious diseases in humans. In double-blind placebo-controlled trials of zinc supplementation, zinc reduced the incidence and duration of acute and chronic diarrhea and acute lower respiratory tract infections in infants and children (11,12). Zinc supplementation of sickle cell anemia patients in a placebo-controlled trial resulted in decreased incidence of staphylococcus aureus pneumonia, streptococcus pneumonia tonsillitis, and *E. coli* urinary tract infections (13). Our recent studies

FOI 26-3132 - Document 5

have shown that zinc supplementation to elderly subjects results in a significant decrease in the incidence of infections (14).

ZINC ACTIVATES NF-κB IN HUT-78 CELLS

The current estimate is that over 2,000 transcription factors may be zinc dependent. However, the present dogma is that the amount of zinc required for the integrity of these transcription factors is so small that, in zinc-deficient cells, one would not see any change.

Because zinc deficiency affects IL-2 production and T-cell activation adversely, we have investigated the role of zinc on NF-κB (nuclear factor-κB) activation in HUT-78, a T helper 0 (Th_0) human malignant lymphoblastoid cell line. We showed for the first time that, in zinc deficient HUT-78 cells, the activation of NF-κB was affected adversely (15).

PHOSPHORYLATION AND UBIQUITINATION OF IκB

Intracellular zinc concentration was decreased by 40% in zinc-deficient HUT-78 cells in comparison to the zinc-sufficient cells after 4 d of incubation. To examine the effect of zinc on κB inhibitory protein (IκB) in HUT-78 cells, we measured phosphorylated IκB-α, Iκκ-α (IκB kinase-α), and ubiquitinated IκB-α in zinc-treated cells. Zinc deficiency caused a 60% decrease in phosphorylated IκB-α in non-stimulated and 40% decrease in phorbol-12 myristate 13 acetate (PMA)/phytohemagglutinin-p (PHA-p)–stimulated cells, compared with zinc-sufficient cells. Zinc deficiency decreased Iκκ-α in PMA/PHA-p–stimulated cells by 30% in comparison to zinc-sufficient cells. Zinc deficiency caused a 50% reduction of ubiquitinated IκB-α after PMA/PHA-p stimulation (15).

We showed that the phosphorylation of IκB and Iκκ, translocation of NF-κB, and its binding to DNA in HUT-78 cells were all zinc dependent (15). The activation of NF-κB was considerably reduced in zinc-deficient HUT-78 cells. Additionally, zinc deficiency decreased the level of NF-κB p105 (the precursor of NF-κB p50) mRNA. All these effects of zinc were cell specific.

ZINC ENHANCES THE EXPRESSION OF IL-2 AND IL-2 RECEPTORS IN HUT-78 CELLS VIA NF-κB ACTIVATION

The production of interleukin-2 (IL-2) is a key and early event in the activation of T-lymphocytes. IL-2 triggers peripheral T-lymphocytes to enter the S phase of the cell cycle and to divide. This is probably a result of the suppressive effect of IL-2 on cell cycle inhibitors, which interfere with the activity of cyclin-dependent kinases (cdks) at checkpoints of the cell cycle (16). IL-2 also is involved in the differentiation of thymocytes, peripheral T- and B-lymphocytes and other cells of hematopoietic origin (16).

A short segment of DNA, 275 base pairs in the promoter area of IL-2 gene, integrates numerous signaling pathways leading to IL-2 synthesis and the activation and proliferation of T-lymphocytes (16). Both the murine and human IL-2 promoters contain one binding site for genuine Rel/NF-κB factors. The sequence of this site, GGGATTTCAC, is identical for both promoters. NF-κB factors are induced rapidly by a variety of stimuli activating T cells. Almost every stimulus leading to T cell activation also activates NF-κB. Induction of IL-2Rα gene expression also is mediated by the induced nuclear expression of NF-κB (17,18).

IL-2 AND SOLUBLE IL-2Rα PRODUCTION

The details of cell culture, zinc assay, and other methods have been published elsewhere (19). We used an Enzyme-Linked ImmunoSorbent Assay (ELISA) to measure the concentration of IL-2 produced by the cells. Unstimulated HUT-78 cells incubated in zinc-deficient (1 μmol/L zinc) and zinc-sufficient (15 μmol/L zinc) media for 4 d produced a very small amount of IL-2. Following PMA/PHA-p stimulation, the IL-2 production and IL-2 mRNA were significantly greater in zinc-sufficient cells in comparison to the zinc-deficient cells (19). Similar results were seen for soluble IL-2 receptor α (soluble IL-2Rα) production and gene expression (19).

ZINC DECREASES OXIDATIVE STRESS AND INFLAMMATORY CYTOKINES

The role of zinc in modulating oxidative stress has recently been recognized. Oxidative stress is an important contributing factor in several chronic human diseases, such as atherosclerosis and related vascular diseases, mutagenesis and cancer, neurodegeneration, immunologic disorders, and the aging process (20–22). Together $O_2^{\cdot-}$, H_2O_2, and $^{\cdot}OH$ are known as reactive oxygen species (ROS), and these are produced continuously *in vivo* under aerobic conditions. The NADPH oxidases are a group of plasma membrane associated enzymes, which catalyze the production of $O_2^{\cdot-}$ from oxygen by using NADPH as the electron donor. Zinc is an inhibitor of this enzyme. The dismutation of $O_2^{\cdot-}$ to H_2O_2 is catalyzed by an enzyme super oxide dismutase (SOD), which contains both copper and zinc. Zinc is known to induce the production of metallothionein, which is very rich in cysteine, and is an excellent scavenger of $^{\cdot}OH$ (6). Iron and copper ions catalyze the production of $^{\cdot}OH$ from H_2O_2. Zinc is known to compete with both iron and copper for binding to cell membrane, thus decreasing the production of $^{\cdot}OH$ (6).

A few investigators have reported that inflammatory cytokines such as TNF-α (tumor necrosis factor-α) and IL-1β, generated by activated monocytes-macrophages, also are known to produce increased amounts of ROS (23,24). Increases in these cytokines are associated with decreased zinc status in patients.

NF-κB is involved in the expression of a variety of responsive specific genes and is activated by several stimuli such as cytokines, radiation, and oxidative stress. *In vitro* activation of NF-κB by TNF-α in MNC has been shown to be an excellent model of oxidative stress-sensitive transactivating factor, and has been used to evaluate the efficacy of compounds in protecting cells from oxidative stress (21). Zinc has been shown to inhibit NF-κB activation in prostate cancer cells, thus enhancing anti-cancer therapy (25), bovine cerebral epithelial

FOI 26-3132 - Document 5

cells (26), as well as reducing increased levels of activated NF-κB in diabetic CD1 mice (27) and zinc deficient cultured human hepatocellular carcinoma-derived cell line (28).

The induction of NF-κB activation pathway appears to be cell specific and is counterbalanced by concomitant activation of NF-κB activation inhibitors. One such inhibitor of NF-κB activation is A20, a zinc finger-transactivating factor which also binds to DNA, producing the A20 protein which inhibits TNF-α-induced NF-κB activation (29–33). A20 plays an important role in reducing IL-1β- and TNF-α-induced NF-κB activation (29–33).

Our data showed that zinc supplementation to normal healthy subjects a) lowers the oxidative stress-related by-products MDA (malondialdehyde), 4-hydroxyalkenals (HAE), and 8-hydroxy deoxyguanine (8-OHdG) generated by cells and released into the plasma, b) inhibits the induction of TNF-α and IL-1β mRNA in MNCs, and c) exhibits a protective effect against TNF-α-induced NF-κB activation in isolated MNCs (34). In addition, we provided evidence to show that, in the human pro-myelocytic leukemia cell line HL-60 which differentiates to the monocyte-macrophage phenotype by PMA, zinc increased the expression of A20 and the binding of A20 transactivating factor to DNA, thereby enhancing inhibition of induced NF-κB activation (34).

The role of zinc in regulation of the gene expression of IL-1β and TNF-α has not been defined. The zinc finger protein A20 has been shown to inhibit NF-κB signaling by TNF-α and IL-1β via TNF-receptor gene (TRAF pathways) in endothelial cells (31,35). A20 is expressed in various types of cells in response to a number of stimuli such as TNF-α, IL-1β, LPS (lipopolysaccharide), PMA, Epstein-Barr virus latent membrane protein, as well as other stimuli (32). A20 expression primarily protects cells from TNF-α-induced cytotoxicity by decreasing the activation of NF-κB, which leads to decreased IL-1β and TNF-α gene expression as has been demonstrated in endothelial cells. We propose that a similar effect of zinc supplementation on the A20 pathway occurs in primary cells. Further studies are ongoing in our laboratory to aid in the understanding the mechanisms of zinc action.

Our study provides molecular evidence for an anti-oxidant effect of zinc in human subjects and shows that zinc supplementation *in vivo* protected MNC against oxidative stress (34). Although there are several possible biochemical mechanisms by which zinc may decrease oxidative stress in cells, our study shows that zinc negatively regulates gene expression of inflammatory cytokines such as TNF-α and IL-1β, which are known to generate ROS and this may be one additional mechanism by which zinc may be functioning as an antioxidant in humans. Thus, our study provides rationale for use of zinc in therapeutic trials either alone or in conjunction with other modalities in chronic diseases, including chemo-prevention of cancer in which oxidative stress is known to play an important role.

The immunological hallmarks of zinc deficiency in humans and higher animals include thymic atrophy, lymphopenia, and compromised cell- and antibody-mediated responses that result in increased incidences of infections (36). In chronic zinc deficiency, a reprogramming of the immune system occurs, beginning with the activation of the stress axis and chronic production of glucocorticoids that accelerate apoptosis of pre-B and pre-T cells (36), resulting in reduced lymphopoeisis and atrophy of thymus. In contrast, myelopoesis is preserved. Changes in the gene expression for cytokines, DNA repair enzymes, zinc transporters, and signaling molecules, suggest that the cells of the immune system are attempting to adapt to the stress of suboptimal zinc (36).

We have observed that, as a result of zinc deficiency, the macrophages-monocytes are stressed and they generate inflammatory cytokines such as TNF-α and IL-1β (14,34). In a recent study, we reported that, in comparison to the younger adults, the elderly subjects had lower plasma zinc, increased oxidative markers, and increased generation of inflammatory cytokines (14). Following zinc supplementation to the elderly subjects, the plasma zinc increased, oxidative stress markers decreased, and generation of inflammatory cytokine decreased, in comparison to the placebo group.

In a large study organized by the National Eye Institute, NIH, (Bethesda, MD, USA) it was reported that zinc and antioxidants (vitamin C, vitamin E, and β carotene) significantly reduced the odds of developing advanced age related macular degeneration (AMD), and prevented blindness in the high-risk group of elderly subjects (37). Also, it was reported that longevity was increased in the zinc supplemented group (38). Although the mechanism of zinc effect was not defined, one may hypothesize that zinc reduced the oxidative stress and thus was beneficial in AMD.

ROLE OF ZINC IN SUPPRESSING ALLOGENEIC REACTION WITHOUT AFFECTING THE ANTIGENIC RESPONSE

Faber *et al*.(39) have shown that *in vivo* zinc supplementation in therapeutic levels resulted in blocking allogeneic response while maintaining the antigenic potency. This observation may have future implication in transplantation subjects where a selective suppression of allogeneic response is desired.

SUMMARY An outbreak of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, which began in Wuhan, China in December 2019, has rapidly spread all over the world. The World Health Organization characterized the disease caused by SARS-CoV-2 (COVID-19) as a pandemic in March 2020. In the absence of specific treatments for the virus, treatment options are being examined. Drug repurposing is a process of identifying new therapeutic uses for approved drugs. It is an effective strategy to discover drug molecules with new therapeutic indications. This strategy is time-saving, low-cost, and has a minimal risk of failure. Several existing approved drugs such as chloroquine, hydroxychloroquine, doxycycline, azithromycin, and ivermectin are currently in use because of their efficacy in inhibiting COVID-19. Multidrug therapy, such as a combination of hydroxychloroquine and azithromycin, a combination of doxycycline and ivermectin, or a combination of ivermectin, doxycycline, and azithromycin, has been successfully administered. Multidrug therapy is efficacious because the mechanisms of action of these drugs differ. Moreover, multidrug therapy may prevent the emergence of drug-resistant SARS-CoV-2.

Keywords hydroxychloroquine, doxycycline, azithromycin, ivermectin, COVID-19

An outbreak of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, which began in Wuhan, China in December 2019, has rapidly spread all over the world. The World Health Organization characterized the disease caused by SARS-CoV-2 (COVID-19) as a pandemic in March 2020. In the absence of specific treatments for the virus, treatment options are being examined. Drug repurposing is a process of identifying new therapeutic uses for approved drugs. It is an effective strategy to discover drug molecules with new therapeutic indications. This strategy is time-saving, low-cost, and has a minimal risk of failure. Several existing approved drugs such as chloroquine, hydroxychloroquine, doxycycline, azithromycin, and ivermectin, are currently in use because of their efficacy in inhibiting COVID-19.

Chloroquine, a drug known for its efficacy in treating malarial and autoimmune diseases such as rheumatoid arthritis and lupus erythematosus, offers promise in inhibiting SARS-CoV-2. Previous studies have revealed that it potentially has broad-spectrum anti-viral activity by increasing the pH of endosomes and lysosomes, thus preventing the process by which the virus fuses with host cells and subsequently replicates (*1*). Chloroquine is the first drug reported to have efficacy against COVID-19 in clinical studies in China (*2*). Feedback from an international meeting that took place to share experiences related to the prevention and control of COVID-19 highlighted the fact that chloroquine demonstrated significant efficacy in reducing the time to virus-negative conversion and in restabilizing body temperature (*3,4*). Hydroxychloroquine, a more tolerable derivative of chloroquine, has also been found to display potent activity against SARS-CoV-2 *in vitro* (*5*). Clinical studies in China have indicated that hydroxychloroquine can help to reduce the time until body temperature returns to normal, decrease the duration of coughing, and improve lung imaging findings (*6*).

Tetracyclines such as doxycycline, minocycline, and tetracycline are well-known antibiotics in clinical use. Tetracyclines are known to inhibit matrix metalloproteinases (MMPs) through their ability to chelate zinc compounds on MMPs. Several functions of the coronavirus, including replication, are associated with the host MMPs complex. Therefore, the zinc-chelating properties of tetracyclines may be efficacious against COVID-19 in humans (*7,8*). Tetracycline was also reported to inhibit the binding of the SARS-CoV-2 spike protein to angiotensin-converting enzyme 2 (ACE2) (*9*). Doxycycline inhibits the entry and replication of SARS-CoV-2 *in vitro* (*10*). Yates *et al*. reported that four high-risk patients with COVID-19

FOI 26-3132 - Document 5

and comorbid pulmonary disease were successfully treated with doxycycline, the doses and durations of which were 100-200 mg/day and 5-14 days, respectively (*11*). Meyboy *et al*. reported that treatment of COVID-19 with doxycycline (100 mg, *b.i.d*., for 7 days) alleviated shortness of breath, coughing, a fever, and O_2 saturation (*12*).

Macrolides such as erythromycin, clarithromycin, and azithromycin exhibit antibacterial activity, immunomodulatory action, and anti-inflammatory action. Recently, the antiviral action of macrolides has attracted considerable attention (*13*). Azithromycin accumulates within lysosomes, increases their pH, and hampers lysosomal functions allowing viral replication (*13*). In addition, azithromycin blocks the interaction points between SARS-CoV-2 and the ACE2 receptor, preventing SARS-CoV-2 from invading host cells (*13*). Tsiakos *et al*. reported that treatment with clarithromycin (500 mg, *b.i.d*., for 7 days) was associated with early clinical improvement in patients with moderate COVID-19 (*14*). Moreover, Ghiasvand *et al*. reported that three patients diagnosed with COVID-19 who did not respond to initial treatment improved after additional treatment with azithromycin (*15*).

Apart from the aforementioned macrolide antibiotics, ivermectin, a macrolide antiparasitic agent, is also an inhibitor of SARS-CoV-2, with a single treatment causing a ~5,000-fold reduction in the virus at 48 h in cell culture (*16*). The mechanism by which ivermectin inhibits SARS-CoV-2 is thought to be *via* the inhibition of the nuclear import of viral and host proteins. In specific terms, importin (IMP) α/β1, a host protein, is a heterodimer that binds to the SARS-CoV-2 cargo protein and moves it into the nucleus, where the complex falls apart and the viral cargo can reduce the host cell's antiviral response. Ivermectin destabilizes the IMPα/β1 heterodimer, preventing it from binding to viral protein and thus from entering the nucleus. As a result, the inhibition of antiviral responses is likely to be reduced, leading to a normal, more efficient antiviral response (*16*). Ivermectin also inhibits the binding of the SARS-CoV-2 spike protein to ACE2, much like macrolide antibiotics (*17*). Ahmed *et al*. reported that a 5-day course of ivermectin (12 mg, daily) for COVID-19 reduced the duration of the illness (*18*).

Examining multidrug therapy for COVID-19, Gautret *et al*. reported that a combination of hydroxychloroquine (200 mg, *t.i.d*., for 10 days) and azithromycin (500 mg on day 1, followed by 250 mg, daily, for the next 4 days) reduced the viral load to an undetectable level on day 6. Moreover, this combined therapy proved to be superior to hydroxychloroquine monotherapy (*19*). Alam *et al*. reported that a combination of ivermectin (0.2 mg/kg, single dose) and doxycycline (100 mg, daily, for 10 days) was efficacious in viral clearance in patients with mild or moderate COVID-19 (*20*). Procter *et al*. treated outpatients with COVID-19 with at least two agents with antiviral activity against SARS-CoV-2 (zinc, hydroxychloroquine, and ivermectin) and one antibiotic (azithromycin, doxycycline, and ceftriaxone) along with inhaled budesonide and/or intramuscular dexamethasone. Consequently, multidrug therapy of early ambulatory patients (not hospitalized and treated at home) was found to be safe, feasible, and associated with low rates of hospitalization and mortality (*21*). Prasad reported a patient with COVID-19 and pulmonary lesions who recovered after receiving early treatment with ivermectin (6 mg, *b.i.d.*, for 3 days), azithromycin (500 mg, daily, for 5 days), doxycycline (100 mg, *b.i.d.*, for 5 days), and prednisolone (50 mg, daily, for 5 days) followed by dexamethasone (6 mg, daily) (*22*). Apart from the aforementioned multidrug therapy, a combination of ivermectin and azithromycin (*23*), a combination of doxycycline and azithromycin (*24*), and a combination of hydroxychloroquine, ivermectin, and azithromycin (*25*) are proposed treatments to be studied in clinical trials.

Multidrug therapy is more efficacious than single-drug therapy because there are differences in the mechanisms of action of the drugs described. Moreover, multidrug therapy may prevent the emergence of drug-resistant SARS-CoV-2. Clinical trials need to be conducted to better assess the efficacy and tolerability of the aforementioned multidrug therapy before it can be adopted on a wider basis.

TIMELINE — TROPICAL INFECTIOUS DISEASES

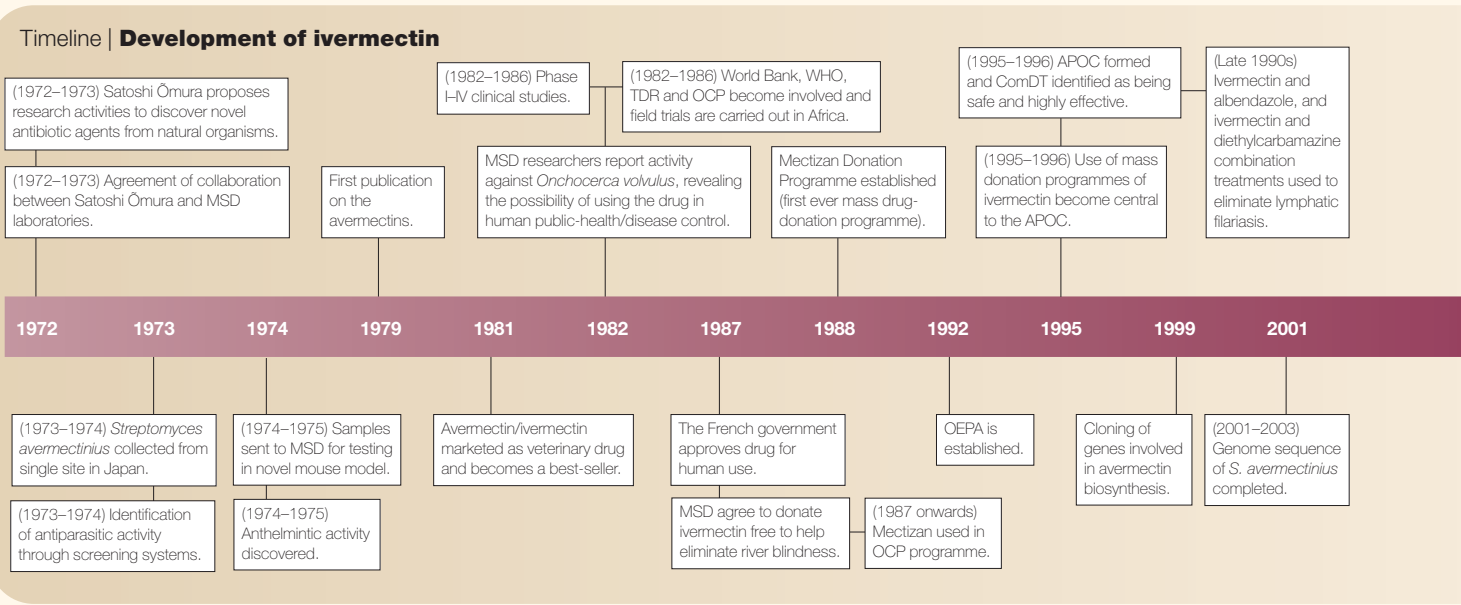
The life and times of ivermectin — a success story

Satoshi Ōmura and Andy Crump

Abstract | Since its introduction more than 20 years ago, ivermectin has proved to be one of the most successful therapeutic drugs in veterinary medicine, as well as the basis of one of the most successful public-health programmes of the past century. The drug arose from a unique international collaboration between the public and private sectors. The development process also incorporated the world's first and largest drug-donation programme and involved a unique association between governments, non-governmental organizations and industry. The drug is now being used, free of charge, in two global disease-elimination programmes that are benefiting millions of the world's poorest people.

In 1973, a research partnership was established between the Kitasato Institute in Japan and the Merck, Sharpe and Dohme (MSD) research laboratories in the United States. The outcome of this alliance led to an important advance in animal health products, through the development of an extremely safe drug with a broad spectrum of antiparasitic activity — a drug that has also provided significant benefits to human health for more than 20 years, improving the lives of hundreds of millions of the world's poorest and worst afflicted in the process (TIMELINE).

The partnership



For most of the important breakthroughs in medical research, serendipity has an important role, and so it proved in the case of the drug ivermectin. Researchers at the Kitasato Institute in Tokyo had established a worldwide reputation for their expertise in detecting bioactive compounds produced by microorganisms that are mainly found in the environment. Novel techniques were developed and screening systems were established to increase the chances of accurately detecting minute samples of active compounds[1]. In 1971, one of the authors (S.O.) took a sabbatical from the Kitasato Institute to take up a research post working with Max Tishler, who, after a successful career at MSD, had moved from industry to Wesleyan University in the United States. The Kitasato team were eager to find an industrial partner to participate in a new line of research to discover microorganisms that produce potentially useful compounds with unique chemical structures. Researchers at MSD routinely carried out extensive and innovative *in vivo* work (thereby complementing the *in vitro* work done in Japan) and had the resources to push promising compounds through the drug-development pipeline. By the early 1970s, the testing of synthetic chemicals at the MSD commercial research laboratories was beginning to realize diminishing returns[2], so the company was keen to explore and take advantage of the new research directions that were proposed by the Japanese group. Consequently, the link between Ōmura and Tishler, with his connections to MSD, formed the basis for the new Kitasato–MSD collaboration, which was formally created in 1973.

When the partnership was founded, only a few of the several thousand active fermentation products that had been isolated had anthelmintic activity. Compounds of significance included anthelmycin, anthelvencin, the antibiotic complex S-15-1, aspiculomycin, the axenomycins, G-418, hygromycin B, the destomycins, myxin, paromomycin and the thiamycins. Only one compound, hygromycin, was considered suitable for further development[3]. To address this shortage, the new, goal-oriented research initiative was focused towards discovering a drug that would be effective against helminth parasites[2].

Discovery and isolation

All of the cultures sent from Japan under the terms of the research partnership were from soil samples that were collected and processed by well-established and sophisticated screening systems. These procedures established the morphological features and physiological properties of organisms and compounds produced in fermentation broths and *in vitro*

Timeline | **Development of ivermectin**

evaluations of the chemical products were carried out. In the second year of the collaboration, the Kitasato team isolated an organism — *Streptomyces avermitilis*, which is a species of actinomycete (FIG. 1) — from soil near a golf course bordering the ocean at Kawana, near Ito City in the Shizuoka region. (In 2002, the Kitasato research group published morphological, physiological, biochemical and phylogenetic evidence arguing for the reclassification of the original microorganism and rename it *Streptomyces avermectinius*[4]). The isolated culture was sent, together with 53 other promising microbial samples, to the MSD laboratories in 1974. MSD researchers screened the samples in a novel mouse model of helminth infection in which mice were infected with the nematode worm *Nematospiroides dubius*. Originally identified as OS-3153, the most promising microbial sample was a *S. avermectinius* strain that was shown to have potent anthelmintic activity with little or no toxicity. The compound responsible for the activity was named avermectin[3] (FIG. 2). Further studies demonstrated that avermectin had biocidal activity against a diverse range of nematodes, insects and arachnids. Moreover, the mode of action of avermectin was both unique and robust, and was 25 times more potent than all currently available anthelmintics. The unique ability of avermectin to kill both ecto- and endoparasites gave rise to the new class of compounds called 'endectocides'. In 1979, the first papers on avermectin and its derivatives were published, describing the molecules as a series of macrocyclic lactone derivatives that lacked antibacterial and antifungal activity but which had powerful anthelmintic properties[5–7].

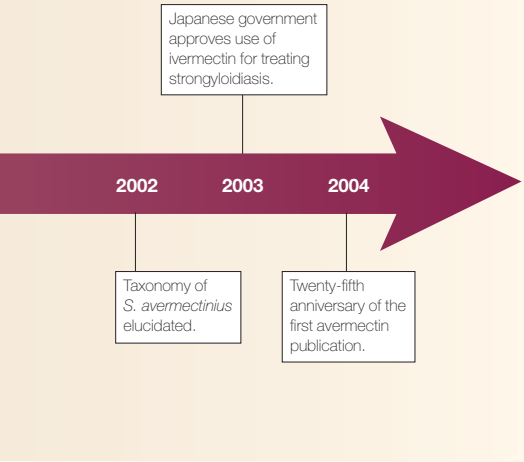


Figure 1 | **Micrograph of *Streptomyces avermectinius*.** *S. avermectinius* is the only organism that has been found to produce the avermectins.

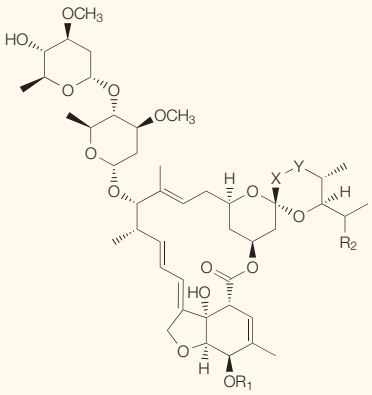
Avermectins are a complex of 16-membered macrocyclic lactones, and fermentation of *S. avermectinius* produces a mixture of eight avermectin compounds (A_{1a}, A_{1b}, A_{2a}, A_{2b}, B_{1a}, B_{1b}, B_{2a} and B_{2b}) (FIG. 2). Compounds of the B-series containing a 5′-hydroxyl group are markedly more active than those of the A-series, which contain a 5′-methoxyl group. The 1-series and 2-series have similar activity against many parasites[8]. An interdisciplinary team at MSD, headed by William Campbell, investigated the eight active compunds, of which avermectins B_{1a} and B_{1b} were found to have the highest activity. Reduction of the C_{22}–C_{23} double bond of B_{1a} and B_{1b} compounds with Wilkinson's catalyst improved both the spectrum of activity and safety (resulting in very low mammalian toxicity), and the resulting 22,23-dihydro B_1 complex (as a mixture of 80% B_{1a} and 20% B_{1b}) was selected for further commercial development under the generic, non-proprietary name, ivermectin[9]. Although structurally similar to macrolide antibiotics and antifungal macrocyclic polyenes, the avermectins have no antibacterial or antifungal activities.

Further analysis revealed that ivermectin was highly efficacious against mite, tick and botfly ectoparasites, which are organisms that cause massive economic losses in the livestock industry. MSD researchers also observed that the compound had remarkable activity against endo- as well as ectoparasites in horses, cattle, pigs and sheep. Ivermectin was also found to be successful in treating larval heartworms, but not adult worms, and could be used to treat mange and other conditions in dogs. However, no activity was found against flatworms, protozoa, bacteria or fungi[10].

In 1999, the Kitasato group reported that 17 genes of *S. avermectinius* encode enzymes that are involved in avermectin biosynthesis. Of these, those encoding four types of I polyketide synthases are concerned with lactone formation, via 12 cycles and 53 steps. The remainder act on pathway-specific regulation, with 12 genes being involved in modification of the lactone ring, biosynthesis of oleandrose and its glycosylation[53].

In 2003, the Kitasato team sequenced the *S. avermectinius* genome, which is the largest bacterial genome sequence reported so far[11,12]. Analysis of the genome allowed identification of the gene cluster involved in secondary metabolite production, shedding light on the biology of microbial secondary metabolite synthesis at the genetic level.



Mode of action

Initially, owing to its rapid and specific antiparasitic and anthelmintic action, it was proposed that ivermectin was an agonist for neurotransmitter function. Experimental studies confirmed this proposal when it was shown that inhibition occurred via glutamate-gated chloride ion channels in nerve and muscle cells[13]. Ivermectin interacts with these channels, preventing their closure. Consequently, synapse membranes become increasingly permeable to chloride ions, which leads to hyperpolarization of the neuronal membrane and decreases, or prevents, neuronal transmission. This, in turn, leads to paralysis of the somatic muscles, particularly the pharyngeal pump, causing the death of the parasite[14,15]. γ-aminobutyric acid (GABA)-related chloride ion channels, which are present only in nematodes, insects and ticks, are only inhibited with greater drug concentrations[16–18]. In mammals, GABA receptors and neurons are found in the central nervous system, whereas in arthropods and nematodes they are located in the peripheral nervous system. This, coupled with the relatively low dose concentrations needed, ensures that mammals can ingest ivermectin with a high degree of safety.

Animal health

Ivermectin was introduced to the market in 1981 as a veterinary antiparasitic drug and soon proved to be the most effective, broad-spectrum antiparasitic drug ever developed. It quickly became a remarkable success, rapidly capturing a large portion of the global veterinary antiparasitic market, and became the market leader within two years — the drug has maintained that position ever since, with annual sales of about US$1 billion. Since the introduction of ivermectin, several other

Figure 2 | **Structure of the avermectins.** The inclusion of different groups at positions R_1, R_2, X and Y create the eight different avermectin compounds A_{1a}, A_{1b}, A_{2a}, A_{2b}, B_{1a}, B_{1b}, B_{2a} and B_{2b}.

endectocides have appeared but none have replaced ivermectin as the market leader.

Five years after its introduction, ivermectin was registered for use in 46 countries and was being used worldwide to treat approximately 320 million cattle, 151 million sheep, 21 million horses and 5.7 million pigs[19]. Most horses in the United States were treated with the drug to the extent that the horse nematode *Onchocerca cervicalis* has now virtually disappeared.

Public health

At the time the collaboration between the Kitasato Institute and MSD was being set up and becoming operational in the mid-1970s, onchocerciasis (or river blindness) had long been a major global health problem. The disease results from infection with *Onchocerca volvulus*, which is a parasitic worm that lives in the human body. Adult female worms live for up to 14–15 years, producing millions of microscopic larvae (microfilariae) that migrate in the body, causing a variety of symptoms (FIG. 3). The bite of infected blackflies (*Simulium* spp.) transmits immature larval forms of the worms from human to human. Adult worms, which take a year to mature, lodge in nodules under the skin, releasing millions of microfilariae into surrounding tissues, which then migrate through the body, living for 9–18 months. When the microfilariae die, the resulting residue causes visual impairment and blindness, skin rashes, lesions, intense itching and depigmentation of the skin, lymphadenitis and general debilitation. Onchocerciasis is found in 35 countries, including 28 nations in tropical Africa where 99% of infected people live (FIG. 4). Isolated foci also occur in Latin America and Yemen. Each year, approximately 18 million people are infected, with more than 6.5 million people suffering from severe itching, dermatitis and impaired visual acuity, and 270,000 patients suffering from complete blindness. The disease is estimated to be responsible for the loss of 1 million disability-adjusted life years (DALYs) annually. In the early 1970s, the only drugs that were available to treat the disease were suramin, which is a highly toxic molecule that had to be administered in repeated injections over a period of several weeks, and diethylcarbamazine, which also had to be administered over several weeks. Diethylcarbamazine can also cause severe side effects due to the accumulation of dead parasitic tissue, a process that can result in blindness. By the mid-1970s, it was clear that both drugs could actually worsen eye lesions and so the use of chemotherapy for onchocerciasis was stopped[20].

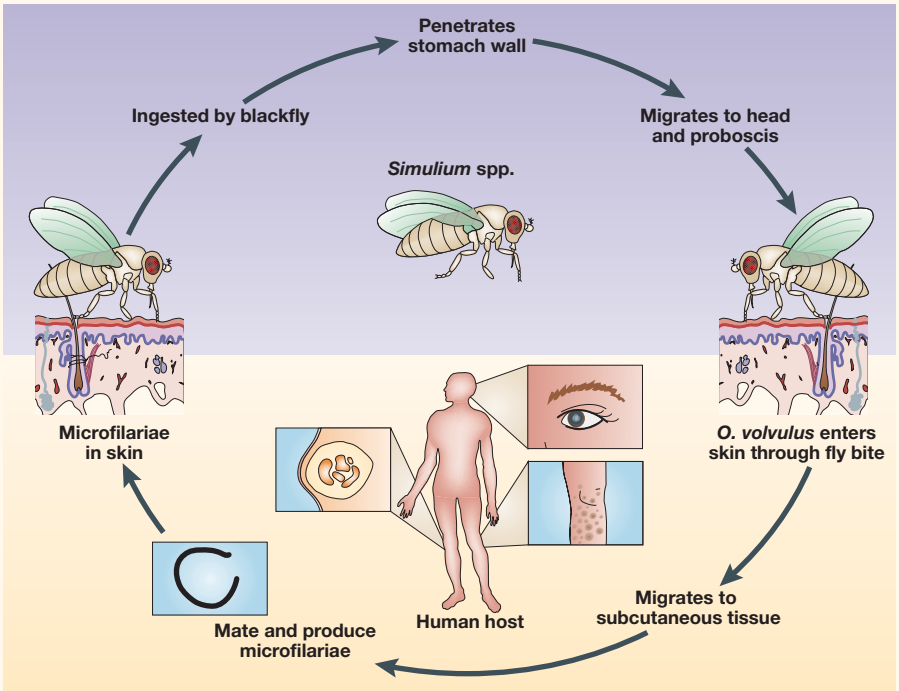

Figure 3 | **Schematic representation of the life cycle of *Onchocerca volvulus*.** When a parasitized female blackfly (*Simulium* spp.) takes a blood meal, infective *Onchocerca* larvae pass into the host through the fly-bite wound. Larvae enter subcutaneous tissue, where they migrate, aggregate in nodules, mature into adult worms and mate. After mating, eggs in female worms develop into immature larvae (microfilariae), each worm is capable of producing 1,000 microfilariae per day. Many thousands of microfilariae are released to migrate in subcutaneous tissue. When they die, they cause skin rashes, lesions, intense itching and skin depigmentation. Microfilariae also migrate to the eye and can cause visual impairment and blindness. When the infected host is bitten by another female fly, microfilariae pass into the blackfly, where they develop into infective larvae, and the life cycle continues.

There was hope, however, for a new and effective treatment. The MSD research in horses had demonstrated that ivermectin killed *Onchocerca cervicalis*, which are nematodes that are closely related to *Onchocerca volvulus*, so work began to investigate the possible use of ivermectin in humans. MSD joined forces with the World Health Organization (WHO), the Special Programme for Research and Training in Tropical Diseases (TDR) and the Onchocerciasis Control Programme in West Africa (OCP) to carry out an extensive collaborative research programme in humans. This proved to be an early example of the so-called public–private partnerships (PPPs) that are now being created in increasing numbers to coordinate the production and distribution of effective therapies for diseases for which there is little likelihood of a financial return on investment.

In 1981, clinical trials of ivermectin, which was produced under the brand name 'Mectizan', began in Senegal[21,22]. Over the next

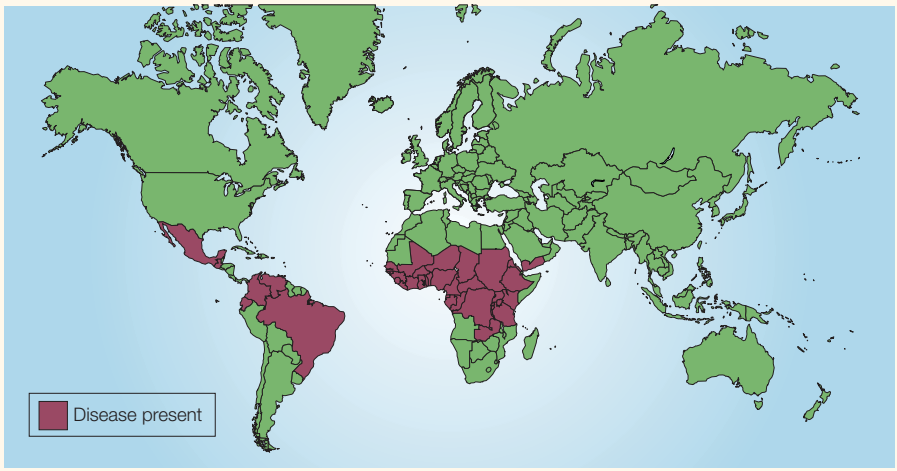

Figure 4 | **Global distribution of onchocerciasis.** Data obtained from the WHO.

four years, large-scale field trials involving hundreds of thousands of individuals were undertaken in Ghana, Guatemala, Cote d'Ivoire, Liberia, Mali, Senegal and Togo. Phase II studies reported that local inflammatory responses in ocular tissue were less severe with ivermectin than with diethylcarbamazine, thereby avoiding the unwanted Mazzotti reaction — by which the accumulation of dead parasitic material can induce blindness. Results showed that a single annual dose of 200 μg per kg of body weight eradicated microfilarial worms from the eye and skin after one month, and patients remained worm-free for up to 12 months after treatment[23–25]. Later, large-scale community trials in various epidemiological conditions, including hyper- and meso-endemic areas, found that ivermectin reduced the levels of skin microfilaria by 96–99% within the first few months of therapy[26]. It has been repeatedly shown that ivermectin has little impact on adult worms and that multiple doses do not have much impact on oogenesis[27]. Adult worms can continue to reproduce, so ivermectin is suppressive rather than curative; however, treatment leads to a marked reduction in the number of immature worms and reduces microfilarial loads after each course of treatment[21,28]. Several follow-up studies have shown that the marked reduction in both prevalence and intensity of microfilaridermia is maintained, even after five years of treatment[29–31]. Ivermectin has the added benefits of allowing the body to repair minor eye lesions and reduces the severity of itching and the prevalence of skin lesions[32]. Some researchers argue that ivermectin alters the mechanisms by which adult worms locate each other and that this explains why fewer males are found in nodules after multiple treatments[33]. More frequent administration of ivermectin, for example bi-annually rather than annually, could have a sterilizing effect on adult female worms and reduce their lifespan[34]. Nevertheless, taking the drug over the lifespan of the adult worms effectively prevents patients from developing the disease.

Following the work of a truly international partnership involving the public and private sectors, governments of disease-endemic countries and affected communities, the human formulation of ivermectin was registered for use by French regulators in 1987 with mass drug administrations commencing in 1988.

The use of ivermectin can cause adverse side effects, the most common being oedema, fever, pruritus and pain[35,36]. They are generally mild and transient, however, and can be easily treated by primary healthcare workers or trained lay members of the community. Indeed, the incidence of adverse reactions in follow-up studies on distribution programmes has actually been less than that observed during clinical trials[37]. Ivermectin can also have serious effects on individuals heavily infected with *Loa loa*, which causes severe encephalopathy that can prove fatal[38]. Consequently, it is essential to take appropriate safety measures to exclude any such people from mass drug-administration programmes. A comprehensive review of serious adverse events following Mectizan treatment carried out in 1989–2001 found 207 cases from a reported 165 million treatments, representing an incidence ratio of 1 per 800,000 treatments[39].

Drug donation

During the latter stages of human trials, discussions took place between the public and private sectors to determine a suitable price for the drug, bearing in mind that the end-users of the product would be poor and marginalized communities. In 1987, after receipt of consent from the Kitasato Institute, which agreed to forego royalties, P. Roy Vagelos, the then chief executive of MSD, announced that ivermectin (under the brand name Mectizan) would be provided free of charge for the treatment of river blindness for "as long as it is needed", a pledge that has been honoured ever since. The advent of this drug donation has transformed the treatment of onchocerciasis to a point where elimination of the disease has become an achievable goal.

Community-directed treatment

Also in 1987, the TDR began to fund pioneering research on the concept of 'community-based treatment' using ivermectin. The rationale behind this concept was that the drug was so safe and easy to use that affected communities should be able to organize their own drug distribution and treatment. In the field, community-directed treatment proved to be remarkably successful and, in 1989, the WHO announced that ivermectin could be administered "with minimal supervision". It was subsequently noted that ivermectin coverage was greatest when affected communities were allowed to design and implement their own drug-distribution programme[40]. The TDR went on to develop the community-directed treatment with ivermectin (ComDT) procedure, which became the operational basis of the African Programme for Onchocerciasis Control (APOC). Established in 1995, the aim of APOC is to create sustainable community-directed distribution systems using mass distribution of ivermectin to all those eligible by 2007, ultimately covering 59 million people in African countries where the disease remains a serious public-health problem and where 15 million people are heavily infected. The goal is to eliminate the disease in the 17 African nations where it still persists after the successful control of the disease in the 11 west-African nations covered by the OCP. Meanwhile, the Onchocerciasis Elimination Programme in the Americas (OEPA), which was launched in 1992, is based on the premise that mass administration of Mectizan tablets can rid the region of the disease relatively quickly, as the vector blackflies in this region transmit the parasite with reduced efficiency. The programme is expected to achieve its goal of eliminating the disease from the region by 2007 (REF. 20). Community-directed treatment is producing excellent results in the fight against onchocerciasis. Affected villages collect Mectizan tablets, deliver them to all those eligible and report back to health authorities — and meet all the costs involved themselves

FOI 26-3132 - Document 5

(the drug being provided free to district health posts). The correct dosage can be calculated simply by measuring the height of the recipient. In 2003, approximately 56 million Africans were taking a single annual dose of ivermectin[41]. The overall goal of these programmes is to eliminate onchocerciasis as a public-health problem globally by 2010.

Economic aspects

Mectizan is viewed by some as one of the finest public-health success stories of the past century, and a model for all future public and private sector partnerships. However, analysis of the economics indicates that success depends on financial commitment from both sectors. Cost-effective analyses of the mass distribution of ivermectin have identified a cost of US$14–30 per DALY that is prevented[42]. This compares reasonably well with other control programmes for priority diseases, but the benefit ratio in this case is only possible due to the huge financial commitment from Merck & Co., which pays the production costs of Mectizan, the costs of transport from the manufacturing facility in France to the recipient countries and the related customs and other handling costs. In total, more than 250 million doses of ivermectin have been administered since the start of the Mectizan donation programme. In 2000, APOC devoted 63% of its total annual budget of US$9.4 million to ivermectin distribution programmes. Using the US$1.50 figure claimed by the Mectizan Donation Programme as being the cost of a single tablet, the value of the ivermectin contributed by Merck & Co. in 2001 is estimated to be US$143.6 million for APOC countries alone. This can be compared with the total 15-year costs of the APOC programme, which are estimated to be US$182.5 million[43].

APOC and others are working towards reducing the actual costs of 'free drug' donation programmes, with APOC focusing on a target distribution cost of US$0.20 per treatment[43]. A study of two villages in Nigeria found that 92–93% of inhabitants were willing to pay US$0.30 and US$0.28, respectively, to meet their ivermectin distribution needs. The actual costs of treatment in the two villages were calculated as US$0.13 and US$0.17, respectively[44,45], which bodes well for maintaining sustainable, long-term mass distribution programmes for the period of time that is needed to achieve disease elimination. The continuing, concerted and long-term commitment of donors (led by the World Bank), non-governmental organizations, governments, health services and affected communities will be essential if the elimination goal is to be achieved.

Lymphatic filariasis

The success of ivermectin does not stop with the potential elimination of onchocerciasis as a public-health threat. Combinations of ivermectin and albendazole or ivermectin and diethylcarbamazine have been adopted as the basis of mass treatment in the Global Alliance to Eliminate Lymphatic Filariasis, which was initiated by the WHO in 1997. The efficacy of the ivermectin and albendazole combination therapy for bancroftian filariasis was first reported in 1997 (REF. 46). Lymphatic filariasis is one of the most prevalent tropical diseases, with an estimated 120 million people being infected annually. The disease is responsible for 5 million DALYs lost each year, ranking it third among tropical diseases in terms of DALYs, after malaria and tuberculosis. Almost 1 in 5 of the world population are at risk of infection and the disease remains a major impediment to socio-economic development in endemic areas — India loses an estimated US$1 billion annually as a result of lymphatic filariasis. In an effort to curb this disease, Merck & Co. confirmed that they would donate Mectizan free of charge to the elimination programmes in regions where onchocerciasis and lymphatic filariasis coexist. GlaxoSmithKline, the manufacturers of albendazole, also announced that they would donate this drug for lymphatic filariasis control programmes, which are working towards the goal of eliminating the disease by 2020.

New uses for ivermectin continue to be found. For example, in 2003, ivermectin was registered for the treatment of strongyloidiasis, an intestinal parasitic disease that is widely distributed in the tropics and subtropics and which is prevalent in south-east Asia and southern Japanese islands. More than 10 million people are infected with the causative microorganism.

Future use

A microorganism from a single site in Japan has provided a drug that has proved to be one of the most successful tools in human and animal health, and one that has been the mainstay of several of the most successful disease-control programmes in the history of public health. Moreover, the benefits continue to accrue. It is common knowledge that malnutrition and undernutrition are major causes of ill health in Africa and throughout the developing world, particularly among young children. Ivermectin is known to be particularly effective against infection with *Ascaris* worms and reasonably effective against hookworm and *Trichuris*[47,48]. Furthermore, the prevalence of head lice is markedly reduced in children taking ivermectin tablets[49]. In Japan, ivermectin may soon be routinely used in special circumstances, such as in homes for the elderly to help control the incidence of scabies.

Perhaps of greater significance, ivermectin became available at a time when resistance to other similar drugs, such as benzimidazole and levamisole, was common. Very few cases of resistance to ivermectin have been reported and any future development of widespread resistance is thought to be unlikely[16]. Parasites that are resistant to the avermectins are also resistant to the milbemycins and it is likely that P-glycoproteins (plasma-membrane-associated drug efflux transporters) are involved in the resistance mechanism[50]. It is also postulated that resistance could be mediated by mutations in the gene encoding the α-subunit of glutamate-gated chloride channels; However, the exact resistance mechanism is still a matter of conjecture[51].

The discovery, development and deployment of ivermectin through the efforts of Merck & Co. and the Kitasato Institute, aided by a group of international partners from a range of disciplines, has been hailed by some commentators as one of the greatest medical achievements of the twentieth century[52]. Vigilance is now needed to ensure that the progress that has been made against several devastating diseases is maintained. The strain of *Streptomyces* found in Japan remains the only microorganism that produces avermectin. The Kitasato Institute, and similar organizations, remain dedicated to the search for further microbiological treasures for use in public health from among the myriad of substances produced by the world's reservoir of environmental microorganisms.

OPINION — ANTI-INFECTIVES

Antibiotic resistance: a view from the prescriber

Roger G. Finch

Abstract | Antibiotic resistance is increasingly affecting the management of infectious diseases. The prescribing clinician is not only important to the development of the problem but also central to its solution. This article addresses the current weaknesses in the information systems and the evidence base that support prescribing. Remedies necessary for improvements in prudent prescribing include better guidance in managing specific diseases where resistance is of prognostic significance and also increasing diagnostic precision.

The increasing prevalence of antibiotic-resistant microorganisms is now an issue of major public concern. Newspaper headlines and media reports regularly feature details of their impact on individuals as well as raising the spectre of widespread and untreatable drug-resistant infections. The breadth and significance of antibiotic-resistant micro-organisms is becoming increasingly apparent. Examples include outbreaks of multiply antibiotic-resistant pathogens in intensive care or neonatal units; the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) in hospitals and, more recently, nursing homes; the global occurrence of drug-resistant malaria in tropical and sub-tropical regions; and drug-resistant tuberculosis, with its links to poverty, HIV and social exclusion.

Reports on antibiotic resistance and concerns raised by infection specialists over the past fifty years were largely unheeded until the mid-1990s when the significance of the problem achieved political recognition. In 1995, the American Society for Microbiology[1], and in 1998, a House of Lords Select Committee in the United Kingdom[2], issued reports that have been influential in establishing national strategies. In the United States, a task force was established[3]. The European Union also published its strategy[4] and addressed the problem through a series of conferences on antibiotic resistance, such

Abstract
Objectives: We investigated the outcomes of Ivermectin-Doxycycline vs. Favipiravir therapy in mild to moderate COVID19 patients.
Methods: Patients were divided randomly into two groups: Ivermectin 200µgm/kg single dose + Doxycycline 100mg BID for ten days in group A, and Favipiravir 1800mg for the first day, then 800mg BID for six days in group B (Control group). RT-PCR for SARS-CoV-2 infection was repeated in all symptomatic patients on the second day onward without symptoms. Repeat PCR was done every two days onward if the result found positive. Time to the negative PCR and symptomatic recovery was measured for each group.
Results: All subjects in Group A reached a negative PCR, at a mean of 8.93 days, and reached symptomatic recovery, at a mean of 5.93 days, with 55.10% symptom-free by the fifth day. In group B, 96.36% reached a negative PCR at a mean of 9.33 days and were symptoms-free at 6.99 days. In group a 31.67% of patients expressed symptoms caused by medication, this was 46.43% in group B.
Conclusion: The combination therapy of Ivermectin-Doxycycline showed a trend towards superiority to the combination of Favipiravir for mild to moderate COVID19 disease.

Keywords: COVID-19, doxycycline, favipiravir, ivermectin

Introduction
Coronavirus disease 2019 (COVID-19) is a global pandemic declared by the world health organization (WHO). Over ninety million people have already been infected by severe acute respiratory syndrome- coronavirus- 2 (SARS-CoV-2), and billions have been affected by the socioeconomic squeal. As SARS-CoV-2 is a novel virus, there are no proven treatment options yet. Early treatment before the disease becomes severe would be optimal. Recently, an anti-parasitic drug Ivermectin has been described as highly effective in an *in vitro* study against SARS-CoV-2 [4]. an encouraging result in a case series of COVID19 patients with a combination of Ivermectin and Doxycycline. Ivermectin is well-tolerated, less toxic, and has fewer adverse effects than Favipiravir.

Methods
Informed Consent was taken. The individuals who gave consent were enrolled in this study. Study Population and Data Collection Patients (16 years to 80 years of age) tested positive for SARS-CoV-2 infection by Real-time polymerase chain reaction (RT-PCR) at Geetanjali Medical College and Hospital from May 2020 to the December 2020, were initially included in this study, including those with and without the symptoms. All patients received a full evaluation, including a history of current illness, comorbid condition, and associated complaints. Patients with unstable comorbid conditions like bronchial asthma, chronic obstructive pulmonary disease (COPD), ischemic heart disease (IHD), uncontrolled diabetes mellitus (DM), advanced renal and hepatic disease, carcinoma, hospitalized, and immuno-compromised patients were excluded. Patients were examined for oxygen saturation and only those with oxygen saturation of 95% or above who fit the outpatient treatment protocol for COVID19 were included. Patients with respiratory symptoms received chest radiographs. Those with normal or near-normal chest radiographs (up to 10% involvement) were

included. Randomization and Treatment Intervention Randomization was done using an odd-even methodology and applied to registration number of study patient, consecutively in a 1:1 ratio. Treatment was given, and the final enrolment was done by the attending physician (investigator). All the patients enrolled in this study were treated as outpatient department (OPD) patients. For the study, patients were divided into two groups, as follows: • Group A (n=60): Ivermectin 200µgm/kg single dose + Doxycycline 100mg BID for ten days. • Group B (n=56): Favipiravir 1800mg for the first day, then 800mg BID for six days. All the subjects were provided with symptomatic treatment such as fever, headache, cough, and myalgia. Drug interactions and contraindications for each individual were considered carefully. The schedule of medication intake was adequately explained to each patient. Group A's instructions included that Ivermectin tablet (200µg/ kg) single dose to be taken on an empty stomach an hour before a meal on the first day. Doxycycline 100 mg capsule be taken twice daily after meal for ten days starting from day one. Group B's instructions included Favipiravir 1800mg for the first day, then 800mg twice daily after meal for six days. Patients were advised to self-isolate, take proper nutrition, hydration, and maintain a sanitary environment. Repeat Nasopharyngeal and Throat Swab PCR All subjects underwent repeat nasopharyngeal and throat swab PCR for SARS-CoV2 every other day until their PCR was negative. These repeat PCR tests began on the fifth day after taking the medication for subjects who began the study and remained symptom-free. The PCR repeat testing began on the second symptom-free day onward for subjects who began the study with symptoms or developed symptoms. The investigators had telephone contact with all the subjects every three days throughout the study to determine any therapy's adverse effects. A re-evaluation PCR was performed after seven days following the first negative PCR.

Data Analysis and Statistics: Data were presented as mean±standard deviation, and statistical analysis was done by Graph pad Prism software. Column analysis was done to find the mean with the standard deviation in each group. T-test was done to see the significance between the values where needed. P>0.05 was considered statistically significant.

Results

181 patients tested positive for SARS-CoV-2 infection in that period. 42 patients had comorbid conditions (some required hospitalization) that might have affected the recovery time, and 14 patients were unwilling to participate in the study. Nonetheless, 9 patients did not show-up (3 from group A and 6 from group B) for the follow-up sample collection, so these were excluded, and 116 patients were finally included in the analysis. Demographic Characteristics of the Study Subjects As shown in Table 1, the total number of patients was 116; male 84 and female 26, age 16 to 80 years, and mean age (33.94±14.12 years). Group A (Ivermectin + Doxycycline): male 43 (71.67%), female 17 (28.33%), age 35.72±15.1 years; males 37 years and female 32.88 years. Group B (Favipiravir): male 47 (83.93%), female 9 (16.07%), age 31.91 years; male 31.35, and female 34.5 years. Among the total, 91 (78.45%) were symptomatic, and 25 (21.55%) were asymptomatic patients with contact history. These were 49 (81.67%) and 11 (18.33%) in group A, 42 (75%) and 14 (25%) in group B. Recovery Rate and Mean Recovery Duration Between Groups In group A, recovery to negative PCR rate was 100% (60/60). The mean recovery duration to negative PCR was 8.93 days (8 to 13 days). 41 (63.3%) of patients had no new complaints other than their presenting symptoms. New symptoms that may have been attributed to adverse drug effects included lethargy in 14 (23.3%), nausea in 11 (18.3%), and occasional vertigo in 7 (11.66%) of patients (Fig. 1c). In group B, out of 56 patients, two male patients were shifted to ICU. They did not recover to a negative PCR as part of the study. Therefore, the recovery rate to negative PCR was 96.36% (54/56). The mean duration of recovery to negative PCR was 9.33 days (5 to 15 days). 30 (53.57%) of the patients had no new complaints other than their presenting symptoms. Fresh symptoms that were recognized as an adverse effect of HCQ included 13(23.21%) with mild blurred vision and headache; 22 (39.2%) with increased lethargy and dizziness, 10 (17.85%) with occasional, mild palpitation, and 9 (16.07%) with nausea and vomiting. Difference in Recovery to Negative PCR between Groups The difference between group A and group B recovery to negative PCR duration was not statistically significant in unpaired t-test, p=0.2314. Subgroup analysis of the recovery duration: male 9.18±1.90 days and female 8.92±1.32 days, p=0.515; in group A male 8.907±1.342 days and female 9±1.173 days, p=0.44; and in group B male 9.18±1.90 days and female 8.92±1.32 days, p=0.407. The recovery duration of both group males and females were not significant, p=0.18 and 0.69, respectively. The mean duration of symptomatic recovery was 5.93 days (5 to 10 days) in group A and 6.99 days (4 to 12 days) in group B. This difference in time to symptomatic recovery between group A and group B is not statistically significant, p=0.071. In group A, over half of the subjects had become symptom-free by five days 27 (55.10%), with the remaining subjects becoming symptom-free on day six (16.32%), day seven (12.24%), day eight (8.16%), day nine (4%), and day ten (2.04%). In group B, recovery was slower with subjects becoming symptoms free on fourth day 3 (7.14%), the fifth day 10 (23.8%), sixth day 9 (21.43%), seventh day 8(19.04%), eighth & ninth day 4 (9.52% each), eleventh day 2 (4.76%), and tenth and twelfth day (2.38% each). Mean Duration of Time to Negative PCR between Groups In the secondary analysis of subjects who began the study with symptoms, the mean duration of time to negative PCR was 9.061 days in group A and 9.738 days in group B. This was not statistically significant in the unpaired t-test, p=0.0714. The mean duration of time to becoming negative PCR of patients without symptoms was 8.364 days in group A and 7.917 days in group B, which was not statistically significant in unpaired t-test, p=0.443. Further analysis showed the highest recovery was achieved on the eighth day among group A patients in case of both asymptomatic (n=11) and symptomatic (n=49) patients, 8 (72.72%) and 22 (44.89%), respectively (Fig. 2 c, d). This recovery was relatively slower in group B. On the sixth day 3 (7.5%), seventh day 1 (2.5%), eighth day 9 (22.5%), ninth and tenth day 8 (20%) each, eleventh and twelfth day 4 (10%) each, thirteenth day 1 (2.5%), and fourteenth day 2 (5%) in group B patients with symptoms (n=40). Among asymptomatic patients (n=14), this was 1 (7.5%) on the fifth day, 2 (14.2%) individually on the sixth, seventh, eighth, tenth day, 4 (28.57%) on the ninth day, and 1 (7.1%) on the eleventh

day. No significant difference in the recovery duration was found in the subgroup analysis of the recovery duration according to the study group's age. 61 to 70 years in group A had the longest recovery duration, 9.5±2.12, and 71 to 80 years was the shortest 8 days. In group B, this was 11.71±2.48 days in the 41 to 50 years and 8.37±2.44 days in the 10 to 20 years age group.

Female	34
Symptomatic	42
Asymptomatic	14

Discussion

The COVID-19 pandemic in India is part of the coronavirus worldwide pandemic disease caused by a newly discovered coronavirus. It was initially called novel coronavirus and later named SARS-CoV-2 due to its similar characteristics with SARS-CoV-1 [7-9]. New concerns about Favipiravir has led us to seek alternatives with shorter recovery time and better tolerability. Thus, we have undertaken a comparative therapeutic analysis, comparing these standard drugs with Ivermectin and Doxycycline. In this treatment study of groups A and B, the presenting symptoms of the COVID19 patients were fever, cough, sore throat, weakness, chest discomfort, breathing difficulty, diarrhea, myalgia, and abdominal pain. To avoid the recovery duration's influence, we solely selected the cases devoid of severe comorbidities. The difference in recovery to negative PCR duration was not significant (p=0.231) among the two groups. The mean recovery duration is shorter, 8.933 days in group A than in group B, 9.33 days. Also, group A had a better outcome ratio of 100% (60/60) recovery to negative PCR compared to that of group B 96.36% (54/56). At present, it has been the topic of discussion concerning Favipiravir potential use to treat patients with COVID-19 [11]. It is thought that the effect of Favipiravir results in the selective killing of the infected cells. Therefore, it may accelerate viral clearance in COVID-19 [13]. Some studies showed that severe deterioration in some patients with COVID-19 had been closely associated with dysregulated and excessive cytokine release termed "cytokine storm [14, 15]." Favipiravir was found to inhibit SARS-CoV-2 infection *in vitro* and significantly decrease cytokine production, especially the pro-inflammatory cytokines [16]. On the other hand, Ivermectin is a relatively safe and well-tolerated anti-parasitic drug that can inhibit nuclear transport activity [20]. Recently, *in-vitro* studies have shown its function against SARS-CoV-2 [21, 22]. A report suggested that Ivermectin reduces mortality rates in hospitalized patients with COVID-19 [23]. However, it is unknown if antiviral levels are attainable while using known dosing regimens of Ivermectin therapy in patients with COVID-19. [24, 25] Thus, it is vital to investigate Ivermectin's dose regimens for COVID-19 treatment or to determine if there is appropriate synergism using combination therapy with another drug. Also, Doxycycline is a tetracycline class of antibiotics with a long history of clinical use [26]. The efficacy and tolerability of Ivermectin and Doxycycline were established in combination with an earlier study to treat onchocerciasis [27]. Several recent studies have suggested a therapeutic role of Doxycycline against COVID-19 [28, 29]. In our study, the difference in recovery to become symptom-free was not statistically significant. Nevertheless, the Ivermectin group showed better symptomatic recovery than the Favipiravir group. According to the age among study groups, the difference was not statistically significant. Ivermectin-Doxycycline combination expressed an earlier and faster relief of COVID features and viral clearance than the favipiravir combination. However, the mean recovery duration is not statistically significant. In the Ivermectin-Doxycycline group a greater number of patients gained faster symptomatic recovery than that of the Favipiravir group. This suggests Ivermectin-Doxycycline may have better efficacy in reducing the COVID-19 symptoms than Favipiravir therapy. The Ivermectin-Doxycycline group had better patient compliance and fewer adverse effects compared to the Favipiravir group. The adverse effects of Favipiravir in our study are similar to others [30, 31]. The sex difference was also examined, but there were no significant differences between males and females in this study. According to this study, the Ivermectin-Doxycycline treatment regimen was well tolerated, and effective treatment for mild to moderate degrees of SARS-CoV-2 infection. Not only concerning the time to become symptom-free and the viral clearance, but also in terms of safety, side-effect profile, and compliance the Ivermectin-Doxycycline combination is superior to Favipiravir therapy for mild to moderate degrees of COVID-19 patients. We strongly believe that increasing the dose and the duration of Ivermectin treatment will further benefit in reducing the recovery period of COVID19 infection beyond that which was seen in our study. This will also prevent disease progression and morbidity in COVID-19 patients. Our study has limitations, and these include relatively small sample size, the dose of Ivermectin, and case selection. The outcome may be biased by factors like disease severity, lack of cooperation of some participants, and unknown comorbidity.

Conclusion

According to our study, the Ivermectin-Doxycycline combination therapy has better symptomatic relief, shortened recovery duration, fewer adverse effects, and

superior patient compliance compared to the Favipiravir. Based on this study's outcomes, the Ivermectin-Doxycycline combination is a superior choice for treating patients with mild to moderate COVID-19 disease. Despite this study's limitation, we tried to select our study group patients without any major or unstable comorbid condition as far as possible to avoid differences in treatment outcomes among the groups.

Comparison of Viral Clearance between Ivermectin with Doxycycline and Hydroxychloroquine with Azithromycin in COVID-19 Patients

MA RAHMAN[a], SA IQBAL[b], MA ISLAM[c], MK NIAZ[d], T HUSSAIN[e], TH SIDDIQUEE[f]

Abstract:

Introduction: The whole world is on the brink of collapse due to the outbreak of COVID-19 with no solution to treat these cases with any specific drug. Extensive search for the Vaccine or effective treatment is going on while alarming infection and death toll is rising every day.

Aim: The study will compare the effect of Ivermectin with Doxycycline and Hydoxychloroquine with Azythromicin on a selective group of COVID -19 positive patients.

Method: This is a comparative study that included 400 patients of COVID 19 positive patient who were divided in to two groups. Group- A Received Ivermectin with Doxycycline and the other group- B received hydroxichloroquine(HCQ) with azithromycin.

Result: Viral clearance is 132 (66%) on day 5 and 167(83.5%) on day 6. Among them 33(16.5%) remain PCR positive after 6th day of Ivermectin ingestion in Group A. Whereas there is154 (77.0%) viral clearance at 11th day and 163(81.5%) viral clearance at 12th day of Hydroxychloroquine ingestion in Group B. Among them 37 (18.5%) remain PCR positive after 12 day in group B. The P value is 0.000427 which is significant considering 5th day viral clearance of Ivermectin ingestion and 11th day of Hydroxychloroquine ingestion. But considering 6th day and 12th day the P-value is 0.59 which is not significant.

Conclusion: It appears Ivermectin and Doxycycline is safeand effective combination drug therapy in COVID-19infected patients but need further extensive study to find out the scope of application on other groups of patients.

Introduction:

While the world is awaiting a vaccine, the death toll is rising day by day. We need to find effective drugs to treat coronavirus disease-19 (COVID-19). Several drugs have been proposed and practiced worldwide but none is confirmed or approved. In this study we are looking for an answer for the large group of population of this poor country.

A novel coronavirus 2019-nCoV was first identified in the state of Wuhan, China, at the end of 2019. Coronaviruses are basically a group of viruses containing nonsegmented, single-stranded RNA. These groups of virusescaused several outbreaks around the world, like 'Severe Acute Respiratory Syndrome (SARS) pandemic'in 2002-2003 and the 'Middle East Respiratory Syndrome (MERS) outbreak' in South Korea in 2015. But most recently,COVID-19 triggered an outbreak in China in December 2019, subsequently become pandemic. Though some of corona patient reached in to devastating epidemics outcome, but others manifested mild to moderate respiratory infections, like the common cold.[1]

Ivermectin is a broad spectrum anti-parasiticagent[2] seems to have some anti-viral activities against a large number of viruses[3,4,5,6] in vitro.Originally identiûed as an inhibitor of inter action between the human immunodeûciency virus-1(HIV-1) integrase protein (IN) and the importin (IMP) á/â1 heterodimer responsible for IN nuclear import.[7] Studies on SARS-CoV proteins have

FOI 26-3132 - Document 5

revealed a potential role for IMPá/â1 during infection in signal dependent nucleocytoplasmic shutting of the SARS-CoVnucleo capsid protein,[8,9,10] that may impact host cell division,[11,12] addition of the SARS-CoV accessory protein ORF6 has been shown to antagonize the antiviral activity of the STAT1 transcription factor by sequestering IMPá/â1 on therough ER/ Golgi membrane13. Taken together, these reports suggested that Ivermectin's nuclear transport inhibitory activity may be eûective against SARS-CoV-2. When doxycycline was combined with macrocyclic lactonesin adult worms, ivermectin efficacy was 80% compared with 9% when treatment was performed with doxycycline alone 14 The largest dose intensity with registered pharmacokinetic parameters in healthy subjects is 120 mg, corresponding to up to 2000 µg/kg.[15]

HCQ has shown antiviral effects at both preinfection and postinfection stages. HCQ could interfere with the glycosylation of angiotensin-converting enzyme 2, thereby reducing the binding efficiency between angiotensin-converting enzyme 2 on host cells and the SARS-CoV-2 spike protein. Moreover, HCQ could be able to block virus fusion with the host cell through the inhibition of protease activity in cleaving corona virus surface spike proteins.[16]

Far less is known about the antiviral effects of azythromicin, which has been suggested to interfere with influenza virus internalization[17]. Interestingly, CLQ is also considered as an inhibitor of endocytic pathways through an elevation of endosomal pH[18]. azithromycin was added to hydroxychloroquine, the efficiency of SARS CoV-2 elimination was significantly improved.[19]

Regarding diagnosis till now no test is gold standard making it more challenging in diagnosing the disease.Specificity of RT-PCR is dependent on site, like 63% for nasal swabs, and only 32% for throat/ pharyngeal swabs.[20]

Method:

It's a prospective comparative studyconducted at Combined Military Hospital Dhaka. Total 400 Covid-19 PCR positive patients were included in this study. Among them 200 cases received ivermectin 18 mg on first day and Doxycycline 100 mg twice daily for 05 days comprising Group A and the rest 200 patients were given hydroxichloroquine 800 mg on first day then 400mg daily for 10 days and azithromycin 500 mg one day then 250 g daily for 4 days comprised Group B.Diagnosis of Covid-19 was done by RT-PCR from nasal and pharyngeal swab. The patients who had mild to moderate disease according to 'National Guideline on clinical management of coronavirus disease 2019 (COVID-19) version 7.0' were included in this study. Severe and critical patients were excluded from the study.Patientswere admitted in corona ward in April 2020 were given RT- PCR on 11th day and 12th day in Group B after completion of the recommended dose. Whereas the PCR test were done on 5th and 6th day after ingestion of Ivermectin in corona ward during May 2020 in Group A. The date of check Rt-PCR was determined by the recommended dose of different drugs used in this study.

Result:

Total 400 patients were included in this study. None developed severe or critical disease during study.

Table-I

Demographic profile (n=400)

Demographic profile	Group A	Group B
Mean age in years	36.4	39.42
Age range in years	17-74	20-79
Male	78.5%(157)	188(94%)
Female	21.5%(43)	12(6%)

Above table shows demographic profile in which 78.5% (157) were male; 21.5% (43) were Female in Group A and 188 (94%) male and 12 (6%) female in group B. Their age range was 17-74 with mean 36.46 years in group A and in group B age range 20-79 with mean 39.42 years.

Symptoms of the patients during admission (n=400)

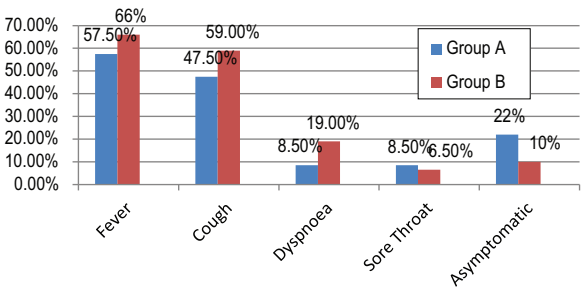

Fig.-1: *Showing Symptoms of Patient during admission*

FOI 26-3132 - Document 5

It shows that maximum patient had fever 57.5% and 66% in group A and B. Then next common symptom was Cough 47.5% and 59%. There were 22% patient who had no Covid symptoms in group A and only 10% in group B

Co-Morbidities of the patients (n=400)

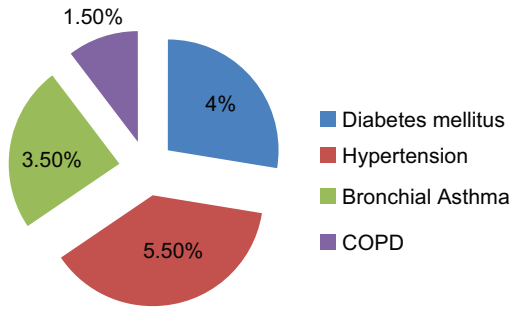

Fig.-2: *Pie chart Showing Co-morbidities of Group A*

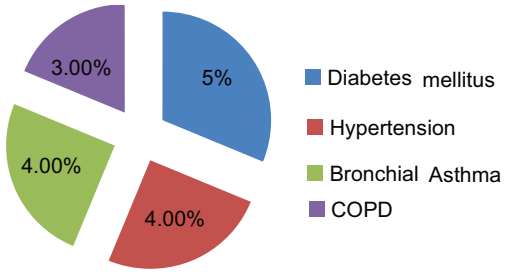

Fig.-3. *Pie chart showing Co- morbidities of GroupB*

Among the patients 11 (5.5%) had hypertension in group A and8 (4%) in Group B, 8(4%) and10 (5%) had diabetes mellitus respectively, 7(3.5 %) and 8(4%) had Bronchial Asthma and 3 (1.50 %)and 6 (3%) had COPD.

Viral Clearance of Group A and B (n=400)

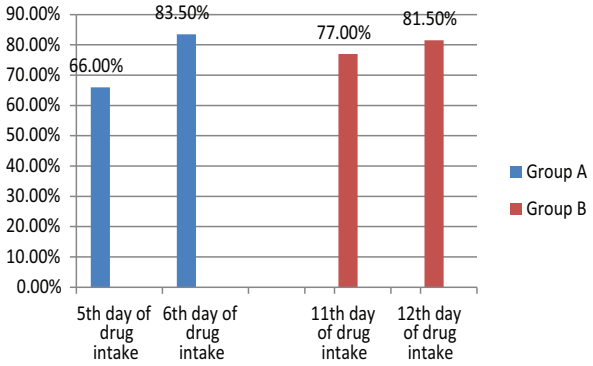

Fig.-4: *showing Viral Clearance*

Diagram showing viral clearance is 132 (66%) on day 5 and 167(83.5%) on day 6. Among them 33(16.5%) remain PCR positive after 6th day of ivermectin ingestion in Group A. Whereas there is154 (77.0%) viral clearance at 11th day and 163(81.5%) viral clearance at 12th day of hydroxychloroquine ingestion in Group B. Among them 37 (18.5%) remain PCR positive after 12 day in group B. The P value is 0.000427 which is significant considering 5th day viral clearance of ivermectin ingestion and 11th day of hydroxychloroquine ingestion. But considering 6th day and 12th day the P-value is 0.59 which is not significant.

Table-II

Uncommon Symptoms in Group A and B

Group A (n=200)		Group B (n=200)	
Symptoms	n (%)	Symptoms	n (%)
Anorexia	47 (23.5)	Anorexia	62 (31)
Vomiting	7 (3.5)	Vomiting	4 (2)
Diarrhoea	24 (12)	Diarrhoea	14 (7)
Skin Rash	20 (10)	Skin Rash	2 (01)

Above table shows some uncommon symptoms of the disease which can also be considered as drug effect due to sharing of the nature of presentation where anorexia (23.5% and 31 %) is the predominant feature is also a documented symptoms of Covid. Next effect was diarrhea (12%) in group A. Others were skin rash (10% and 1 %) and vomiting (3.5% and 2 %).

Table-III

Liver and Renal biochemical changes after drug intake in Group A and B

Group A	Group B	
Parameter	Mean	Mean
Serum Bilirubin	0.55±0.19 mg/dl	0.58±0.07 mg/dl
ALT	34.16±21.7 IU/l	29.16±18.8 IU/l
ALP	79.95±28.56 IU/l	88.6±23.77 IU/l
GGT	51.23±56.18 IU/l	49.23±66.18 IU/l
INR	1.142±0.084	1.1±0.062
Serum Creatinine	0.87±0.33 mg/dl	0.91±0.44 mg/dl

Above table showing the distribution of the liver and renal biochemical parameters in Group A and B. It shows that Bilirubinelevel is0.55 mg/dl and 0.58 mg/dl respectively. ALT level is 34.16 IU/L and 29.16 IU/L. ALP is 79.95 and 88.6 IU/Lin groupA and B. GGT is 51.23 IU/L and 49.23 IU/L. INR is 1.14 and 1.1 respectively.

FOI 26-3132 - Document 5

Creatinine is 0.87 mg/dl and 0.91 mg/dl in Group A and group B.

Discussion:

The search of effective anti-viral treatment against COVID-19 has led us to look into the existing drugs with anti-viral properties which may be effective against this novel CORONA virus. Ivermectin is a well-established anti-parasite drug used in both human and livestock animals. In-vitro studies have found profound anti-viral effect of this drug against several RNA viruses5including SARS-CoV-2.21 doxycycline has been is claimed to have antiviral properties by several mechanisms. 22It may also have a role of the anti-inflammatory effect of doxycycline in COVID-19 infection.23In this study, 200 patients received the combination of ivermectin (18 mg single dose) and Doxycycline (100 mg twice daily for 5 days). Majority (78.5%) were male, mean age was 36 years (range 17 to 74 years).Fever (57.5%) was the commonest symptom followed by cough (47.5%), sore throat (8.5%), dyspnoea (8.5%). A significant number of patients (22%) were asymptomatic (Non-specific symptoms) in Group-A. On 5thand 6thday viral clearance were achieved by 66% and 83.5% respectively. ivermectin and doxycycline combination were well tolerated by the patients though some unusual symptoms were seen might have been attributed to the effect of drugs or to rare Covid related symptoms which were anorexia (23.5%), diarrhoea (12%), skin rash (10%) and vomiting (3.5%). No significant renal or hepatic impairment was found. ivermectin was found to be safe at current dose. 24 In Group-B Fever (66%) was also the commonest symptom followed by cough (59%), sore throat (6.5%), dyspnoea (19%). Asymptomatic (Non-specific symptoms) patients were only 10%. The effect of hydroxychloroquine (HCQ) with or without azithromycin, on COVID-19 was promising in several studies where HCQ and azithromycin showed earlier viral clearance than placebo. 25 In this study, 200 patients received HCQ & azithromycin combination. Mean age was 39.4 years (range 20-79 years) and 94% were male. All had mild to moderate disease.Viral clearance by RT-PCR of nasal and pharyngeal swab were 77% at day 11 and 81.5% at day 12. No major adverse effect were observed other than minor overlapping symptoms (anorexia 31%, diarrhoea 7%, vomiting 2%, skin rash 1%). In this study only mild to moderate COVID-19 cases were included. ivermectin and doxycycline combination was associated with earlier viral clearance than HCQ & azithromycin combination. No severe adverse effect was observed in either group. This is a new study; So far no definite study was found on human being affecting viral clearance of covid-19. This is a observational study and we have choose very low dose of ivermectin keeping consideration of individual safety.The exact dose which will be absolutely beneficial for viral clearance of covid-19 on human being need to be determined in future by further control study.

Limitations

There are few limitations of the study like a) no severe cases were included in this study, b) effect of drug combination on clinical follow up outcome were not assessed and compared, c) false negative result could not be excluded and d) cardiac effect due to drugs could not be monitored. e) Effective dose of Ivermectin to clear virus not measured.

Conclusion:

Ivermectin and Doxycycline is a safe combination and found effective in early viral clearance in mild to moderate COVID-19 patients. On the other hand Hydroxychloroquine (HCQ) and Azithromycinewas also found safe but took more time in viral clearance and it itself might putting extra adverse effect on already compromised heart from viral effect. Nevertheles further control study is required to know more about the effects of ivermectin and doxycyclin on covid -19 patient

Use of Ivermectin Is Associated With Lower Mortality in Hospitalized Patients With Coronavirus Disease 2019

The Ivermectin in COVID Nineteen Study

Juliana Cepelowicz Rajter, MD; Michael S. Sherman, MD, FCCP; Naaz Fatteh, MD; Fabio Vogel, PharmD, BCPS; Jamie Sacks, PharmD; and Jean-Jacques Rajter, MD

BACKGROUND: Ivermectin was shown to inhibit severe acute respiratory syndrome coronavirus 2 replication in vitro, which has led to off-label use, but clinical efficacy has not been described previously.

RESEARCH QUESTION: Does ivermectin benefit hospitalized coronavirus disease 2019 (COVID-19) patients?

STUDY DESIGN AND METHODS: Charts of consecutive patients hospitalized at four Broward Health hospitals in Florida with confirmed COVID-19 between March 15 and May 11, 2020, treated with or without ivermectin were reviewed. Hospital ivermectin dosing guidelines were provided, but treatment decisions were at the treating physician's discretion. The primary outcome was all-cause in-hospital mortality. Secondary outcomes included mortality in patients with severe pulmonary involvement, extubation rates for mechanically ventilated patients, and length of stay. Severe pulmonary involvement was defined as need for $F_{IO_2} \geq 50\%$, noninvasive ventilation, or invasive ventilation at study entry. Logistic regression and propensity score matching were used to adjust for confounders.

RESULTS: Two hundred eighty patients, 173 treated with ivermectin and 107 without ivermectin, were reviewed. Most patients in both groups also received hydroxychloroquine, azithromycin, or both. Univariate analysis showed lower mortality in the ivermectin group (15.0% vs 25.2%; OR, 0.52; 95% CI, 0.29-0.96; $P = .03$). Mortality also was lower among ivermectin-treated patients with severe pulmonary involvement (38.8% vs 80.7%; OR, 0.15; 95% CI, 0.05-0.47; $P = .001$). No significant differences were found in extubation rates (36.1% vs 15.4%; OR, 3.11; 95% CI, 0.88-11.00; $P = .07$) or length of stay. After multivariate adjustment for confounders and mortality risks, the mortality difference remained significant (OR, 0.27; 95% CI, 0.09-0.80; $P = .03$). One hundred ninety-six patients were included in the propensity-matched cohort. Mortality was significantly lower in the ivermectin group (13.3% vs 24.5%; OR, 0.47; 95% CI, 0.22-0.99; $P < .05$), an 11.2% (95% CI, 0.38%-22.1%) absolute risk reduction, with a number needed to treat of 8.9 (95% CI, 4.5-263).

INTERPRETATION: Ivermectin treatment was associated with lower mortality during treatment of COVID-19, especially in patients with severe pulmonary involvement. Randomized controlled trials are needed to confirm these findings. CHEST 2021; 159(1):85-92

KEY WORDS: hospitalized COVID-19; in-hospital mortality; ivermectin; mechanical ventilation; number needed to treat; severe pulmonary involvement; survival

Take-home Points

Study Question: Is ivermectin associated with lower mortality rate in patients hospitalized with coronavirus disease 2019 (COVID-19)?

Results: A retrospective cohort study of consecutive patients hospitalized with confirmed severe acute respiratory syndrome coronavirus 2 infection at a four-hospital consortium in South Florida. Analysis showed statistically significant lower mortality rates in the group treated with ivermectin as compared with the group treated with usual care (15.0% vs 25.2%).

Interpretation: Ivermectin was associated with lower mortality during treatment of COVID-19 patients, especially in patients who required higher inspired oxygen or ventilatory support.

Ivermectin previously was studied as a therapeutic option for viral infections, with data showing some in vitro activity against a broad range of viruses, including HIV, dengue, influenza, and Zika virus, likely through inhibition of importin α/β1-mediated nuclear import of viral proteins.[1-3] Wagstaff et al[4] demonstrated that ivermectin was a potent in vitro inhibitor of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), showing a 99.8% reduction in viral RNA after 48 h. Reports can be found on the Internet of physicians worldwide treating Coronavirus disease 2019 (COVID-19) empirically with ivermectin since late April 2020. According to ClinicalTrials.gov, currently 37 studies are investigating the usefulness of ivermectin in COVID-19. However, in vivo efficacy of ivermectin in SARS-CoV-2 infection in humans has not been reported previously.

In the late 1970s, ivermectin was developed as a new class of drug to treat parasitic infections. Initially used in veterinary medicine, it soon was found to be safe and effective in humans. It has been used successfully to treat onchocerciasis and lymphatic filariasis in millions of people worldwide as part of a global drug donation program. About 3.7 billion doses of ivermectin have been distributed in mass drug administration campaigns globally over the past 30 years. Presently, ivermectin is approved for use in humans in several countries to treat onchocerciasis, lymphatic filariasis, strongyloidiasis, and scabies.[1]

Based on the data drug safety sheet for ivermectin (New Drug Application Identifier: 50-742/S-022), side effects were uncommon and limited. Reported side effects with more than 1% occurrence included elevation in alanine aminotransferase and aspartate aminotransferase (2%), nausea (2%), diarrhea (2%), decreased leukocyte count (3%), peripheral edema (3%), tachycardia (3%), dizziness (3%), and pruritus (3%). A pharmacokinetic study of 166 patients reported side effects of headache (6%), dysmenorrhea (5.5%), upper respiratory infection symptoms (1.8%), and diarrhea (1.8%).[5]

Methods

Patients

Sequentially consecutive hospitalized patients at four Broward Health-associated hospitals in South Florida with laboratory-confirmed infection with SARS-CoV-2 during their admission were reviewed in this study. The list of confirmed cases was provided by the hospitals' epidemiology departments. Enrollment dates ranged from March 15, 2020, through May 11, 2020. Confirmatory testing was performed by nasopharyngeal swab using a Food and Drug Administration Emergency Use Authorized COVID-19 molecular assay for the detection of SARS-CoV-2 RNA. Patients younger than 18 years and those who were pregnant or incarcerated were excluded from data collection based on institutional review board requirements. Patients who had at least two separate admissions placing them in both groups also were excluded.

Study Procedures

Records were abstracted by four of the authors (J. C. R., N. F., J. S., and J.-J. R.), and all data were reviewed subsequently and confirmed by the lead author. Baseline data were collected at the time of ivermectin administration for the ivermectin group; for the usual care group, baseline was either the time of administration of hydroxychloroquine or, if not used, at the time of admission. Information collected included COVID-19 testing results, patient demographics, pre-existing comorbid conditions, initial vital signs, laboratory results, and the use of corticosteroids, hydroxychloroquine, and azithromycin to describe the cohort and to identify potential confounders between groups. Severity of pulmonary involvement was assessed at the time of baseline data collection and was categorized

Philadelphia, PA; and the Florida International University (J.-J. R.), Miami, FL.

FUNDING/SUPPORT: The authors have reported to *CHEST* that no funding was received for this study.

as severe or nonsevere. Patients were considered to have severe pulmonary involvement if they required an F_{IO_2} of 50% or more, high-flow nasal oxygen, noninvasive ventilation, or intubation and mechanical ventilation. The nonsevere pulmonary criteria encompassed patients who required no supplemental oxygen or low F_{IO_2} (ie, venturi mask 40% or less or up to 6 L/min of low-flow nasal cannula), independent of laboratory findings.

Patients were categorized into two treatment groups based on whether they received ivermectin at any time during the hospitalization. Patients in the ivermectin group received at least one oral dose of ivermectin at 200 μg/kg in addition to usual clinical care. A second dose could be given at the discretion of the treating physician at day 7 of treatment. Ivermectin is not currently approved by the Food and Drug Administration for COVID-19 treatment. The decision to prescribe ivermectin, hydroxychloroquine, azithromycin, or other medications was at the discretion of the treating physicians; however, hospital guidelines were established for the safe use and dosing of these agents. These guidelines included a baseline ECG and mandatory cardiac and corrected QT interval (QTc) monitoring for patients receiving hydroxychloroquine (alone or in combination with azithromycin), avoidance of azithromycin if patient's baseline QTc was more than 460 msec, and discontinuation of hydroxychloroquine if a concerning elevation in QTc occurred or if the patient's cardiologist recommended discontinuation. Oxygen and ventilatory support were applied per the customary care. Empiric use of ivermectin was given explicitly for COVID-19.

Outcomes

The primary outcome was all-cause in-hospital mortality. A patient was considered a survivor if he or she left the hospital alive or if his or her status in the hospital changed from active care to awaiting transfer to a skilled facility. Two consecutive nasopharyngeal swab specimens showing negative results for SARS-CoV-2, collected ≥ 24 h apart, were necessary for a patient to be accepted to the local skilled nursing facilities.

Secondary outcomes included subgroup mortality of patients with severe pulmonary involvement, extubation rates for patients requiring mechanical ventilation, and length of hospital stay. Length of stay was calculated from day of admission to either the day of discharge or to patient death.

Statistical Analysis

Univariate analysis of the primary mortality outcome and comparisons between treatment groups were determined by the Student *t* test for parametric continuous variables or the Mann-Whitney *U* test for nonparametric continuous variables as appropriate, and by the Pearson χ^2 test for categorical variables. The method of Hodges-Lehman was used to estimate median differences with 95% CIs.

To adjust for confounders and between-group differences, a multivariate analysis was performed using stepwise binary logistic regression. Patient variables included in the analysis were age, sex, comorbidities of diabetes, chronic lung disease, cardiovascular disease, and hypertension, smoking status, severity of pulmonary involvement, need for mechanical ventilation at study entry, BMI, peripheral white blood count, absolute lymphocyte count, and use of corticosteroids based on bivariate associations within our data, a priori plausibility, and documented associations with mortality from previous studies. Adjusted ORs with 95% CIs were computed to show level of certainty. Analyses were based on nonmissing data, and missing data were not imputed. Missingness of 1% was found for peripheral WBC count, 5% for smoking status, and 7% for absolute lymphocyte count.

We performed a secondary analysis using propensity score matching to reduce the effects of confounding and the likelihood of selection bias. Propensity matching was performed using a nearest-neighbor algorithm with 1:1 matching without replacement and a caliper distance of less than 0.2. Variables for propensity scoring included those variables from the univariate between-groups analysis of the unmatched cohort that had a *P* value of less than .2 (age, sex, pulmonary condition, hypertension , HIV status, severe pulmonary presentation, and exposure to corticosteroids, hydroxychloroquine, or azithromycin). Race, WBC count, absolute lymphocyte count, and need for mechanical ventilation before or on the day of study entry also were added as potential clinical confounders.

All tests were two-sided and a P value $< .05$ was considered statistically significant. Statistical analyses were conducted using IBM SPSS version 26.0 software, R version 3.5.3 software (R Foundation for Statistical Computing), and SPSS PS-matching software (sourceforge.net).

This study was conducted in accordance with tenets of the amended Declaration of Helsinki. The protocol was approved by the institutional review board for the Broward Health Hospital System (Identifier: 2020-034-BHMC). The authors assume responsibility for the accuracy and completeness of the data and analyses, as well as for the fidelity of the study.

Results

Characteristics of the Patients

Three hundred seven patients were admitted for COVID-19 during the period studied. Four patients were not reviewed because of multiple admissions, 11 did not have COVID-19 confirmed at the time of the study, and 12 were excluded because their age was younger than 18 years, they were pregnant, or they were incarcerated. The remaining cohort of 280 patients comprised 173 treated with ivermectin and 107 in the usual care group. Most patients received a single dose of ivermectin; however, 13 patients received a second dose of ivermectin for ongoing signs or symptoms on day 7 of treatment. Follow-up data for all outcomes were available through May 19, 2020. No patients were lost to follow-up for the primary outcome. At the time of analysis, all patients in both groups had met the end point of death, discharge alive, or awaiting transfer to a skilled facility. Of those awaiting transfer, in the control group, one patient was awaiting transfer to hospice because of an unrelated terminal illness and one patient was awaiting negative COVID-19 test results to proceed with unrelated surgery. In the ivermectin group, five patients were in stable condition, awaiting transfer to skilled facility or rehabilitation, and one patient was improving clinically.

Baseline characteristics and between-group comparisons for unmatched and propensity-matched cohorts are shown in Table 1. Before matching, hypertension and

Data are presented as No. (%), mean ± SD, or median (interquartile range), unless otherwise indicated. Current and former smoker is given as a proportion of the population with known smoking status documented in their medical records. MAP = mean arterial pressure.
[a]Asian, Native American, Pacific Islander, or not identified.

corticosteroid use were more prevalent in the ivermectin group, whereas the use of hydroxychloroquine and hydroxychloroquine plus azithromycin were higher in the usual care group.

Propensity score matching created a total of 98 matched pairs. After matching, no statistically significant differences were found between the two groups. Eight patients in the propensity-matched group received a second dose of ivermectin on day 7.

Outcomes

Unadjusted outcomes for the unmatched cohort and outcomes in the propensity-matched cohort are shown in Table 2. For the unmatched cohort, overall mortality was significantly lower in the ivermectin group than in the usual care group (15.0% vs 25.2% for ivermectin and usual care, respectively; $P = .03$). Mortality also was lower for ivermectin-treated patients in the subgroup of patients with severe pulmonary involvement (38.8% vs. 80.7% for ivermectin and usual care, respectively; $P = .001$). On univariate analysis, patients receiving corticosteroids showed a higher mortality than those who did not receive corticosteroids (30.0% vs 13.7%; OR, 2.7; 95% CI, 1.47-4.99; $P = .001$); however, corticosteroids were more likely to have been prescribed for severe patients (58.6% vs 22.4% for severe and nonsevere, respectively; OR, 4.91; 95% CI, 2.78-8.63; $P < .001$).

Results were similar, with lower mortality in the ivermectin-treated patients for the matched cohort for the group as a whole and for the subgroup with severe pulmonary involvement (Table 2). In the matched cohort, ivermectin was associated with an absolute risk reduction of 11.2% (95% CI, 0.38%-22.1%) and a corresponding number needed to treat of 8.9 (95% CI, 4.5-263) to prevent one death. We found no difference in median hospital length of stay or in extubation rates in either the unmatched or matched cohorts. Of note, 1 of the 13 patients who received a second dose of ivermectin died; this patient was not in the propensity-matched cohort.

Multivariate analysis was performed on the unmatched cohort, adjusting for demographic factors and between-group differences in mortality risks. Independent predictors of in-hospital mortality included treatment group, age, severe pulmonary disease category, and reduced lymphocyte count (Table 3). Because race was not a significant predictor after adjustment, a further analysis was performed that showed that White patients were significantly older than Black patients (mean age, 66.8 vs 59.1 y; mean difference, 7.7 y; 95% CI, 3.0-12.4 y;

Discussion

In this multihospital retrospective cohort study, we observed a significant association of ivermectin with improved survival for patients admitted with COVID-19. This association also was seen in the subset of patients with severe pulmonary disease. These findings were confirmed after multivariate adjustment for comorbidities and differences between groups, and also in a propensity score-matched cohort. Similar to other studies, we noted that older age, cardiac disease, current or former smoking, more severe pulmonary involvement at presentation, higher WBC counts, and lower lymphocyte counts emerged as risk markers for in-hospital mortality.

The overall mortality, and mortality in intubated patients, in our usual care group was similar to what was reported in previous studies. Richardson et al[6] reported an overall mortality of 21% in a New York City cohort, with a mortality of 88% in intubated patients. Zhou et al[7] reported 28.2% mortality in a cohort of hospitalized patients in Wuhan, China; the intubated patients showed a mortality of 96.9%. In contrast to Magagnoli et al,[8] we did not see a higher mortality effect for hydroxychloroquine. This may have been because of the small number of patients who were not treated with this agent; thus, our study was underpowered to detect a difference in mortality from hydroxychloroquine treatment. We also hypothesize that precautionary measures in the hospitals' protocol for hydroxychloroquine use could have prevented fatal arrhythmias from developing. These included baseline electrocardiography and daily QTc monitoring by telemetry for any patient receiving hydroxychloroquine or combination therapy, avoidance of azithromycin if patient's baseline QTc was more than 460 msec, and discontinuation of hydroxychloroquine if a concerning elevation in QTc occurred or if the patient's cardiologist recommended discontinuation. In contrast to Horby et al,[9] we did not find a mortality benefit for patients who were prescribed corticosteroids in our multivariate analysis, which included several severity covariates. These findings are likely explainable by physicians' choice to reserve use of corticosteroids for the most seriously ill patients, because the study was performed before the results of the Randomised Evaluation of COVID-19 Therapy (RECOVERY) trial were published.[9]

TABLE 3] Multivariate Analysis of Factors Associated With Mortality

Lymphocyte count	3.65 (1.25-10.60)	.02

MAP = mean arterial pressure.

We also did not confirm a higher risk of mortality in Black patients in comparison with White patients after controlling for age. Prior reports showed lower survival rates among Black and Hispanic patients[10]; however, Price et al[11] also found no racial differences in mortality. In our hospital population, White patients were significantly older, which is reflective of our catchment area and may be responsible for the discrepancy.

We did not observe a significant difference in hospital length of stay between the groups (median, 7 days for both groups) despite the lower mortality. Possible explanation could include delay in discharging patients to other facilities (skilled nursing facilities, inpatient rehabs, and so forth) because of a delay in obtaining required repeat COVID-19 testing results. Patients who died were included in length-of-stay measurements.

Use of mechanical ventilation was not adopted as an outcome of interest, because guidelines and practice patterns for intubation criteria changed throughout the length of the study. We were unable to determine ICU length of stay and ventilatory-free days in the ICU because overflow conditions during the pandemic placed critically ill patients in the emergency room and other non-ICU environments, and therefore, we could not determine ICU stay accurately. We did not find a lower mortality in the subgroup of nonsevere patients treated with ivermectin; however, our study was not powered to assess these differences because the overall mortality in nonsevere patients was low. Similarly, the study was not powered to determine whether extubation rates were higher in the ivermectin group. These should be investigated further with a larger randomized controlled trial.

Interpretation

Our study has several limitations. Because of the retrospective observational nature of the study, despite adjustment for known confounders and propensity score matching, we cannot exclude the possibility of unmeasured confounding factors. Although more of the control group was enrolled in the first weeks of the study, suggesting the possibility of timing bias, this may be offset by preferential treatment of more severe patients with ivermectin early in the study because of low initial availability. We also did not find consistently different mortality outcomes with time over the short duration of this study. We also did not find evidence of immortal time bias, because only one of the control patients died fewer than 5 days from admission, the average time from admission to death was 11 days, and the vast majority of patients received ivermectin in 2 days or fewer. If we omit the patient with potential immortal time from the analysis, the mortality difference remains significant in both unmatched (15.0% vs 24.5% for ivermectin and usual care, respectively; $P < .05$) and matched (12.4% vs 25.0% for ivermectin and usual care, respectively; $P < .03$) cohorts. Most of the studied patients received hydroxychloroquine with or without azithromycin, and we are unable to determine whether these medications had an added benefit or whether mortality would have been better in both groups without these agents.

We showed that ivermectin administration was associated significantly with lower mortality among patients with COVID-19, particularly in patients with more severe pulmonary involvement. Interpretation of these findings are tempered by the limitations of the retrospective design and the possibility of confounding. Appropriate dosing for this indication is not known, nor are the effects of ivermectin on viral load or in patients with milder disease. Further studies in appropriately designed randomized trials are recommended before any conclusions can be made.

Zinc for the common cold—not *if*, but when

A new meta-analysis shows that zinc supplementation can reduce the duration and severity of a cold, if it's started early on.

PRACTICE CHANGER

Advise patients to start taking zinc supplements (available as tablets, syrup, or lozenges) within 24 hours of the onset of a cold.[1]

Singh M, Das RR. Zinc for the common cold. *Cochrane Database Syst Rev.* 2011;(2):CD001364.

STRENGTH OF RECOMMENDATION

A: Based on a meta-analysis of 13 randomized placebo-controlled trials.

ILLUSTRATIVE CASE

A healthy 31-year-old woman schedules a visit because of congestion and rhinorrhea. She tells you that her cold symptoms developed in the last day or 2 and asks for something to speed her recovery. What can you suggest?

Americans experience roughly 500 million episodes of noninfluenza-related viral respiratory tract infections annually (ie, common colds), or roughly 2.5 episodes per person each year. The total economic burden of the common cold is nearly $40 billion annually.[2]

Most cold remedies offer little relief

We've all cared for patients with cold symptoms. And despite the desire to help, many of us have been frustrated by the fact that there is no cure for the common cold, and most over-the-counter therapies offer little or no relief.

What about zinc? Zinc has been in and out of favor as a treatment for the common cold, based on contradictory findings, since the first randomized trial was published in 1984.[3]

A 1998 systematic review (which did not include a quantitative synthesis of data) suggested that zinc was beneficial in reducing the duration and severity of cold symptoms.[4] A meta-analysis published in 2000 found that zinc was ineffective compared with placebo in reducing the likelihood that cold symptoms were present after 7 days.[5] A meta-analysis published in June 2011 concluded that zinc lozenges reduce the duration of cold symptoms by 12% to 48%, but only at daily doses >75 mg.[6]

These conflicting results have made it difficult to recommend zinc to patients—until now.

STUDY SUMMARY

Zinc for colds? Cochrane review provides convincing evidence

The 2011 Cochrane review that's the focus of this PURL[1] addressed the question: Does zinc reduce the duration and severity of the common cold? The review also assessed zinc's ability to prevent colds, although only 2 studies focused on prevention.

The researchers included only randomized, double-blind, placebo-controlled trials in which oral zinc supplementation was used for ≥5 consecutive days for treatment or ≥5 months for prevention. Studies included patients of any age, taking any dosage and any formulation of zinc.

Primary outcomes included the duration of symptoms, the severity of symptoms, and the incidence of the common cold in preven-

FOI 26-3132 - Document 5

tion studies. Secondary outcomes included the proportion of patients symptomatic after 3, 5, and 7 days of treatment, the time to resolution of individual symptoms (eg, cough), change in individual symptom scores, school absences, antibiotic use, and adverse effects.

Thirteen therapeutic trials and 2 prevention trials met the inclusion criteria. These studies, all of which were judged to be of high quality with a low risk of bias, had a total of 996 patients in the therapeutic trials and 394 patients in the prevention trials. Participants ranged in age from 1 to 65 years.

Therapeutic trials. In general, therapeutic studies included lozenges containing 10 to 24 mg zinc gluconate, with one lozenge taken every 1 to 4 hours during the day for 3 to 7 days. In one therapeutic trial that enrolled only children ages 1 to 10, the intervention group took zinc sulfate syrup (15 mg bid) for 10 days. In 11 of the 13 therapeutic studies, treatment began in the first 24 hours of symptoms; in the remaining 2, it began within 48 hours of symptoms.

Ten studies reported on duration of symptoms; 6 of them were similar enough to allow for pooling of results. The pooled results showed that patients who took zinc had a shorter duration of cold symptoms (0.97 days; 95% confidence interval [CI], -1.56 to -0.38), compared with those on placebo. Pooled results from 5 trials revealed that zinc significantly reduced the severity of symptoms by a standard effect size of 0.39 (95% CI, -0.77 to -0.02), which is considered a small to moderate effect.

Prevention trials. In one prevention trial, which included only children ages 6½ to 10 years, those in the intervention group took one 10-mg zinc sulfate tablet 6 days a week for 5 months. In the other trial, children in the intervention group took 15 mg zinc sulfate syrup daily for 7 months.

Pooled results from these 2 studies revealed that daily zinc supplementation substantially reduced the incidence of colds. The incident rate ratio (the number of children who developed colds while taking zinc compared with the number who developed colds while on placebo) was 0.64 (95% CI, 0.47-0.88). In the original trials, one study found a difference of 0.5 colds (1.7 in the control group vs 1.2 in the intervention group) per season, and the other found a difference of 1.8 colds per season (3.15 in the control group vs 1.37 in the intervention group).

WHAT'S NEW

Evidence of zinc's cold relief properties is conclusive

This Cochrane review provides convincing evidence from 13 randomized placebo-controlled trials that taking zinc soon after the onset of symptoms of the common cold significantly reduces both the duration and severity of symptoms. Zinc supplements are widely available over the counter, so you can recommend that patients take zinc the next time they develop a cold.

In addition, 2 prevention trials found that zinc can reduce the incidence of colds in children, whether it is taken as a syrup or in tablet form. There have been few trials of zinc for prophylaxis of the common cold, and no previous meta-analyses included preventive studies.[7] This Cochrane review substantiates the effectiveness of zinc for prophylaxis of the common cold in young children.

However, children need to take zinc daily for prophylaxis, which may be inconvenient. Long-term safety information is not yet available. Given these considerations, parents may choose to wait for additional evidence about safety before considering daily prophylaxis.

CAVEATS

Adverse effects, long-term use may create problems

In this meta-analysis, side effects from zinc were common. The 2 most frequently reported were bad taste (pooled odds ratio [OR], 2.64; 95% CI, 1.91-3.64) and nausea (pooled OR, 2.15; 95% CI, 1.44-3.23). When you recommend zinc, warn your patients about these adverse effects. The side effects are not severe, so patients can decide for themselves whether the benefit of a reduction in cold duration is worth the downside of nausea and a bad taste in the mouth.

It is also important to note that the trials included in the meta-analysis enrolled healthy children and adults ≤65 years old.

INSTANT POLL QUESTION

Do you recommend that patients take zinc to reduce the duration and severity of cold symptoms?

- ☐ *Yes, frequently*
- ☐ *No, but I plan to do so*
- ☐ *No; the side effects are unpleasant*
- ☐ *Other*_____

Go to jfponline.com and take our instant poll

Whether zinc benefits people with chronic illnesses (eg, chronic obstructive pulmonary disease) who develop colds is unknown.

Prolonged elevated serum zinc levels can interfere with copper metabolism, and the adverse effects of long-term use of zinc as prophylaxis are unknown. The trials included in the meta-analysis took place in relatively affluent countries in which zinc deficiency is uncommon. It is not known what impact zinc supplementation would have on people in poor countries.

Of the 15 studies included in the meta-analysis, 10 received support from pharmaceutical companies, 4 received support from foundations, and one received support from both.

CHALLENGES TO IMPLEMENTATION

When to talk to patients about zinc

Most patients do not seek medical care for colds. Those who do typically present only after having symptoms for several days, and it is not clear whether zinc supplementation has the same beneficial effects when started after the first 24 hours.[2]

Thus, you may have few opportunities in the office to recommend zinc for patients with colds, for whom there is evidence of immediate benefit. More likely, you'll need to incorporate a zinc recommendation into your overall advice about colds.

Zinc is available over the counter in various forms and dosage. After recommending zinc, you may be confronted with the question of which dose, brand, and formulation is best—a question which, unfortunately, remains unanswered. JFP

REVIEW

The Role of Zinc in Antiviral Immunity

Scott A Read,[1,2] Stephanie Obeid,[3] Chantelle Ahlenstiel,[3] and Golo Ahlenstiel[1,2]

ABSTRACT

Zinc is an essential trace element that is crucial for growth, development, and the maintenance of immune function. Its influence reaches all organs and cell types, representing an integral component of approximately 10% of the human proteome, and encompassing hundreds of key enzymes and transcription factors. Zinc deficiency is strikingly common, affecting up to a quarter of the population in developing countries, but also affecting distinct populations in the developed world as a result of lifestyle, age, and disease-mediated factors. Consequently, zinc status is a critical factor that can influence antiviral immunity, particularly as zinc-deficient populations are often most at risk of acquiring viral infections such as HIV or hepatitis C virus. This review summarizes current basic science and clinical evidence examining zinc as a direct antiviral, as well as a stimulant of antiviral immunity. An abundance of evidence has accumulated over the past 50 y to demonstrate the antiviral activity of zinc against a variety of viruses, and via numerous mechanisms. The therapeutic use of zinc for viral infections such as herpes simplex virus and the common cold has stemmed from these findings; however, there remains much to be learned regarding the antiviral mechanisms and clinical benefit of zinc supplementation as a preventative and therapeutic treatment for viral infections. *Adv Nutr* 2019;10:696–710.

Keywords: zinc, virus, metallothionein, antiviral, immunity, zinc deficiency, zinc supplementation

Introduction

Zinc deficiency was first recognized by Prasad et al. >50 y ago in a malnourished group of individuals presenting with hepatosplenomegaly, dwarfism, hypogonadism, and an elevated risk of infection (1). Unbeknownst to Dr. Prasad and his colleagues at the time, their discovery would highlight the importance of zinc as an integral component of human physiology, and inspire decades of zinc research. It is now understood that zinc is the second-most abundant trace metal in the human body after iron, and an essential component of protein structure and function. Importantly, zinc is a structural constituent of ∼750 zinc-finger transcription factors (2) enabling gene transcription, and is a catalytic component of approximately 2000 enzymes, encompassing all 6 classes (hydrolase, transferase, oxido-reductase, ligase, lyase, and isomerase) (3). Hence, zinc is biologically essential for cellular processes, including growth and development, as well as DNA synthesis and RNA transcription (4).

The global prevalence of zinc deficiency is estimated to range from ∼17% to 20% (5, 6), with the vast majority occurring in developing countries of Africa and Asia. Although significantly less common in high-income nations, zinc deficiency occurs most frequently in the elderly, vegans/vegetarians, and individuals with chronic disease such as liver cirrhosis (7) or inflammatory bowel disease (8). Importantly, zinc deficiency results in a compromised immune system, as evidenced by thymic atrophy, lymphopenia, and defective lymphocyte responses in animal studies (9). These data underscore the importance of zinc nutrition, particularly in underdeveloped countries where the risk of infection is heightened because of poor sanitation, public health, and vaccination strategies (5).

This review focuses on the role of zinc as an essential micronutrient that is required to mount an effective antiviral response. Although zinc possesses direct antiviral properties (e.g. influenza), it is also critical in generating both innate and acquired (humoral) antiviral responses. To complicate matters, zinc is an integral component of many viral enzymes, proteases, and polymerases, highlighting the importance of regulating cellular and systemic zinc distribution to inhibit viral replication and dissemination.

Current Status of Knowledge

Zinc homeostasis and viral infection

Systemic and intracellular zinc are tightly regulated, such that free zinc ions (Zn^{2+}) represent a minimal fraction of total cellular zinc (~0.0001%) (10–12). The vast majority of zinc remains bound to zinc-binding proteins such as serum albumin or intracellular metallothionein proteins, where it can be transferred to zinc-binding enzymes and transcription factors as necessary. Zinc transport is principally mediated by 2 groups of proteins: the ZnT [solute-linked carrier 30 (*SLC30A*)] family, which is responsible for efflux of zinc outside the cell or influx into organelles, and the ZIP [Zrt- and Irt-like proteins (*SLC39A*)] family of proteins, which performs the opposite role, transporting zinc into the cytoplasm from extracellular sources or cellular organelles (13). The >30 human proteins responsible for zinc homeostasis collectively ensure that zinc does not become toxic in the case of dietary excess, nor limited in the case of dietary insufficiency. Of course, this balance cannot be maintained indefinitely, and may result in zinc-induced copper deficiency if consumed in excess (14), and severe zinc deficiency if it is lacking in the diet (1).

Sequestration and toxic accumulation of metals are well-documented antibacterial immune responses. Calprotectin is a prime example, binding and sequestering extracellular calcium and zinc, thus preventing bacterial and fungal overgrowth (15). Conversely, toxic endosomal zinc accumulation can inhibit intracellular *Mycobacterium* growth in macrophages (16). Unfortunately, these mechanisms are not well described in the case of viral infections, perhaps because of a lack of efficacy. Calprotectin, for example, has no proven antiviral role, nor is it significantly upregulated in response to viral gastroenteritis (17). This absence of a zinc-mediated antiviral response may reflect the "parasitic" nature of viral infection, hijacking host machinery to self-replicate. Changes in intracellular zinc concentrations necessary to inhibit viral replication may also prove toxic to eukaryotic cells for the same reason.

Although antiviral modulation of zinc homeostasis in humans remains unproven, papilloma viruses have evolved mechanisms to alter zinc homeostasis to favor viral replication and persistence (18). The human papilloma virus (HPV) E5 protein can interact with the zinc transporter ZnT-1 in complex with EVER2, thus stimulating nuclear accumulation of zinc (19). The ZnT-1:EVER2 complex responsible for zinc export from the nucleus is inhibited by HPV E5, subsequently increasing both nuclear zinc and the activation of AP1 (20), a transcription factor required for HPV genome expression. Interestingly, homozygous mutations in either EVER1 or EVER2 result in a rare condition termed *epidermodysplasia verruciformis* (EV). EV patients are particularly susceptible to HPV strains 5 and 8, which significantly increases the risk of developing nonmelanoma skin cancers. HPV strains 5 and 8 lack expression of the E5 protein, which may explain *1*) their limited replication in the normal population because of their inability to control zinc homeostasis, and *2*) the susceptibility of EV patients to strains 5 and 8 from the loss of EVER protein function, favoring HPV replication. Interestingly, HPV E5 genes have co-evolved with the major HPV oncogenes, E6 and E7, and indicate the potential involvement of E5 in carcinogenesis (21, 22). Clinical trials using both oral and topical zinc have proven effective for the treatment of viral warts, and will be reviewed in a later section.

Metallothioneins, zinc homeostasis, and antiviral activity. Metallothioneins are small, cysteine-rich proteins capable of binding divalent cations such as zinc and copper. As vessels for much of the labile intracellular zinc pool, metallothioneins possess numerous functions through their ability to bind and release metals from their thiol groups. These include storage and transfer of zinc ions and heavy metal detoxification, as well as involvement in oxidative stress, apoptosis, and immune responses (23). Humans express 4 metallothionein isoforms (MT1–4), including the ubiquitously expressed MT1 and MT2 genes (MT1A, B, E, F, G, H, I, J, L, M, X, MT2A), as well as MT3 and MT4 whose expression is limited, and function remains poorly understood (24). Importantly, MT1 and 2 gene expression is extremely responsive to zinc, and therefore serves as an ideal indicator of an individual's zinc status (25). Upon taking a zinc supplement, for example, an increase in protein-bound zinc in the bloodstream is internalized by cells in various tissues and organs through the ZIP transporters. In response to increased intracellular zinc, the metal-responsive transcription factor (MTF1) becomes active, and binds the metal responsive element in metallothionein gene promoters to upregulate their transcription (26). Although there are additional stimuli that influence metallothionein expression, this primarily occurs in a zinc-dependent fashion. Oxidative stress, for example, induces zinc release from metallothioneins as a mechanism to reduce reactive oxygen species generated by mitochondrial dysfunction or viral infection (26). Zinc released from metallothioneins binds MTF1 to stimulate additional metallothionein expression.

It should be noted that metallothioneins, although highly responsive to zinc, have long been classified as interferon stimulated genes (ISGs) (27). IFNs are immunostimulatory cytokines secreted from infected cells and nearby immune cells that induce the expression of hundreds of antiviral genes. They possess diverse roles including chemoattraction, immune cell activation, and direct antiviral activity. In response to IFNs, we suggest that there are 2 mechanisms of metallothionein induction. Most ISGs possess binding sites for STAT- or IFN regulatory factor (IRF) transcription factor-mediated expression, as is the case for MT1X and MT2A (28, 29). Other metallothioneins such as MT1F and MT1G do not possess known IFN regulatory regions in their promoters, but are instead more sensitive to zinc (28). IFNs stimulate an influx of zinc into the target cell, as is the case with some inflammatory cytokines such as IL-6, which in turn drives metallothionein expression.

Because metallothioneins possess such a diverse functional repertoire, their specific roles during viral infection remain undefined. However, both in vitro and in vivo studies have made it abundantly clear that metallothioneins are induced by viruses. The mechanisms often remain undefined; however, metallothionein expression has been attributed to zinc influx or redistribution (19, 28), by viral means, cytokine exposure, or oxidative stress (30). Metallothionein upregulation has been observed in response to measles virus (31), influenza (31, 32), HIV (33), hepatitis C virus (HCV) (34), and coxsackie virus (35), among others. In the case of HIV, zinc appears to be the key driver of metallothionein expression to favor viral persistence. HIV-infected monocytes demonstrate a significant increase in both MT1 gene expression as well as intracellular zinc (33). Elevated intracellular zinc increases monocyte resistance to apoptosis via inhibition of caspase 3 activation [as has been reported previously (36)], thus providing a reservoir for HIV replication. The role of metallothioneins remains unclear in this study; however, they have been described as negative regulators of apoptosis, albeit not through direct caspase 3 inhibition (37). Zinc and metallothioneins also facilitate human cytomegalovirus (HCMV) replication by activating the immediate-early HCMV promoter (38, 39). Kanekiyo et al. demonstrated that both zinc and metallothionein overexpression increased NF-κB binding in the HCMV promoter. Because no complex was detected between metallothionein and NF-κB, it was suggested that metallothioneins served as a zinc donor necessary for NF-κB binding. In addition, as NF-κB transcription factors are known potent activators of HIV and HSV replication, and several other viruses (40), metallothioneins may be proviral. Zinc has also been reported to inhibit NF-κB in numerous studies (41–43). Despite these contrasting data, Kim et al. have bridged these inconsistencies, demonstrating that MT2A can serve as a sink for excess zinc (44), thus limiting its proximity to NF-κB and favoring NF-κB-mediated transcription.

In the case of HCV infection, metallothioneins possess an antiviral role. Using a pan-metallothionein siRNA to knockdown all MT1 and 2 genes, we demonstrated both an increase in HCV replication and a decrease in intracellular zinc content in vitro (34). Interestingly, although $ZnSO_4$ can reduce HCV replication, this effect was ablated when metallothionein genes were knocked down. These data suggest that metallothioneins are either *1*) directly antiviral, potentially by sequestering zinc away from viral metalloproteins such as HCV NS5A (45), or *2*) indirectly antiviral by acting as zinc chaperones and facilitating antiviral signaling. Further, metallothioneins possess antiviral properties against other viruses as well, as demonstrated in an antiviral screen of 380 human ISGs performed by Schoggins et al. (46). Overexpression of multiple members of the MT1 family inhibited replication of flaviviruses including yellow fever virus and HCV, as well as the alphavirus Venezuelan equine encephalitis virus. This effect was not observed in West Nile virus, and Chikungunya virus. These data indicate that metallothioneins, like many ISGs, are selectively antiviral, perhaps reflecting specific viral zinc requirements during replication. This is particularly evident for HIV, which demonstrated an increase in viral replication as a result of metallothionein overexpression in the Schoggins et al. ISG screen (46), validating previous works (33).

Zinc as an antiviral: bench to bedside and back again

Many studies have evaluated the efficacy of zinc as an antiviral agent in vitro. Unfortunately, zinc concentrations used to assess antiviral activity often far exceed physiological concentrations. Human plasma zinc, for example, ranges from approximately 10 to 18 μM (47), whereas antiviral concentrations of zinc can reach into mM concentrations (48). Intracellular zinc concentrations range from 10s to 100s of μM, but are significantly buffered by zinc-binding proteins such as metallothioneins, rendering free zinc concentrations at picomolar to low nanomolar concentrations (49, 50). The antiviral properties of zinc are certainly virus-specific, but it would appear that zinc ion availability plays a significant role in the antiviral efficacy of zinc (51). Here we describe the role of zinc as a virus-specific antiviral: both in vitro mechanistic studies, as well as human-based clinical trials using zinc supplementation. In vitro and in vivo studies are summarized in **Tables 1** and **2**, respectively.

Herpesviridae.

The effect of zinc on HSV-1 and -2 has been studied for >40 y, with in vitro studies suggesting that zinc plays an inhibitory role on almost every aspect of the viral life cycle: viral polymerase function (52), protein production and processing (53), and free virus inactivation (48, 54). Although these studies were performed >20 y ago, a more recent study using the zinc ionophore pyrithione demonstrated a reduction in HSV replication from reduced NF-κB activation by interfering with the protein ubiquitination pathway (41). Unfortunately, no recent experimental data can demonstrate with any certainty the mechanism by which zinc inhibits HSV infection. Nonetheless, in vivo studies in mice and humans have shown a significant reduction of infection and disease burden. Mouse studies performing intravaginal zinc inoculation in liquid (55) or gel (56) form both resulted in significant reductions in HSV-2 infection. Several topical zinc application studies have been performed in humans, which demonstrated a significantly reduced recurrence and duration of infection (outbreak) (57–58). The efficacy of topical application, together with in vitro results (48, 54), suggest that free zinc may indeed coat HSV virions, thus preventing infection. Further research into this molecular mechanism is warranted.

Apart from HCMV mentioned above, the effect of zinc on other members of the *Herpesviridae* family remains unknown because of a lack of clinical data. Mechanistically, zinc ions have been shown to inhibit Varicella-Zoster virus by inactivating free virus in vitro (59). Both HSV and Varicella-Zoster virus belong to the *Alphaherpesvirinae* subfamily, reflecting their genetic relatedness, and similar mechanism of inhibition.

TABLE 1 In vitro studies assessing the antiviral efficacy of zinc[1]

Virus	Antiviral effect	Zinc	Effective dose	Reference
Coronavirus	Inhibition of RdRp template binding and elongation	PT + $Zn(OAc)_2$	2–320 μM PT + 2–500 μM Zn	(60)
Encephalomyocarditis virus	Inhibition of viral polyprotein cleavage	$ZnCl_2$	0.4–1.5 mM	(61)
	Inhibition of viral polyprotein cleavage	$ZnCl_2$	0.1–1 mM	(62)
	Inhibition of viral polyprotein tertiary structure	PT, HK	5–20 μM PT, 60–125 μM HK	(63)
	Inhibition of viral polyprotein tertiary structure	PDTC	15–125 μM PDTC	(63)
Foot and mouth disease virus	Inhibition of viral polyprotein cleavage	$ZnCl_2$, $Zn(OAc)_2$	0.1–2 mM	(64)
	Inhibition of viral RNA and procapsid synthesis	$ZnCl_2$	10–150 μM	(65)
Hepatitis C virus	Inhibition of RNA polymerase	$ZnCl_2$	60–300 μM	(66)
	Inhibition of viral replication	$ZnCl_2$, $ZnSO_4$	50–150 μM	(67)
	Metallothionein-dependent inhibition of viral replication	$ZnSO_4$	50 μM	(34)
Herpes simplex virus	Viral protein synthesis	$ZnSO_4$	N/A	(53)
	Inhibition of viral DNA polymerase	$Zn(OAc)_2$	0.1–2 mM	(52)
	Free virus inactivation	$ZnSO_4$	0.1–6 mM	(48)
	Free virus inactivation	$Zn(Glu)_2$, $Zn(Lac)_2$	1–50 mM	(54)
	Inhibition of protein ubiquitination and NF-κB activity	PT	1.2–18.9 mM	(41)
Human immunodeficiency virus	HIV protease inhibition	Not listed	0.2–2 mM	(68)
	Inhibition of viral transcription and particle production	$ZnCl_2$	70–700 μM	(69)
	Inhibition of reverse transcriptase	$ZnCl_2$	25–800 μM	(70)
Human papilloma virus	Stimulates proviral transcription factor activity, reversed by EVER2	N/A	N/A	(19)
	Inhibition of viral protein E6 and E7 synthesis stimulating apoptosis	CIZAR	500–750 μM	(71)
Respiratory syncytial virus	Reduction in viral titer and plaque count	$ZnCl_2$, $Zn(OAc)_2$, $Zn(Lac)_2$	0.01–10 mM	(72)
Rhinovirus	Inhibition of viral polyprotein cleavage	$ZnCl_2$	100–800 μM	(73, 74)
	Inhibition of viral polyprotein cleavage	$ZnCl_2$	0.1–1.2 mM	(61)
	Inhibition of viral polymerase	not listed	>0.6 μM	(75)
	Inhibition of viral polyprotein processing	PT, HK	5–20 μM PT, 60–125 μM HK	(63)
	Inhibition of viral polyprotein processing	PDTC	15–125 μM PDTC	(63)
Semliki Forest virus	Inhibition of endosomal membrane fusion	$ZnCl_2$	25–100 μM	(76)
	Inhibition of endosomal membrane fusion	$ZnCl_2$	2 mM	(77)
Sindbis virus	Inhibition of viral particle production and polyprotein cleavage	$ZnCl_2$	0.1–1.8 mM	(78)
Transmissible gastroenteritis virus	Inhibition of viral RNA and protein synthesis	$ZnCl_2$, $ZnSO_4$	10–200 μM	(79)
Vaccinia virus	Inhibition of RNA synthesis and viral yield	$ZnSO_4$	100–300 μM	(80)
	Inhibition of viral particle production and polyprotein cleavage	$ZnCl_2$	50–400 μM	(81)
	Inhibition of viral topoisomerase	Not listed	2.5 mM	(82)
Varicella-zoster virus	Free virus inactivation	$Zn(Pic)_2$, $Zn(Asp)_2$	10 μM	(59)

TABLE 2 Human clinical studies using zinc as an antiviral therapy [1]

Viral infection/condition	Antiviral/therapeutic effect	Effective dose	Treatment	Reference
Torque teno virus	Reduced viral load following stem cell transplant	600 mg $ZnSO_4$/d	Oral	(83)
Herpes simplex	Reduced duration and severity of outbreak	ZnO/glycine cream (0.3% ionic Zn)	Topical	(57)
	Reduction in outbreak recurrence	0.025% $ZnSO_4$ solution	Topical	(84)
	Reduction in outbreak recurrence	1–4% $ZnSO_4$ solution	Topical	(58)
Experimental rhinovirus	Reduced duration of illness with $Zn(Glu)_2$ only	$Zn(Glu)_2$ (13.3 mg) or $Zn(OAc)_2$ (5/11.5 mg) lozenges, every 2–3 h/d	Lozenge	(85)
Common cold	Reduced symptom severity, frequency, and duration	ZGG lozenges containing 23 mg Zn, every 2 h/d	Lozenge	(86)
	Reduced symptom severity, frequency, and duration	ZGG lozenges containing 24 mg Zn, every 2–3 h/d (Max 8)	Lozenge	(87)
	Reduced duration of symptoms	ZGG lozenges containing 13 mg Zn, every 2 h/d	Lozenge	(88)
	Reduced symptom severity and duration	$Zn(OAc)_2$ lozenges each containing 9 mg Zn, every 2 h/d	Lozenge	(89)
	Reduced symptom severity and duration	$Zn(OAc)_2$ lozenges each containing 13 mg Zn, every 2–3 h/d	Lozenge	(90)
	No effect on duration or severity	$Zn(Glu)_2$ (13.3 mg) or $Zn(OAc)_2$ (5/11.5 mg) lozenges, every 2–3 h/d	Lozenge	(85)
	Reduced symptom severity and duration	$Zn(OAc)_2$ lozenges each containing 13 mg Zn, every 2–3 h/d	Lozenge	(91)
Viral warts	Improved clearance of warts after 1–2 mo	10 mg/ kg $ZnSO_4$ to a maximum dose of 600 mg/d	Oral	(92)
	Clearance of warts based on concentration of zinc used	3 × 5 or 10% $ZnSO_4$/d	Topical	(93)
	Improved clearance of warts after 1–2 mo	10 mg/ kg $ZnSO_4$ to a maximum dose of 600 mg/d	Oral	(94)
	No benefit	10 mg/ kg $ZnSO_4$/d	Oral	(95)
	Resolution of 88% of lesions after 6 wk/3 sessions	Up to 3 intralesional injections with 2% $ZnSO_4$	Injection	(96)
Laryngeal papillomatosis	Resolution of papillomatosis (2 case studies)	10 mg/ kg $ZnSO_4$/d	Oral	(97)
HIV	Reduced infection, increased CD4 T cell count	200 mg/d $ZnSO_4$/d	Oral	(98)
	Increased CD4 T cell count	45 mg $Zn(Glu)_2$ every 8 h for 15 d, then 15 mg for 15 d	Oral	(99)
	Reduced incidence of diarrhea	10 mg elemental zinc as $ZnSO_4$/d	Oral	(100)
	No benefit	25 mg/d $ZnSO_4$/d	Oral	(101)
Chronic hepatitis C virus	Enhanced response to IFN treatment	2 × 75 mg polaprezinc/d	Oral	(102)
	No benefit to IFN treatment response	5 × 78 mg $Zn(Glu)_2$/d	Oral	(103)
	Reduced serum AST, ALT, and ferritin	3 × 75 mg polaprezinc/d	Oral	(104)
	Reduced serum ALT and Th2 cells (%)	2 × 75 mg polaprezinc/d	Oral	(105)
	Reduced incidence of HCC (albumin-dependent)	2 × 150 mg polaprezinc/d	Oral	(106)

[1] ALT, alanine aminotransferase; AST, aspartate aminotransferase; HCC, hepatocellular carcinoma; ZGG, zinc gluconate/glycine; $Zn(Glu)_2$, zinc gluconate; ZnO, zinc oxide; $Zn(OAc)_2$, zinc acetate; $ZnSO_4$, zinc sulfate.

Picornaviridae.

It was clear as early as 1974 that zinc possessed an inhibitory effect on picornovirus polyprotein processing (73). Before 1980, zinc inhibition of picornovirus proteases from human rhinovirus isolates (73, 74), encephalomyocarditis virus (62), poliovirus (61), and foot and mouth disease virus (64, 65) had all been demonstrated. More recent studies using zinc ionophores have illustrated that zinc interferes with the autocatalytic processing of the viral protease $3CD^{pro}$ into $3C^{pro}$ in the picornavirus coxsackievirus B3, thus inhibiting processing of the viral polyprotein (107). However, this was not the case for encephalomyocarditis virus, where zinc appeared to inhibit the tertiary structure within the viral polyprotein (107). Together, these data suggest that zinc may interfere with proteolytic processing of the viral polyprotein because of misfolding, or through direct actions on the viral protease $3CD^{pro}$.

Clinical studies using zinc supplementation are primarily limited to rhinovirus infection, and are often grouped with other "common cold" viruses such as influenza and coronaviruses. The majority of studies use zinc lozenges with various zinc formulations and concentrations, possibly explaining the large variability in results [extensively reviewed in (108) and (109)]. Importantly, the amount of ionic zinc present at the site of infection (oral and nasal mucosa) is highly correlated to the study outcome (51, 108), and is dependent on the zinc formulation. At a physiological pH and 37°C, zinc gluconate for example, releases high amounts of ionic zinc, whereas zinc aspartate releases none (108). Upon examining only the relevant studies where high doses of ionic zinc were used, a clear reduction in cold duration of 42% was calculated (109). Whether this was caused by viral inhibition, improved local immune response, or an amelioration of symptoms remains uncertain.

Other respiratory tract infections: influenza, coronavirus, and metapneumovirus.

Few studies have examined the antiviral effects of zinc on other respiratory viruses. In vitro replication of influenza (PR/8/34) is significantly inhibited by the addition of the zinc ionophore pyrrolidine dithiocarbamate (110), perhaps through inhibition of the RNA-dependent RNA polymerase (RdRp), as had been suggested 30 y earlier (111). In similar fashion, severe acute respiratory syndrome (SARS) coronavirus RdRp template binding and elongation was inhibited by zinc in Vero-E6 cells (60). Moreover, zinc salts were shown to inhibit respiratory syncytial virus, even while zinc was incubated with HEp-2 cells only before infection, and then removed (72). The authors suggest that this indicates an inhibitory mechanism similar to HSV by preventing viral membrane fusion; however, no measures were taken to assess changes in intracellular zinc content, nor inhibition of other aspects of the viral life cycle.

Flaviviridae: a focus on HCV.

Flaviviruses represent a number of insect-borne viruses including dengue and West Nile virus, as well as the hepatotrophic virus, HCV. The effect of zinc on insect-borne flaviviruses is scarce; however, in vitro studies by our group (34) and others (67) have demonstrated that zinc salts can reduce HCV replication (~50% at 100 μM $ZnSO_4$), perhaps by inhibiting the HCV RdRp, as shown in *E. coli* [half maximal inhibitory concentration (IC50) ~60 μM] (66). Although this is a potential mechanism, it has not been examined in eukaryotic cells in which zinc homeostasis is significantly different.

If left untreated, HCV becomes a chronic hepatic infection in around two-thirds of individuals (112), resulting in a significant reduction in plasma zinc (113). Consequently, zinc supplementation in HCV studies have focused on improved patient outcomes, particularly decreased liver inflammation, and enhanced response to antiviral treatment. Supplementation with 150 mg/d polaprezinc (a bioavailable zinc L-carnosine chelate) has been shown to reduce markers of hepatic inflammation alanine aminotransferase and aspartate aminotransferase alone (105), and in combination with the antiviral treatment IFN-α (106). Moreover, polaprezinc significantly improved the rate of viral clearance, particularly in patients with lower viral loads at baseline (102). The mechanisms underlying these observations remain uncertain; however, are likely a combination of direct antiviral effects and strengthening of the antiviral response. Zinc supplementation and the antiviral response is reviewed below.

Togaviridae.

Like flaviviruses, togaviruses primarily consist of arthropod-borne viruses such as Semliki Forest virus, Western equine encephalitis virus, and Chikungunya virus. Viral infection occurs by receptor-mediated endocytosis, followed by fusion of virus and endosomal membranes, and particle release into the cytoplasm (114). Using liposome (76), red blood cell (115), and BHK-21 (77) cell model systems, zinc has been shown to efficiently inhibit membrane fusion of Semliki Forest virus and sindbis viruses. Zinc ions interfere with membrane fusion by binding to a specific histidine residue revealed on the viral E1 protein at low endosomal pH (77). Unfortunately, the in vivo relevance of this model is unclear because of the high concentration of zinc (>1 mM) used. Notably, concentrated zinc is present in vesicular zincosomes that are thought to serve as intracellular zinc storage vesicles (116). Similar to the mechanism used by macrophages to inhibit intracellular *Mycobacterium spp*., zincosome fusion to viral endosomes may inhibit key aspects of the viral life cycle such as togavirus membrane fusion.

Retroviridae: HIV.

Retroviruses are named after their ability to transcribe RNA into DNA using their unique reverse transcriptase (RT), consequently allowing integration of retroviral DNA into the host genome. The integrated provirus can then establish a latent infection for the life of the host and is a major barrier to virus cure strategies, particularly for HIV-1 (117). Similar to viral RdRps, zinc has also been identified as

an inhibitor of retrovirus RTs (118, 119). Fenstermacher and DeStefano demonstrated in 2011 that Zn^{2+} cations can displace Mg^{2+} ions from HIV-1 RT, promoting the formation of an excessively stable, but incredibly slow and inefficient replication complex (70). Zinc was also shown to inhibit the HIV-1 protease in 1991 (68), and to inhibit viral transcription in 1999 (69), but has received little attention since, with the exception of molecular simulation experiments that identified the zinc-binding sites at the catalytic aspartate-25 residue (120). As stated above, HIV can also stimulate zinc influx into monocytes (33), which may appear contradictory based on its antiretroviral properties. Latently infected monocytes and macrophages, however, can act as viral reservoirs for HIV (121), and could therefore benefit from zinc-mediated inhibition of cell death. In fact, unlike the majority of $CD4^+$ T cells, low levels of replication in macrophages do not result in cell death (122), making them a viable reservoir, in addition to long-lived resting $CD4^+$ T cells, for viral recrudescence after cessation of antiretroviral treatment.

Zinc deficiency is common in HIV-infected individuals, where it is associated with inflammation (123), immunological failure (124), and death (125). A recent Cochrane Review examined the role of micronutrient supplementation in people living with HIV (126). Although a number of studies demonstrated beneficial effects of zinc supplementation, the majority were underpowered. The authors concluded that zinc supplementation probably increases blood zinc concentration (moderate certainty), and may increase $CD4^+$ counts (low certainty).

Unlike zinc supplements, prophylactic zinc gels have shown a substantial benefit to limit HIV infection in vivo. Complete protection against vaginal SHIV-RT (a simian HIV virus expressing the human RT) infection in macaques was obtained by pretreating animals with an antiviral gel containing 14 mM zinc acetate and 50 μM MIV-150, a reverse transcriptase inhibitor (127). When used alone, zinc acetate is a potent antiviral, providing 66% protection against SHIV-RT vaginal infection (56) and an EC50 <100 μM in peripheral blood mononuclear cells against a range of HIV strains (128). Importantly, zinc treatment did not affect viral titers in macaques that became infected, nor did it result in zinc resistant HIV mutants with conserved *pol* (RT) mutations. These data suggest that zinc may not interfere with the HIV RT, but instead inactivate free virus or prevent viral attachment/penetration as reported for HSV (48, 54).

Papillomaviridae.

HPVs are oncogenic viruses that infect basal epithelial cells, where they stimulate proliferation resulting in warts. Although cutaneous warts are usually self-limiting and harmless, mucosal strains of HPV (e.g. high risk HPV-16 and -18) are a primary cause of cervical cancers (129). HPV oncoproteins E6 and E7 in particular, are significant drivers of cell proliferation and resistance to cell death by stimulating the degradation of tumor suppressor p53 and pRb, respectively [reviewed in (130)]. Although nuclear zinc appears to enhance HPV replication (see ***Zinc homeostasis and viral infection***), exogenous zinc treatment (CIZAR, zinc chloride and citric acid anhydrous) can effectively inhibit production of viral oncogenic proteins E6 and E7 (71). The inhibition of E6 and E7 by zinc results in apoptosis of cervical carcinoma cells, as they regain the function of tumor suppressors p53 and pRb (71). The mechanism by which zinc downregulates E6 and E7 expression is unknown, but may be preceded by a zinc-driven blockade in another component of the viral life cycle.

It would appear that both topical and oral zinc supplementation strategies have proven tremendously effective for cutaneous and genital warts. Unfortunately, the vast majority of studies are either underpowered, lacking suitable controls, or single case studies. Nonetheless, a recent systematic review concluded that zinc supplementation was the most effective systemic treatment for cutaneous warts, when compared to other available options (131). It should be noted, however, that individuals with persistent viral warts are often zinc-deficient or have lower concentrations than their healthy counterparts (132). In fact, studies demonstrating the most significant responses to zinc treatment had engaged patients that were primarily zinc-deficient (>70 μg/dL) (92, 94). Nonetheless, 78% (94) and 100% (92) of patients showed clearance of lesions in response to oral zinc sulfate (10 mg/kg up to 600 mg/d) compared to 13% and 0% of the placebo group, respectively. Topical zinc formulations have also proved efficacious for treatment of viral warts. A small study using a 4-wk topical 10% zinc sulfate regimen for plane warts demonstrated an 86% response rate (6/7), compared to a 10% response rate (1/10) in the control group (93).

Recent work suggests that treatment of vaginal HPV infections with topical zinc formulations may benefit the millions of women that remain unvaccinated against HPV. A recent pilot study demonstrated that intravaginal infusion of 500 μM zinc citrate in women diagnosed with high-risk HPV resulted in a 64% clearance rate, compared to 15% in the control group (133). Additional studies in mice have demonstrated that MZC, a formulation containing MIV-50, zinc acetate, and carrageenan, efficiently inhibited vaginal and anorectal HPV-16 pseudoviral particle infection (134).

In summary, it is evident that zinc possesses antiviral properties against a number of viral species. Although mechanistic studies are lacking, zinc appears to inhibit viral protease and polymerase enzymatic processes, as well as physical processes such as virus attachment, infection, and uncoating (**Figure 1**). Unfortunately, these mechanisms have not been well scrutinized in clinical studies, where zinc may provide inexpensive and effective adjunct treatments for many viral infections.

The role of zinc in antiviral immune signaling

Ionic zinc possesses unique and distinct antiviral properties against a number of human viruses; however, the antiviral immune response led by IFNs is invariably required to clear infections. Zinc has been shown to contribute to a number of innate and adaptive immune signaling pathways that have

FOI 26-3132 - Document 5

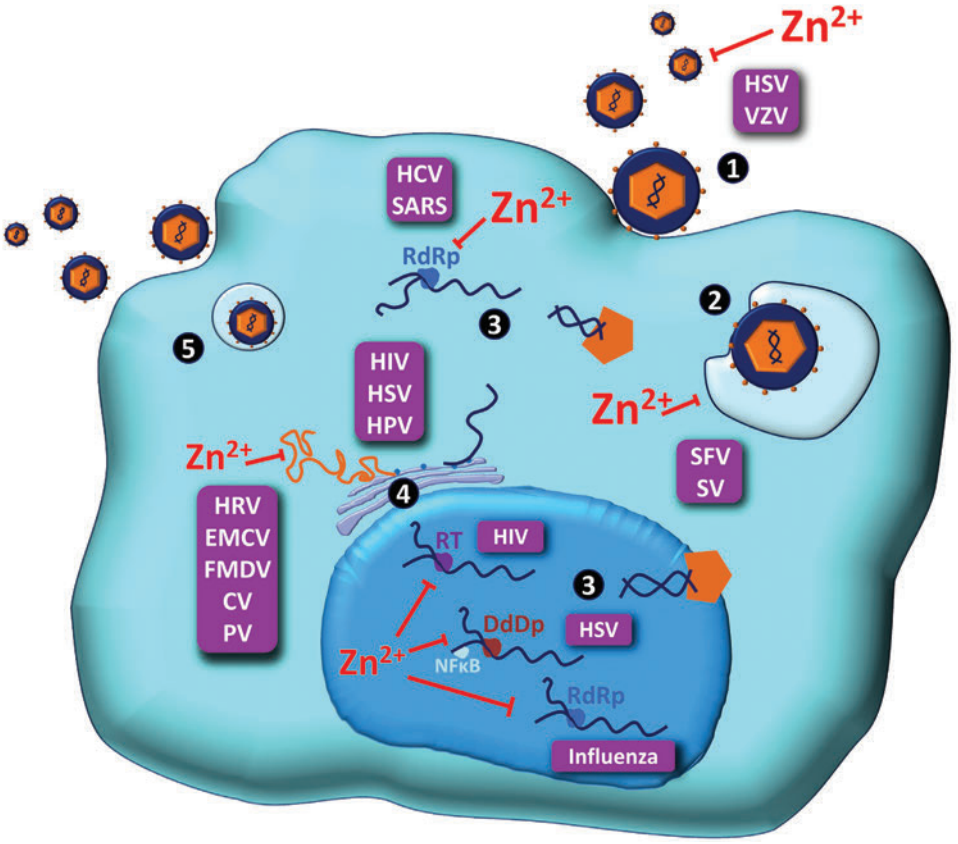

FIGURE 1 The diverse stages of viral replication cycles that are inhibited by zinc. In vitro studies have demonstrated a number of mechanisms by which zinc interferes with the viral replication cycle. These include free virus inactivation (1), inhibition of viral uncoating (2), viral genome transcription (3), and viral protein translation and polyprotein processing (4). No studies to date, however, have demonstrated zinc-mediated inhibition of virus assembly and/or particle release. CV, coronavirus; DdDp, DNA-dependent DNA polymerase; EMCV, encephalomyocarditis virus; FMDV, foot and mouth disease virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papilloma virus; HRV, human rhinovirus; HSV, herpes simplex virus; PV, polio virus; RdRp, RNA-dependent RNA polymerase; RT, reverse transcriptase; SARS, severe acute respiratory syndrome coronavirus; SFV, Semliki Forest virus; SV, sindbis virus; VZV, varicella-zoster virus; Zn, zinc.

been comprehensively reviewed recently (135). As such, this review will focus specifically on the role of zinc in the immune response to viruses.

Viral infections are recognized by a number of innate immune receptors termed pattern recognition receptors (PRRs). These include the cell surface and endosomal Toll-like receptors (TLRs), as well as a variety of cytosolic PRRs such as RIGI, MDA5, and IFI16 that primarily bind viral nucleic acids (136). Following ligand binding, PRRs share a number of downstream signaling intermediates, that ultimately activate both inflammatory (NF-κB, AP1) and innate immune (IRF1/3/7) transcription factors. These transcription factors cooperate to induce expression of IFNs, of which there are 3 types: type I (IFN-α and IFN-β), type II (IFN-γ), and type III (IFN-λs). Type I and III IFNs activate very similar antiviral signaling pathways; however, the type I IFN response is ubiquitous, whereas the type III IFN response is limited to a subset of immune cells, as well as epithelial cells of the liver, gastrointestinal, and pulmonary tracts (137). Although both IFN types bind unique receptors, they activate a common signaling cascade where STAT1 and STAT2 heterodimerize and bind IRF9, followed by translocation into the nucleus and subsequent binding of the IFN-sensitive response element that is present in hundreds of gene promoters. As stated previously, these ISGs possess numerous roles including immune cell chemotaxis and activation, as well as numerous antiviral mechanisms to inhibit viral replication within infected and neighboring cells.

Zinc and pathogen recognition.

Upon recognition of microbial antigens by TLRs, a rapid and transient influx of free zinc ions occurs. Interestingly, this has been demonstrated in response to viral stimuli, imiquimod, ssRNA40 (TLR7), and CpG (TLR9), but not polyI: C (TLR3) in the mouse macrophage RAW 264.7 cell line (138). In response to TLR7 activation, zinc was shown to reduce the production of type I IFNs and ISGs CD80

and CD86. Based on results using other stimuli, the authors suggest that zinc can inhibit IRF3-, and perhaps IRF7-dependent IFNB production, by limiting activation and/or nuclear translocation (138). The role of the zinc influx in this context remains undefined, but may reflect a regulatory mechanism to prevent excessive IFN production.

Although no direct inhibition of IRF signaling by zinc has been demonstrated, zinc can modulate a number of factors upstream of IRF activation. For example, the IκB kinase (IKK) members IKKα and IKKβ are inhibited by zinc, albeit at high concentrations of ∼0.5 μM (139). IKKα has been shown to activate IRF7 in response to TLR7/9 stimulation (140), whereas IKKβ (141), IKKε and TANK-binding kinase-1 (TBK1) (142) can activate IRF3 following TLR3 stimuli. Zinc can also stimulate expression of the deubiquitinating enzyme A20 (43) to inhibit the pathogen response. A20 is a regulator of NF-κB- (143), TLR3- (144), and RIGI-mediated (145) IFN production, most likely by targeting PRR signaling components TIR-domain-containing adapter-inducing interferon-β (TRIF), TNF Receptor Associated Factor (TRAF) 2, and TRAF6. A20-deficient cells are hyper-responsive to viral infection, possess increased activation of NF-κB, IRF3, and IRF7, and improved viral clearance (146).

Zinc and the interferon response.

After pathogen recognition, NF-κB, AP1, and IRF3/7 bind IFN promoters to stimulate type I/III IFN production. Zinc plays a significant role in the response to IFNs by modulating secretion, cytokine potency, and receptor binding, as well as influencing signaling intermediates and pathway inhibitors. A recent study has demonstrated that intracellular zinc can reduce IFN secretion by destabilizing *sortilin* mRNA transcripts (147). Sortilin is an endosomal protein that facilitates secretion of cytokines such as IFN-γ and IL6 (148), and its depletion results in a significant reduction in secretion of IFN-α. Consequently, because sortilin ensures trafficking and secretion of numerous cytokines, it is possible that zinc also inhibits the secretion of other IFNs.

Structural studies have demonstrated that zinc ions can mediate dimerization of IFNA molecules (149). Nonetheless, apart from crystallization studies, dimers were difficult to generate despite using concentrated IFN (50 μM) and zinc (1 mM). It is therefore likely that the circulating active form of IFN-α is monomeric. A single study performed in 2001 showed that zinc can increase the antiviral activity of IFN-α 10-fold against rhinovirus challenge (150). Although this study drew radical conclusions, antiviral activity was based on cytopathic effect alone, and its results have not been reproduced since. Moreover, zinc was added before viral infection, which is known to interfere with rhinovirus polyprotein processing (73, 74), as reviewed above.

Unlike type I IFNs, a recent study by our group has shown that zinc can inhibit IFN-λ3 signaling, most likely by preventing receptor binding and subsequent signaling (28). Upon demonstrating in 2014 that metallothionein expression was *IFNL* genotype-dependent, and inversely associated with ISG expression in HCV (151), we showed that serum zinc was the driver of hepatic metallothionein expression. Although zinc had minimal effect on IFN-α signaling, it could almost ablate IFN-λ3 signaling at a concentration of 50 μM, resulting in a significant reduction in its antiviral activity (28). Interestingly, we found no inhibition of IFN-λ1 activity using 50 μM $ZnSO_4$, suggesting a highly specific interaction. The mechanism by which zinc interferes with the IFN:receptor interaction remains uncertain; however, we have ruled out an effect of zinc on IFN-λ3 disulfide bond formation.

Type I and III IFNs bind to unique receptor complexes composed of IFN-α receptors IFNAR1/IFNAR2 and IFN-λ receptors IFNLR1/IL10RB, respectively, but signal via almost identical pathways. Consequently, zinc may act to reinforce the shared IFN signaling cascade by inhibiting protein tyrosine phosphatase enzymatic activity (152). Following receptor engagement by IFNs, intracellular Janus protein tyrosine kinases Jak1 and Tyk2 become phosphorylated, which in turn phosphorylate STAT molecules to stimulate ISG expression. By dephosphorylating these key signaling molecules, a number of phosphatases have been shown to "put the brakes" on IFN signaling. Phosphatases tyrosine-protein phosphatase non-receptor type 6 (SHP1), type 11 (SHP2), and protein phosphatase 2A (PP2A) have all been shown to inhibit JAK-STAT phosphorylation (153–155), and are all inhibited by zinc ions, predominantly in the nanomolar range (156–158). Interestingly, PP2A can also inhibit the phosphorylation of IRF3, thus regulating antigen recognition by PRRs (159). Conversely, the tumor suppressor phosphatase and tensin homologue (PTEN) stimulates IRF3 activation by removing inhibitory phosphorylation at Ser97 (160), and is also inhibited by zinc at nanomolar concentrations (161). Zinc inhibits numerous pro- and antiviral phosphatases, with the net effect on virus recognition and response being undefined, which clearly requires further study.

To enable a highly controlled IFN response, negative regulators of IFN signaling are often ISGs. These include the suppressors of cytokine signaling (SOCS-1 and SOCS-3), which bind and inhibit JAK protein signaling, thus preventing signaling from numerous inflammatory (IL-6) and antiviral stimuli (162). Interestingly, zinc-driven activation of the MTF-1 transcription factor can induce expression of SOCS-3 in HepG2 cells (163). The zinc importer ZIP-14, which is responsible for zinc influx following inflammatory stimuli, was required for SOCS-3 expression, and may represent yet another zinc-mediated mechanism to limit the inflammatory response. Although the transporter responsible for hepatic zinc influx following IFN stimulation remains unknown, it is perceivable that ZIP-14 may drive zinc influx and subsequent SOCS-3 expression.

Zinc deficiency caused by disease, age, and lifestyle factors: lessons from supplementation

Zinc status is primarily determined by dietary zinc intake; however, additional factors such as dietary composition, alcohol intake, and disease state can significantly reduce zinc uptake and storage, or increase zinc excretion (164). With respect to dietary composition, zinc supplementation as part of a meal can significantly reduce zinc absorption when compared to water-based solutions of zinc (164). Moreover, dietary phytate, a natural chelator of zinc ions that is present in corn, rice, and cereals, can severely restrict zinc absorption (165). Consequently, diets containing high phytate: zinc molar ratios, can result in zinc deficiency, even with adequate zinc intake. Unfortunately, rural diets in low-income nations are often zinc-poor and phytate-rich because of a dietary reliance on rice and vegetables.

Aged individuals are also significantly more susceptible to zinc deficiency, increasing their likelihood of acquiring life-threatening viral infections (166). Ex vivo, zinc supplementation has been shown to improve leukocyte IFN-α production (167) and to reduce mononuclear cell TNF production (168). Year-long supplementation with 45 mg elemental zinc/d in elderly subjects (aged 55–87 y), has also demonstrated a dramatic reduction in the incidence of infection as well as plasma oxidative stress markers (168).

Alcoholism can stimulate severe zinc deficiency developed via numerous sociological and physiological mechanisms, with factors including but not limited to *1*) increased urinary zinc excretion (169), *2*) reduced zinc intake (poor diet) (170), *3*) reduced zinc absorption (171), and *4*) and a reduction in hepatic zinc stores (172). Alcohol also stimulates microbial dysbiosis and gastrointestinal permeability (173), a phenotype that can increase the likelihood of viral infection in the gut (174). Importantly, dietary zinc supplementation can improve intestinal barrier dysfunction as a result of alcohol and microbial infection (175, 176).

As previously discussed, zinc deficiency is common among chronic infections such as HPV, HCV, and HIV (113, 123). Consequently, a number of studies have examined the effects of zinc supplementation on antiviral immunity, inflammation, and treatment response. As described above, zinc supplementation can improve HCV treatment response and liver inflammation caused by chronic infection. In addition, long-term zinc treatment over 7 y has been shown to reduce the risk of hepatocellular carcinoma progression in chronic HCV patients, as assessed by multivariate analysis, compared to controls ($P < 0.05$) (105). Zinc supplementation has also been assessed as an adjunct therapy to antiretroviral administration in patients with HIV. One study reported a 4-fold reduction in the rate of immune failure, as well as decreased diarrhea in patients treated with zinc compared to controls ($P < 0.05$ for both groups) (124). A more recent study revealed an increase in $CD4^+$ T cell count in patients treated with a combination of zinc and antiretroviral therapy, compared to patients on antiretroviral therapy alone ($P < 0.05$) (177). Taken together, these data indicate that zinc deficiency is associated with greater disease activity in the context of chronic viral infection. Oral zinc supplementation may act in a synergistic manner when co-administered with antiviral therapy and contribute to improved clinical outcomes.

Vaccination studies.

Zinc supplementation during vaccination strategies has provided an opportunity to examine the role of zinc in the humoral response to viruses. A particular focus has been applied to the effect of zinc supplementation on rotavirus vaccination because of the high rate of mortality associated with childhood diarrhea in developing countries. Unfortunately, although zinc deficiency is associated with increased risk of rotavirus gastroenteritis (178), it does not greatly increase the development of humoral immunity followed by vaccination (rotarix), as defined by seroconversion rate (179). Nonetheless, a pooled analysis of randomized trials performed in 2000, demonstrated that zinc supplementation shortens the length of diarrheal episodes and reduced the rate of treatment failure or death by 42% in zinc-deficient children (180).

Comparable studies of supplementation with zinc before vaccination have produced similar disappointing results. Zinc supplementation did not improve seroconversion following administration of the oral poliovirus vaccine in infants (181), nor did it improve the immunological response to HBV (182) or influenza vaccination (183) in the elderly. Although there remains little evidence that zinc improves viral vaccination responses, a small number of studies suggest that zinc may improve antibody titers and antibacterial responses to pneumococcus (184) and cholera infections (185).

Conclusions and Future Perspectives

The tight regulation of zinc homeostasis both systemically and intracellularly indicates that zinc plays an essential role in human health. Although zinc is a component of ~10% of the human proteome, zinc in different forms (free compared with protein-bound) can stimulate a variety of signaling events, including the antiviral response. In vitro studies suggest that free zinc may possess potent antiviral effects, and are supported by trials of creams, lozenges, and supplements with high free zinc content. Moreover, zinc-binding proteins such as the metallothioneins may possess antiviral roles, although their specific function remains uncertain. Nonetheless, zinc treatment applied at a therapeutic dose and in the right form has the potential to drastically improve the clearance of both chronic and acute viral infections, as well as their accompanying pathologies and symptoms. Consequently, the role of zinc as an antiviral can be separated into 2 categories: *1*) zinc supplementation implemented to improve the antiviral response and systemic immunity in patients with zinc deficiency, and *2*) zinc treatment performed to specifically inhibit viral replication or infection-related symptoms (75, 78–82, 83, 85–91, 95–101, 103, 104).

Acknowledgments

The authors' responsibilities were as follows—SR and GA designed the review, all authors performed the study selection, all authors read and approved the final manuscript.

BRIEF COMMUNICATION

Ivermectin, antiviral properties and COVID-19: a possible new mechanism of action

Emanuele Rizzo [1,2]

Abstract

Ivermectin is an antiparasitic drug that has shown also an effective pharmacological activity towards various infective agents, including viruses. This paper proposes an alternative mechanism of action for this drug that makes it capable of having an antiviral action, also against the novel coronavirus, in addition to the processes already reported in literature.

Keywords Ivermectin · Antiviral · Ionophore · COVID-19 · SARS-CoV-2

Ivermectin [mixture of 22, 23-dihydroavermectin B1a (80%) and 22, 23-dihydroavermectin B1b (20%)] (Fig. 1) is a macrocyclic lactone with a broad-spectrum antiparasitic pharmacological activity (Gonzalez Canga et al. 2008). It is the safest and most effective semi-synthetic derivative of the entire class of avermectins, discovered in 1975 by Professor Satoshi Ōmura as fermentation products of the actinomycete bacterium *Streptomyces avermitilis* (Crump 2017) (later reclassified in *S. avermectinius* (Takahashi et al. 2002)). Its main pharmacodynamics is to bind some channel proteins for chlorine controlled by glutamate, typical of specific classes of invertebrates, causing a greater permeability to this electrolyte: all this causes a hyperpolarization of the cell membrane, blocking inhibitory neurotransmission in neurons and myocytes, resulting in paralysis and death (Geary 2005). Commercialized since 1981, its low cost, its high efficacy and safety, and the marked tropism for helminths (therefore with an almost zero impact on the biochemistry of human beings) have led to its inclusion in the twenty-first World Health Organization's List of Essential Medicines (World Health Organization 2019).

Ivermectin is a versatile drug with unique characteristics, which make it interesting also for basic and applied research (in particular for drug repurposing): it seems to reveal an antibacterial (Lim et al. 2013; Ashraf et al. 2018), antiviral, and anticancer activity (Juarez et al. 2018; Intuyod et al. 2019), besides being potentially useful for the treatment of some chronic pathologies (Ashraf and Prichard 2016; Ventre et al. 2017), result of an action on a wide range of cellular targets.

Regarding its role as an antiviral agent, its efficacy has been demonstrated on several viruses, both in vitro and in vivo. Among the many mechanisms by which it performs its function, the most consolidated one sees ivermectin as an inhibitor of nuclear transport mediated by the importin α/β1 heterodimer, responsible for the translocation of various viral species proteins (HIV-1, SV40), indispensable for their replication (Wagstaff et al. 2011; Wagstaff et al. 2012). This inhibition appears to affect a considerable number of RNA viruses (Jans et al. 2019; Caly et al. 2012), such as Dengue Virus 1-4 (DENV) (Tay et al. 2013), West Nile Virus (WNV) (Yang et al. 2020), Venezuelan Equine Encephalitis Virus (VEEV) (Lundberg et al. 2013), and Influenza (Gotz et al. 2016). In addition, ivermectin has been shown to be effective against the Pseudorabies virus (PRV, with a DNA-based genome), both in vitro and in vivo (Lv et al. 2018), using the same mechanism. Caly et al. (Caly et al. 2020) have recently shown that the drug also inhibits the replication of the SARS-CoV-2 virus in vitro, however not clarifying how it occurs. Since the causative agent of COVID-19 is an RNA virus, it can be reasonably expected an interference with the same proteins and the same molecular processes described above.

However, ivermectin could prove to be a powerful antiviral, therefore also useful for a possible treatment of the new coronavirus associated syndrome, even from a new perspective. This could happen assuming its role as an ionophore agent, only hinted in the recent past but never fully described (Juarez et al.

2018). Ionophores are molecules that typically have a hydrophilic pocket which constitutes a specific binding site for one or more ions (usually cations), while its external surface is hydrophobic, allowing the complex thus formed to cross the cell membranes, affecting the hydro-electrolyte balance (Freedman 2012). These chemical species have historically been used to study the mitochondrial respiratory chain and ATP synthesis in eukaryotes (in this case also known as decoupling agents, such as 2, 4-dinitrophenol), and their antibiotic activity has long been appreciated (Bakker 1979). It is also hypothesized their role as antiviral drugs (Krenn et al. 2009; Sandler et al. 2020) and anticancer chemotherapeutic agents (Kaushik et al. 2018). Thinking of the structure of two of the most important ionophores, monensin A and valinomycin, respectively a polyether and a depsipeptide antibiotic, it is clear that they internally present many oxygen atoms (with related free electron doublets), indispensable for binding cations and transporting them through phospholipidic bilayers.

At a first glance, the two structures that make up the ivermectin formula do not have these chemical properties, nor those mentioned above, essential for a compound to be defined as ionophore. However, it can be hypothesized that two ivermectin molecules, reacting with each other in a "head-tail" mode, can create a complex suitable to be considered such (Fig. 2). This interaction could occur spontaneously or be mediated by the binding of the same molecules to some plasma transport proteins, in particular albumin (Klotz et al. 1990), which would have the role of positioning them in the correct way to obtain the proposed configuration.

As it can be seen, in this way, an internal cavity is formed: the oxygen atoms (indicated in red), now present in greater number, work as Lewis bases and could therefore coordinate a series of cations (Lewis acids). On the other hand, the –OH groups are highlighted in blue and they could have a decisive role in the stabilization of the new structure, with the establishment of chemical bonds between these functional groups: one or more –O– bridges (however, it is difficult the formation of ether bonds, since acid catalysis at high temperature is not possible under normal conditions, both in vitro and in vivo) or more probably hydrogen bonds could be formed, even among more molecular complexes of this type. However, the formation of other weak and strong interactions of various kinds cannot be excluded. Otherwise, specific cations could bind the two molecules in the proposed way, creating themselves the final structure and stabilizing it: there are examples already known in literature (Abbott et al. 1979). The external part of the complex, then, would already have in itself all the hydrophobic characteristics necessary to carry ions through the viral membrane. As a consequence, it would be determined an ionic imbalance between the external and internal environment, with the recall of water and consequent osmotic lysis. This would allow to neutralize the virus at an early stage of the

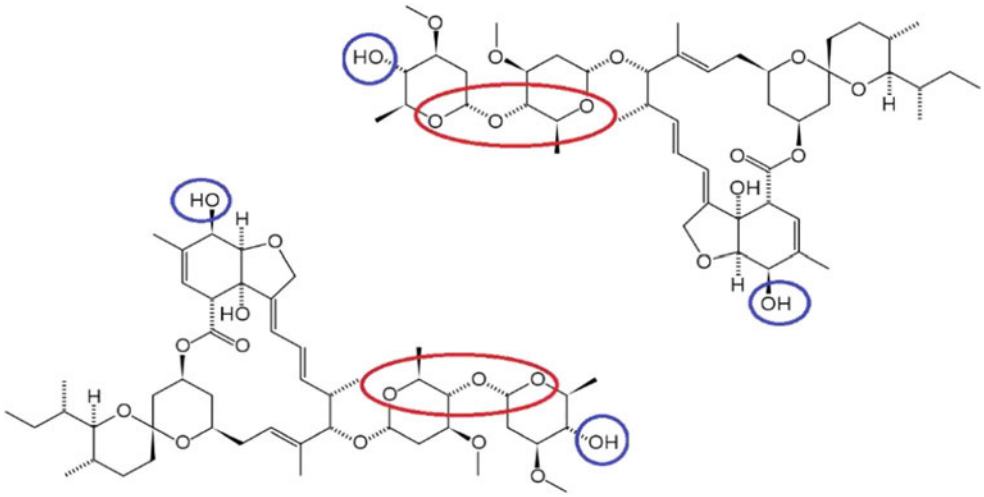

Fig. 2 Possible interaction mechanism between two ivermectin molecules

infection, before; therefore, it can adhere to the host cells and enter it to exploit their biochemical machinery for the production of other viral particles. However, this hypothesis would concern only viruses without a proteic capsid, a structure that shows a certain resistance to osmotic pressure, even if to a lesser extent than a bacterial, fungal, or plant cell wall (Cordova et al. 2003). The new coronavirus is one of these, presenting only a phospholipid envelope in defense of the genetic material, where its few proteins are inserted and which it acquires in the act of exiting the infected cells (Sigrist et al. 2020). This unconventional electrolyte uptake mode could also affect the potential of the viral membrane, threatening its integrity and functionality. The same goes for the viral proteins present here. Furthermore, the concentration variation of some cations, thus determined, could inhibit some key enzymes in the viral replication, such as RNA-dependent RNA polymerases (RdRp) (te Velthuis et al. 2010), already used as pharmacological targets.

Another indication in favor of a possible ionophore role for ivermectin comes from the analysis of molecular similarity that can be carried out through the Drugbank database (www.drugbank.ca). By setting a minimum similarity threshold for ivermectin equal to 0.7, about 14 results are obtained. Among the various selected molecules, the majority of which have antiparasitic and antibiotic activity (already not only on the market but also in the study and experimentation phase), a compound that has high structural similarity is nystatin (score of 0.72), an antimycotic drug with an ionophoric activity at the plasma membrane level, where it forms channels (Yamasaki et al. 2011; Stillwell 2016; Rang 2015).

Immediately afterwards, with a slightly lower similarity, it can be find amphotericin B and natamycin, all pharmacological molecules of assured ionophoric activity (score of 0.71 and 0.706, respectively) (Stillwell 2016; Rang 2015; Ramos 1989; Ikehara et al. 1986).

In conclusion, pending computational simulations and chemical-physical laboratory analysis, this hypothesis could be applied to other known pharmacological molecules, in order to identify compounds with probable ionophore nature to be used in research and clinical practice.

Authors' contributions All research phases (idea, drafting of the paper, and proofreading) were conducted by the only author, ER.

Zinc supplementation reduced morbidity, but neither zinc nor iron supplementation affected growth or body composition of Mexican preschoolers[1–3]

Jorge L Rosado, Patricia López, Elsa Muñoz, Homero Martinez, and Lindsay H Allen

See corresponding editorial on page 160.

ABSTRACT In rural Mexico and in many developing countries micronutrient deficiencies, growth stunting, and morbidity from infectious diseases are highly prevalent in young children. We assessed the extent to which growth stunting could be reversed and the number of infectious disease episodes reduced by zinc and/or iron supplementation. In a double-blind, randomized community trial 219 Mexican preschoolers were supplemented with either 20 mg Zn as zinc methionine, 20 mg Fe as ferrous sulfate, 20 mg Zn + 20 mg Fe, or a placebo. After 12 mo, plasma zinc increased significantly in the two zinc-treated groups, and plasma ferritin was significantly higher in the two iron-treated groups. There was no effect of treatments on growth velocity or body composition. Children in both zinc-supplemented groups had fewer episodes of disease (zinc alone, 3.9 ± 0.3; zinc + iron, 3.7 ± 0.4; placebo, 4.6 ± 0.5; $P < 0.03$), including diarrhea (zinc alone, 0.7 ± 0.1; zinc + iron, 0.8 ± 0.1; placebo, 1.1 ± 0.2; $P < 0.01$). Zinc and zinc + iron supplements reduced morbidity but had no effect on growth or body composition. *Am J Clin Nutr* 1997;65:13–9.

KEY WORDS Zinc, iron, Mexico, supplementation, growth, body composition, morbidity, children

INTRODUCTION

Undernutrition is manifested in most developing countries by early growth stunting and a high prevalence of micronutrient deficiencies. National surveys in Mexico showed that 25–50% of preschool children in rural areas are stunted (1), and that anemia affects 16–51% of urban children and ≤ 91% of those in poorer rural regions (2, 3).

The present study was conducted in the Valley of Solís, a rural region in central Mexico, as a logical intervention based on previous information about the nutritional status of children and adults in the valley. The children have been of normal weight and length when born, but compared with international reference values length *Z* scores fall immediately after birth, and weight *Z* scores start to fall at ≈3 mo of age (4). This growth faltering continues until 22 mo of age after which time growth rate is comparable with international reference values. Similar growth patterns have been reported in studies in other countries (5–7). The early growth stunting is likely to persist through adolescence if children remain in the same location (8) but may be at least somewhat reversed if diet and environmental conditions are improved (9, 10).

The causes of early growth stunting are not yet understood (11), but may include a nutritionally inadequate diet as well as clinical (12) or subclinical (13) infections. Although growth stunting has been traditionally attributed to protein-energy malnutrition, it is widespread even where protein and energy intakes are adequate (5, 6, 11) such as in Solís (14). Stunting is associated with habitual consumption of a diet that is low in animal products and accompanying micronutrients, and high in plant constituents such as phytate that inhibit the absorption of minerals (15, 16). We showed previously that the absorption of both zinc and iron is lower from a rural Mexican diet consisting primarily of maize than from a more refined urban Mexican diet (17). Because zinc supplementation has improved the growth and/or body composition of stunted children in countries such as the United States, Canada, Ecuador, China, and Guatemala (11, 18), the present study was designed to measure the effect of zinc supplementation on the growth and body composition of Mexican preschoolers. Unlike most of the previous zinc-supplementation studies reported in the literature, iron supplements were also provided because of the high prevalence of iron deficiency in this community (19). There is some, albeit limited, evidence that iron deficiency causes poor appetite and growth stunting (20), so we were concerned that simultaneous iron deficiency might have limited any zinc-induced growth response.

Both zinc and iron deficiency cause impaired immune response (21, 22), but it remains to be determined whether community-level supplementation with zinc or iron will reduce morbidity in marginally malnourished populations. We

therefore measured morbidity as an outcome of zinc and iron supplementation and as a potential confounder of the effect of supplementation on growth and body composition.

SUBJECTS AND METHODS

Subjects and location

The study was conducted in five rural communities in the Valley of Solís, located in the central highland plateau of the state of Mexico ≈150 km northwest of Mexico City. The communities ranged in size from 700 to 1500 individuals, or from ≈100 to 214 households. A census revealed that 290 children met our eligibility criterion of being between 18 and 36 mo old. The mothers of all of these children were invited to attend a meeting during which they were informed about the study purpose and protocol and potential risks and benefits. The mothers of 219 children attended the meeting, agreed to participate, and signed consent forms. This number of children met our goal of 48 per treatment group (192 total), which would have detected a difference of 1 cm in height with 80% power, assuming the SD of height change would be 1.5.

The protocol was approved by the Committee on Biomedical Research in Human Subjects of the National Institute of Nutrition, Mexico, and the Committee on the Use of Human Subjects in Research at the University of Connecticut.

Zinc and iron supplementation

Children were stratified by age and sex, and ranked by height, then they were randomly assigned to one of four treatment groups within each stratum. Ages were confirmed by birth certificates.

The four groups received a daily supplement consisting of 20 mL of a solution containing either 20 mg elemental Zn as zinc methionine, 20 mg Fe as ferrous sulfate, 20 mg Zn + 20 mg Fe, or a placebo (solution alone). Zinc methionine (Inter Health Co, Concord, CA) was chosen as the zinc source after we showed that it was better absorbed than other sources of zinc (23) and theoretically would reduce the risk of the zinc being bound by dietary phytate in the intestine. Ferrous sulfate was selected because it is the form of iron that is most commonly used for supplementation. Both the zinc and the iron salts were dissolved in a solution to disguise their bad taste and to ensure similar appearance. This solution contained sugar, citric acid, water, and artificial flavor (either orange or lemon). Before the study, the acceptability of the supplements was tested by sensory evaluation in children of the same age. The solutions were coded in such a way that their content was unknown to any of the project personnel, and the code was not broken until the end of data analysis.

Children in each group received the supplements for 12 mo. They were visited in their homes from Monday through Friday by a fieldworker who gave the supplement and ensured that it was completely consumed in her presence. The flavor of the supplement (lemon or orange) was changed every week to improve compliance. Compliance was excellent; the supplements were consumed on average on 97% of the days they were administered. Only 25 children were dropped from the study before the end of the 12 mo, primarily because of a changing family situation. Data from these children were not used in the statistical analyses.

Anthropometry

Anthropometric data were collected at baseline (before supplementation) and within 2 wk after 6 and 12 mo of supplementation. Measurements on all three occasions were performed by the same examiner (PL) following standard procedures (24). Measures included weight to 0.1 kg on a pediatric scale, standing height to 0.1 cm with an anthropometer, midupper arm circumference (MAC) to 0.1 cm by using a fiberglass tape measure on the left arm, and triceps skinfold thickness accurate to 0.1 mm by using a Lange skinfold caliper.

Clinical examinations and morbidity data

A clinical exam was conducted by a physician in the field clinic at baseline and at 6 and 12 mo after supplementation. Data collected during this exam included signs of nutrient deficiencies or other diseases. Any current diseases received appropriate treatment. No clinical symptoms of micronutrient deficiencies were apparent, and no child was dropped from the study on the basis of the relatively minor diseases that were detected.

Morbidity of the preschoolers was evaluated twice weekly by a questionnaire administered by a trained fieldworker who visited each child at home. Information was obtained from the child's mother about the presence or absence of illness on the day of the visit and since the previous visit. Any illness was recorded by the fieldworker on a precoded list that included the most common diseases and their symptoms, as well as the date when the symptoms started and the date when they disappeared. When the fieldworker had any doubt about the diagnosis or course of the disease, the physician in charge of the field clinic visited the child to confirm the diagnosis. Only data on infectious diseases were analyzed, with symptoms classified by a physician into the following categories: upper and lower respiratory disease (combined because there were only four episodes of lower respiratory disease), diarrhea, fever, and "other." "Respiratory disease" was defined as having any symptom such as runny nose, common cold, sore throat, or cough. "Diarrhea" was defined by the mothers based on their observation of frequent, loose stools. In this study and in our previous research in these communities we found a strong association between mothers' reporting and the physician's diagnosis of diarrhea (19). "Fever" was based on maternal reporting.

Biochemical indicators of zinc and iron status, and other nutrient deficiencies

A 2-mL sample of venous blood was collected from every preschooler at baseline and at 6 and 12 mo after supplementation. After the children had fasted overnight, blood samples were collected in an evacuated container and transferred to a tube that contained 0.05 mL sodium citrate as an anticoagulant. Duplicate hemoglobin and hematocrit determinations were performed within 3 h of blood collection. Hemoglobin was determined by using a Coulter counter (Coulter Electronics, Hialeah, FL). Plasma and red blood cells were dispensed as aliquots and frozen at −70 °C until analyzed. Plasma zinc was determined in duplicate by atomic absorption spectrophotometry, and plasma ferritin was measured by using a solid-phase radioimmunassay (Coat-A-Count Ferritin IRMA; Diagnostic

FOI 26-3132 - Document 5

Products, Los Angeles) and an international standard obtained from the World Health Organization Internal Laboratory for Biological Standards (National Institute of Biological Standards and Control, Hertsfordshire, United Kingdom). To detect infections or inflammation, plasma C-reactive protein (CRP) was measured by a Behring laser nephelometer after adding antiserum for CRP (Behring Diagnostics, Inc, Somerville, NJ); a protein control serum was included in the test (Behring Diagnostics, Inc).

Statistical analysis

All analyses were conducted by using SAS software for microcomputers. Analyses of the differences among the groups, and between each treatment group and the placebo group, were tested by analysis of covariance using initial values as covariates. *Z* scores were calculated from National Center for Health Statistics (NCHS) reference values for weight and height (25). Midarm fat area (MAFA) and midarm muscle area (MAMA) were derived from MAC and triceps-skinfold-thickness measurements (26). Changes in anthropometric measures were also analyzed separately for children who were stunted [height-for-age *Z* score (HAZ) < -2.0]. Morbidity data, combined from the entire 12 mo of the study because of the relatively low prevalence of illness, were analyzed by a two-way nonparametric analysis of variance and significant differences among groups were compared by the Kruskal-Wallis test (27). A P value < 0.05 was considered significant.

RESULTS

Assessment of growth and body composition

The characteristics of subjects in each group are shown in **Table 1**. No characteristic differed significantly among treatment groups. The children were growth stunted, with a mean (± SEM) HAZ of -1.6 ± 0.8. However, as expected, their weight-for-height was normal on average, showing that wasting was not a general problem in the group. No sex differences in anthropometry were found initially or in response to treatment, so that data are presented for the sexes combined.

Changes in weight, height, and *Z* scores after the 12 mo of intervention are shown in **Table 2**. The average linear growth rate varied from 8.9 to 9.3 cm/y among the treatment groups and was unaffected by type of treatment. In addition, in the three nutrient-supplemented groups final *Z* scores for weight-for-age (WAZ) and weight-for-height (WHZ) were similar to those in the placebo group. The growth velocities among treatments for only those children with an initial HAZ < -2.0 are also compared in Table 2. Although the group supplemented with zinc alone had a faster rate of height growth and a larger improvement in HAZ than the other groups, these differences were not significant. Similar results were found when all anthropometric data were analyzed 6 mo after the start of supplementation (not reported). We also analyzed the growth response of children with plasma zinc concentrations < 10.7 μmol/L at baseline, and found it to be unaffected by any treatment.

Changes in indicators of body composition after 12 mo of intervention are shown in **Table 3**. There were no significant differences among groups in any of the body composition indicators. This lack of treatment effect on body composition persisted when data were analyzed separately for children with an initial HAZ < -2.0 (Table 3), and when data were analyzed after the first 6 mo of intervention or for the group with initial plasma zinc < 10.7 μmol/L (data not shown).

Biochemical responses to supplementation

Changes in hemoglobin and biochemical indicators of nutritional status after 12 mo of intervention are described in **Table 4**. Both iron-supplemented groups (ie, iron alone, and zinc + iron) responded to supplementation with a highly significant increment in ferritin, whereas there was no increase in ferritin in the placebo- or zinc-supplemented groups. The prevalence of iron deficiency (plasma ferritin < 12 μg/L) was 43–57% in the four groups at baseline, falling 12 mo later to 24% and 23% in the placebo and zinc groups, respectively, and to zero in the two iron-supplemented groups. The mean hemoglobin concentration increased in all groups during the 12 mo, regardless of iron supplementation.

Plasma zinc increased significantly in the zinc- and zinc + iron–supplemented groups over the 12 mo, indicating that the supplemental zinc was absorbed. The mean prevalence of low plasma zinc (< 10.7 μmol/L) was 20% at baseline for all children combined. After 12 mo of supplementation the prevalence of low zinc concentrations was 27% and 21% in the placebo and iron-supplemented groups, respectively, but fell to 14% in the group supplemented with zinc alone and to 8% after supplementation with both zinc and iron. The children who had

low plasma zinc after supplementation had values < 9.2 μmol/L.

Morbidity response

The effect of supplementation on the number of diarrhea and respiratory disease episodes is shown in **Table 5**. The total number of disease episodes was substantially lower in both groups supplemented with zinc, although the reduction was significant ($P < 0.05$) only in the group that received iron as well as zinc. Diarrhea episodes were reduced by 37% in the zinc group ($P < 0.05$) and by 28% in the zinc + iron group ($P < 0.05$). Although the differences were not significant, there were fewer total episodes of respiratory disease and fewer episodes per child in both groups supplemented with zinc. When data were combined for both groups who received zinc, compared with the other two groups combined, there was a significant reduction in the total number of episodes of disease (3.8 ± 0.3 compared with 5.0 ± 0, 3, $P < 0.01$) and of diarrhea (0.8 ± 0.1 compared with 1.3 ± 0.2, $P < 0.01$), but not in the number of episodes of respiratory illness (2.7 ± 0.2 compared with 3.4 ± 0.3) or other disease. None of the supplements reduced the duration of either diarrheal or respiratory disease or affected the number of episodes of fever. Iron supplementation alone had no effect on any morbidity.

DISCUSSION

Neither zinc nor iron supplementation for 12 mo produced any improvement in the anthropometry of these growth-stunted preschoolers. At baseline the children had a high prevalence of iron deficiency. Iron supplementation produced a significant increase in mean plasma ferritin concentrations and low ferritin values disappeared in the two iron-supplemented groups. There was a spontaneous improvement in hemoglobin in the placebo group, for reasons that are unknown, so that there was no significant effect of the iron supplements on the final hemoglobin concentration. From this and previous studies in these communities (28) it is apparent that hemoglobin synthesis is being limited by multiple micronutrient deficiencies. It is less certain that these children were severely zinc depleted, because their initial mean plasma zinc concentration was > 13.8 μmol/L. However, 20% of them had a baseline value < 10.7 μmol/L. After 12 mo of supplementation mean plasma zinc

concentration rose by > 3 μmol/L in the zinc group and by > 1.5 μmol/L in the group supplemented with both zinc and iron. The fact that zinc supplementation reduced morbidity could be taken as evidence that initial zinc status was suboptimal in the study sample as a whole.

From a recent meta-analysis of data from zinc intervention trials designed to improve growth, the predictors of length or height growth response to zinc supplementation were low initial HAZ and low initial plasma zinc concentration, but not age at the time of supplementation (KH Brown, J Pearson, LH Allen, unpublished observations, 1996). Several studies have reported a positive effect of zinc on growth in older, but more severely stunted, children (11). Thus, one possible explanation for lack of growth or body composition response to zinc supplementation in these Mexican children is that they were not severely stunted or zinc deficient. Although there was no significant effect of the supplement on growth of those children with an initial HAZ < −2 or with an initial plasma zinc concentration < 10.7 μmol/L, the lack of significance might be due to the small number of these children in each treatment group. However, the largest difference in height velocity between any of the groups was 0.6 cm among stunted children, which would have needed a sample size of > 300 children per group to be detected with 80% power. Also, a height difference of 0.6 cm over the course of a year is likely to be unimportant from a practical or functional point of view. Likewise, a sample size of 350 initially stunted children per group would have been needed for the triceps-skinfold-thickness differences to be significant.

Based on previous data from Mexico, it was surprising that only 20% of the children had a plasma zinc concentration < 10.7 μmol/L at baseline. We observed the apparent absorption of zinc from similar maize-based, high-phytate Mexican diets to be < 5% when they were fed to well-nourished adults (17). Using food intake data from children of the same age collected during previous research in this community, Murphy et al (29) calculated their mean zinc intake to be 5.3 mg/d, and predicted that 68% of the children had an inadequate zinc intake, after correction for zinc bioavailability. It is possible that zinc status was protected to some extent by adaptations such as reduced endogenous secretion of the mineral (30). Calculated iron intakes for the same age group averaged 6.8 mg/d. The amount of absorbable iron consumed was predicted

FOI 26-3132 - Document 5

to be inadequate to prevent anemia in 43% of the children, or to provide adequate iron stores for 88% of them (29).

Another possible reason for the lack of an effect of zinc on linear growth in our study could be the coexistence of other micronutrient deficiencies that could be limiting growth. At baseline, 64% of these children had deficient plasma α-tocopherol concentrations (< 5 mg/L), 24% had low (< 200 μg/L), and 5% had deficient (< 100 μg/L) plasma retinol concentrations, 33% had low (< 200 ng/L) and 10% had deficient (< 300 ng/L) plasma vitamin B-12 concentrations, and 5% had deficient and 28% had low riboflavin intakes based on the erythrocyte glutathione reductase activity coefficient (unpublished observations). There has been little systematic study of how these or other micronutrient deficiencies might limit the growth of young children (11, 31).

Most studies have reported no evidence for an effect of iron supplementation on the growth of anemic or iron-deficient children (11). Exceptions include the work of Angeles et al (20), who showed a positive effect of iron (30 mg/d) and ascorbic acid (20 mg/d) supplementation on linear growth of anemic Indonesian children compared with a supplement of ascorbic acid alone. The effect was attributed to a reduction in the episodes of respiratory infections and diarrhea observed with iron supplementation. Lawless et al (32) showed a significant increase in appetite and growth when anemic primary schoolchildren in Kenya were supplemented with 30 mg Fe/d for 14 wk. We conclude that iron supplementation did not affect the growth or body composition of these Mexican children, even though there was a high prevalence of iron deficiency before supplementation, the duration of the intervention was long, and the iron deficiency was corrected.

Zinc supplementation reduced the number of morbid episodes in these growth-stunted rural Mexican preschoolers. Specifically, those who received a zinc supplement for 12 mo, either as zinc alone or zinc + iron, had significantly fewer episodes of disease and diarrhea compared with children who received the placebo or iron alone. Zinc is important for the integrity of the immune system (21), and supplements have improved the immunocompetence of malnourished children (33, 34). Both severe and mild zinc deficiency can contribute to the duration and severity of existing diarrheal disease (35, 36). In addition, zinc supplementation of infants with acute and persistent diarrhea was shown in one study to improve mucosal integrity (37). Future studies should investigate the mechanism by which zinc reduces the number of morbid episodes. Diarrhea has been shown in other studies to be associated with stunting, malabsorption and excessive excretion of nutrients, and childhood mortality. Thus, if the results of the present study are confirmed, improving the zinc status of growth-stunted, marginally zinc-deficient children might prove to be an important public health strategy. Because providing iron in addition to zinc did not affect growth or morbidity in this study, and iron and zinc deficiency are likely to occur simultaneously in populations whose diets are high in phytate and/or low in animal products, it is logical to provide iron as well as zinc supplements in regions where iron deficiency is endemic.

Abstract: The pandemic caused by SARS-CoV-2 is not over yet, despite all the efforts from the scientific community. Vaccination is a crucial weapon to fight this virus; however, we still urge the development of antivirals to reduce the severity and progression of the COVID-19 disease. For that, a deep understanding of the mechanisms involved in viral replication is necessary. nsp15 is an endoribonuclease critical for the degradation of viral polyuridine sequences that activate host immune sensors. This enzyme is known as one of the major interferon antagonists from SARS-CoV-2. In this work, a biochemical characterization of SARS-CoV-2 nsp15 was performed. We saw that nsp15 is active as a hexamer, and zinc can block its activity. The role of conserved residues from SARS-CoV-2 nsp15 was investigated, and N164 was found to be important for protein hexamerization and to contribute to the specificity to degrade uridines. Several chemical groups that impact the activity of this ribonuclease were also identified. Additionally, FDA-approved drugs with the capacity to inhibit the in vitro activity of nsp15 are reported in this work. This study is of utmost importance by adding highly valuable information that can be used for the development and rational design of therapeutic strategies.

1. Introduction

Severe Acute Respiratory Syndrome coronavirus 2 (SARS-CoV-2) emerged in 2019 in Wuhan, China [1] and rapidly spread worldwide, initiating a global pandemic. This virus has caused a major impact on health systems and in the world economy. In the last two years, scientists all around the world have extensively worked to better understand how this virus functions. A profound knowledge of the mechanisms involved in viral replication is of the utmost urgency and will surely contribute to the development of new treatments against COVID-19, the disease caused by SARS-CoV-2.

SARS-CoV-2 is a (+)-sense single-stranded RNA virus with a genomic RNA (gRNA) of ~30 kb in length [2] from the *Nidovirales* order. The gRNA, similar to what is observed in human RNA molecules, has a cap at the 5′-end and a poly(A) tail at the 3′-end. The presence of these traits allows the immediate translation of the viral genome in order to produce viral proteins, and prevent its degradation by intracellular ribonucleases (RNases) [3,4]. SARS-CoV-2 replication is a complex and crucial process. It involves the concerted action of viral and host proteins engaged in RNA polymerization, proofreading and capping of the RNA molecule essential in producing new viral proteins [5]. As an RNA virus, it requires a

FOI 26-3132 - Document 5

tight control on the production and processing of the RNA molecules. Ribonucleases are key proteins in this process [6]. The SARS-CoV-2 genome contains two large open reading frames (ORF), ORF1a and ORF1ab, with the latest coding for nonstructural proteins (nsp). Among the nsp proteins, we can find two ribonucleases, the exoribonuclease nsp14 and the endoribonuclease nsp15 [3]. Nsp14 has recently been characterized [7].

nsp15 is a conserved uridine-specific endoribonuclease only found in viruses from the order *Nidovirales* [8,9]. Considering that no homologs are present in any other RNA viruses, nsp15 is considered a genetic marker of this order of viruses [8,9]. Only distant homologs (XendoU) were identified in some prokaryotes and eukaryotes, which were shown to be involved in the processing of intron-encoded small nucleolar RNAs [10,11]. Nsp15 is a member of the nidoviral EndoU (also known as NendoU) family of proteins. It specifically cleaves RNA substrates endonucleolytically at the 3′ of pyrimidines, with a preference for uridine bases, releasing products with 2′ to 3′ cyclic phosphate and 5′-hydroxyl ends [12]. Nsp15 activity can be influenced by the secondary structure of the RNA, and has a preference for cleaving unpaired uridine bases in hairpin-structured RNAs [12]. It was also reported that the presence of 2′-*O*-ribose methyl groups on the RNA substrate can block the nsp15 activity [8]. Downstream to nsp15, the *nsp16* gene encodes for 2′-*O*-ribose methyltransferase [3]. Taking this into account, we can hypothesize that nsp16 may be a regulator of nsp15 activity by avoiding the cleavage of important viral RNA molecules during the infection process.

Biochemical studies performed with purified nsp15 from SARS-CoV and HCoV-229E revealed that this ribonuclease requires divalent ions as a cofactor to perform RNA cleavage, with a marked preference for Mn^{2+} [8,13]. These studies also revealed that Mn^{2+} influences nsp15 conformation, enhances RNA binding and, consequently, its NendoU activity [8,13]. Structural studies with nsp15 from different coronaviruses revealed that this protein is a hexamer formed by dimers of trimers, with a distinctive folding from other ribonucleases (Figure 1A) [14–19]. Each monomer is composed of three domains: N-terminal domain (ND), middle domain (MD) and the C-terminal catalytic NendoU domain (Figure 1B,C) [14–19]. The NDs are lined in the center of the hexamer, while the NendoU domains are facing the surface, which means that nsp15 has six active sites (Figure 1C) [14–19]. The stabilization of the hexamer is achieved through interactions of the ND, which contains the residues required for oligomerization, but the other domains also contribute to the oligomer interface [18,20]. The hexamer of nsp15 is the active form that exhibits the ability to bind RNA and the endonucleolytic activity [20]. The catalytic site at the NendoU domain is composed of the highly conserved residues H235, H250 and K290 (numbering according to the SARS-CoV-2 PDB 6VWW [17]) (Figure 1D) that constitute the catalytic triad, similar to what was described for bovine RNase A [21]. This suggests a similar mechanism of action, but while RNase A does not require a cofactor, nsp15 activity is stimulated by Mn^{2+} [12]. S294 and Y343 residues were postulated to interact with the substrate and confer a specificity for uridines [16]. The highly conserved T341 can also be involved in substrate recognition [14].

nsp15 plays an important role in coronavirus pathogenesis. It was reported that this RNase is responsible for the degradation of viral dsRNA intermediates, thus preventing host recognition [22,23]. By obstructing the recognition of the viral RNA, nsp15 directly contributes to delaying the type I interferon response. Several studies using live viruses in primary cells have confirmed that nsp15 acts as an interferon antagonist [22,23]. Later on, it was described that coronaviruses with mutations in the NendoU domain are less virulent, and their ability to activate the innate immune response is compromised [24]. For a review on this topic, please read Reference [25]. Taking all this into consideration, plus the fact that nsp15 is only found in nidoviruses with no close human homologs identified, this endoribonuclease is a very attractive target for developing new drugs to treat SARS-CoV-2 infections.

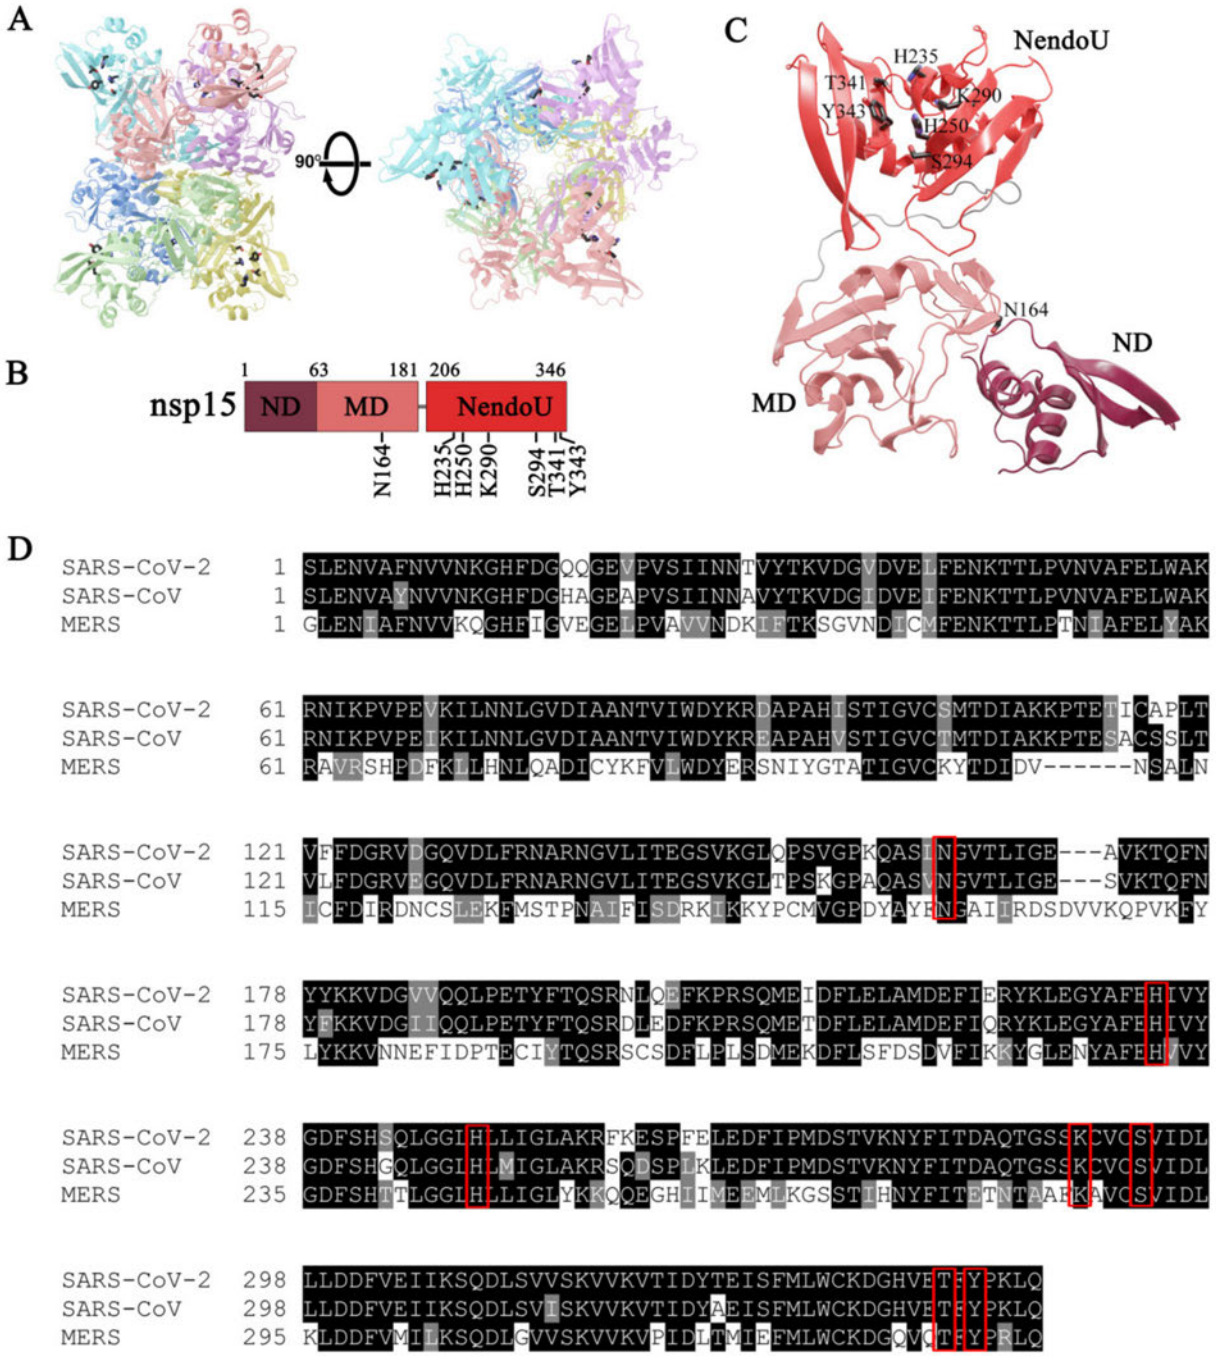

Figure 1. (**A**) Orthogonal views of the hexameric form of nsp15, which is formed by dimers of trimers. Monomers are colored in cyan, pink, violet, blue, green and yellow. Active site residues are shown as sticks. (**B**) nsp15 domain organization. ND, amino acids (aa) 1–63; MD, aa 64–181; NendoU, aa 206–346. The location of the conserved residues is represented. (**C**) Localization of the nsp15 domains in the monomer (PDB code 6W01). Mutated residues are shown as sticks. (**D**) Sequence alignment of nsp15 from SARS-CoV-2 (UniProt ID: P0DTD1), SARS-CoV (UniProt ID: P0C6X7) and MERS-CoV (YP_009047225). Residues are colored according to their conservation: in black, residues that are identical; in grey, residues that are not identical but have similar properties; in white, residues that are different. Residues mutated in this work are highlighted with a red box.

In this work, we elucidated the mechanism of action of nsp15 from SARS-CoV-2. Based on this knowledge, we also performed an *in silico* screening to find the best commercially available and approved drugs that might inhibit the NendoU activity of nsp15.

2. Materials and Methods

2.1. Plasmid Construction

Full-length nsp15 gene from SARS-CoV-2 (UniProt ID P0DTD1) was optimized for *Escherichia coli* expression and synthesized by GenScript (Piscataway, NJ, USA). The synthesized gene was subsequently cloned into the *Nde*I–*Bam*HI sites of commercial pET15b to generate pET15b_nsp15, which expresses an N-terminal His-tagged version of nsp15.

The single-point mutations N164A, H235A, H250A, K290A, S294A, T341A and Y343A and the double mutant T341A_Y342A were introduced into pET15b_nsp15 by overlapping PCR using the primers listed in Table S1. The double mutants S294A_T341A and S294_Y343A and the triple mutant S294A_T341A-Y343A were introduced into pET15b_nsp15_S294A also by overlapping PCR (Table S1). All the constructions were verified by sequencing at StabVida (Caparica, Portugal).

2.2. Protein Expression and Purification

Plasmids expressing nsp15 WT and mutant proteins were transformed into *E. coli* Rosetta cells (Novagen, Gibbstown, NJ, USA) for the expression of the recombinant proteins. Cells were grown in Terrific Broth medium supplemented with 150 μg/mL ampicillin and 50-μg/mL chloramphenicol at 30 °C to an OD_{600} of 0.5. At this point, protein expression was induced by addition of 0.5 mM IPTG, and bacteria were incubated for 4 h. Cells were pelleted by centrifugation and stored at −80 °C. Cell suspensions were lysed using the FastPrep-24 (MP Biomedical, Santa Ana, California, USA) at 6.5 m/s for 60 s in the presence of 0.5-mM PMSF. The crude extract was treated with Benzonase (Sigma-Aldrich, St. Louis, MO, USA) to degrade the nucleic acids, and clarified by a 30-min centrifugation at 10,000× *g*. Purification was performed in an ÄKTA FPLC™ system (Cytiva, Marlborough, MA, USA). The cleared lysate was subjected to a histidine affinity chromatography in a HisTrap HP column (Cytiva) equilibrated in Buffer A (40-mM Tris-HCl, pH 8, 150-mM NaCl and 10-mM imidazole). Proteins were eluted by a continuous imidazole gradient up to 500 mM in Buffer A. The fractions containing the purified protein were pooled together and concentrated by centrifugation at 4 °C with Amicon Ultra Centrifugal Filter Devices of 10000 MWCO (Millipore, Burlington, Massachusetts, EUA) and the buffer exchanged to Buffer B (20-mM Tris-HCl, pH 8). The proteins were then added to a HiTrap Q HP column (Cytiva) equilibrated in Buffer B to perform an anion exchange. Protein elution was achieved by a continuous NaCl gradient up to 1 M in Buffer B. Eluted proteins were concentrated by centrifugation at 4 °C with Amicon Ultra Centrifugal Filter Devices of 10000 MWCO (Millipore) and the buffer exchanged to Buffer C (20-mM Tris-HCl, pH 8 and 150-mM NaCl). Afterwards, the proteins were subjected to a size exclusion chromatography using a Superdex 200 Increase column (Cytiva) with a flow rate of 0.5 mL/min using buffer C. The samples collected were analyzed in a Novex™ 8–16% Tris-Glycine gel (Invitrogen™, Waltham, Massachusetts, EUA), followed by BlueSafe staining (NZYTech, Lisbon, Portugal). Samples with the highest purity were pooled together and concentrated by centrifugation at 4 °C with Amicon Ultra Centrifugal Filter Devices of 10000 MWCO (Millipore). All protein versions were purified at least twice in independent experiments to ensure reproducibility of the results. Proteins were quantified using the Bradford method, and 50% (*v/v*) glycerol was added to the final fractions prior storage at −20 °C. The purified proteins were analyzed by Western blot. One and a half micrograms of each protein was separated in a Novex™ 8–16% Tris-Glycine gel (Invitrogen™) and transferred to a nitrocellulose membrane (Hybond ECL, Cytiva) by electroblotting using the Trans-Blot SD semidry electrophoretic system (Bio-Rad, Hercules, CA, USA). Membranes were probed with a 1:10,000 dilution of anti-His antibody (Thermo Fisher Scientific, Waltham, MA, USA). ECL anti-mouse IgG conjugated horseradish peroxidase (Sigma-Aldrich, St. Louis, MO, USA) was used as the secondary reagent in a 1:10,000 dilution. Immunodetection was conducted via a chemiluminescence reaction using Amersham ECL Western Blotting Detection Reagents (Cytiva).

FOI 26-3132 - Document 5

2.3. RNase Activity Assays

The synthetic 16-mer oligoribonucleotides R16.4 (5′-GAAGCGAAACCCUAAG-3′), 16comp (5′-AGUGGUUGGUGUCGGG-3′) and 30-mer (5′-CCCGACACCAACCACUAAAAAAAAAAAAAA-3′) (StabVida, Portugal) were used as substrates in the RNase activity assays. The RNA substrates were labeled at their 5′ end with [^{32}P]-γ-ATP and T4 Polynucleotide Kinase (Ambion, Austin, TX, USA) in a standard reaction. MicroSpin G-50 columns (Cytiva) were used to remove excess [^{32}P]-γ-ATP. In order to fold the R16.4 into its native structure, the RNA was resuspended in 10 mM of Tris-HCl, pH 8.0 and incubated 10 min at 80 °C, followed by 45 min at 37 °C. To obtain the double-stranded substrate 16–30 ds, the labeled 30-mer was hybridized to the unlabeled 16comp oligoribonucleotide. The hybridization was performed in a 1:5 (mol:mol) ratio by incubation for 10 min at 80 °C, followed by 45 min at 37 °C.

The activity assays were performed in a final volume of 12 µL containing an activity buffer with 25-mM HEPES, pH 7.4; 50-mM NaCl; 1-mM DTT; 10-mM $NaHPO_4$ and 5 mM of either $MgCl_2$, $MnCl_2$, $CaCl_2$, $NiCl_2$, $CuCl_2$, $CoCl_2$ or $ZnCl_2$, plus the protein nsp15 WT or respective mutants (protein concentrations are indicated in the figure legends). Some assays were performed with different concentrations of $MnCl_2$ (1 mM, 5 mM, 10 mM, 15 mM or 20 mM) or with an activity buffer containing citrate or ammonium sulphate instead of sodium phosphate. A reaction was also done only in a HEPES buffer, without citrate, sulphate or $NaHPO_4$ (as indicated in the figure legends). All the reactions were started by adding 50 nM of the RNA substrate and further incubated at 37 °C. Reaction controls were performed with all the components of the reaction without the enzymes. They were incubated in the same conditions as in the enzymatic reactions.

To test the drugs (Dutasteride, Etoposide, Golvatinib, Irinotecan, Meprednisone and Tasosartan), the compounds were previously incubated for 7 min at room temperature with nsp15 WT before the reactions were started (through the addition of RNA). All the drug compounds were solubilized in DMSO and serially diluted. Reaction controls were performed with the RNA substrates (without the enzymes), with either the activity buffer or buffer supplemented with DMSO. The DMSO concentration was kept constant, corresponding to the maximum amount of drugs tested in the assay. The control reactions were incubated in the same conditions.

For all the assays, aliquots of 4 µL were withdrawn at the time points indicated in the respective figures, and the reactions were stopped by adding a gel-loading buffer containing 80% *(v/v)* formamide and 10-mM EDTA. Reaction products were resolved in a 20% denaturant polyacrylamide gel (7-M urea). Signals were visualized by PhosphorImaging (TLA-5100 Series, Fuji, Cytiva). All the experiments were performed at least in triplicate for each independent purification. Disappearance of the substrate over time was quantified using ImageQuant software (Cytiva).

2.4. Sequence Alignment

nsp15 sequences from SARS-CoV-2 (UniProt ID: P0DTD1), SARS-CoV (UniProt ID: P0C6X7) and MERS-CoV (YP_009047226) were aligned using T-coffee [26]. The final figure presented was built with Boxshade (https://embnet.vital-it.ch/software/BOX_form.html, accessed on 3 September 2021). Sequence identity and similarity were determined in https://www.bioinformatics.org/sms2/ident_sim.html, accessed on 3 September 2021).

2.5. Docking Calculations

The tridimensional structures of the target molecules were obtained from the Approved, Investigational and Experimental subsets of the Drugbank database [27]. All molecules were prepared using AutoDockTools [28] by adding Gasteiger charges and AutoDock4 atom types. Flexible bonds were allowed to rotate, nonpolar hydrogens were merged and missing polar hydrogens were added. The structure present in PDB ID 6WXC was chosen to be the receptor, since this protein was co-crystalized with a drug and a phosphate ion bound together to the active site. The protein was prepared with AutoDock-

FOI 26-3132 - Document 5

Tools in a similar way as the drugs, and all atoms that were not part of the protein or the phosphate ion were removed. Docking calculations were performed with the program AutoDock Vina [29] in a searching box with sizes 22 Å, 24 Å and 20 Å (*x*-, *y*- and *z*-axis, respectively) centered at the nsp15 active site. The exhaustiveness parameter was set to 20 for all runs, and only the poses with the lowest binding energies were considered for further analysis.

3. Results

3.1. nsp15 Endoribonuclease Is Active as a Hexamer

We purified the SARS-CoV-2 nsp15 recombinant protein. As presented in Figure 2A, the chromatogram obtained during the size exclusion chromatography step shows the presence of three main protein peaks that elute between 9 and 16 mL of column volume. It was already demonstrated that nsp15 is a hexamer formed by dimers of trimers [14–19]. As such, and taking into consideration the chromatograms with standard components, we postulate that the first peak corresponds to the hexamer (H), the second and smaller peak to the trimer (T) and the last one to the monomer (M) (Figure 2A). The fractions collected for each peak were analyzed in an SDS-PAGE gel. We confirmed the presence of a protein that migrates at 41 kDa (Figure 2A), which is consistent with the expected molecular weight of the recombinant His-tagged nsp15. It is possible to observe bands with higher molecular weight in the gel, namely in the fractions that correspond to the hexameric and trimeric forms. By Western blot, using antibodies specific for the His-tag tail of the protein, we confirmed that those bands correspond to nsp15 oligomers, which are not present in the fraction of the monomeric form (Figure 2A). We could also observe the presence of bands with lower molecular weights in the trimer and monomer fractions (Figure 2A). These bands most likely corresponded to nsp15 that was degraded during the purification process.

We tested the endonucleolytic activity of the purified fractions, using the synthetic RNA substrate R16.4, previously reported in Bhardwaj et al. [12]. This substrate is a 16-nucleotide (nt)-long RNA that contains only one uridine, rendering an unique cleavage event by nsp15 [12]. The results in Figure 2B show that nsp15 is more active as a hexamer. It retains some activity in the trimeric form, and only residual cleavage is observed in the monomeric form (Figure 2B). These results are in agreement with previous studies [20]. Moreover, it is possible to observe that the incubation of SARS-CoV-2 nsp15 with the R16.4 RNA substrate originates a single degradation product, due to cleavage on the U residue (Figure 2B), which demonstrates the preference of this enzyme for uridines. We also tested the activity of nsp15 over the ssRNA 16comp that presents five uridines in its sequence (Figure 2C). As expected, it is possible to observe the generation of five degradation products that correspond to the cleavage at the uridines (Figure 2C, left panel), reinforcing the marked preference of nsp15 for U residues. It was recently described that nsp15 has a preference for purines at the 3′ position of the cleaved uridines [30]. Interestingly, the 16comp RNA has purines in the 3′ position of the first four uridines (U3, U6, U7 and U10) counting from the 5′ end, whereas the last uridine (U12) is followed by a pyrimidine residue (Figure 2C). Analyzing the degradation pattern obtained, we can observe that cleavage is much less efficient at U12 (Figure 2C, left panel), confirming that SARS-CoV-2 nsp15 prefers purines 3′ to uridines.

It was already reported that nsp15 can cleave both ssRNA and dsRNA [8,13]. Therefore, we also tested SARS-CoV-2 nsp15 activity using the 16–30 ds RNA molecule. Our results show that this endoribonuclease is able to cleave this substrate (Figure 2C, right panel), confirming that SARS-CoV-2 nsp15 can cleave both ss and dsRNA molecules.

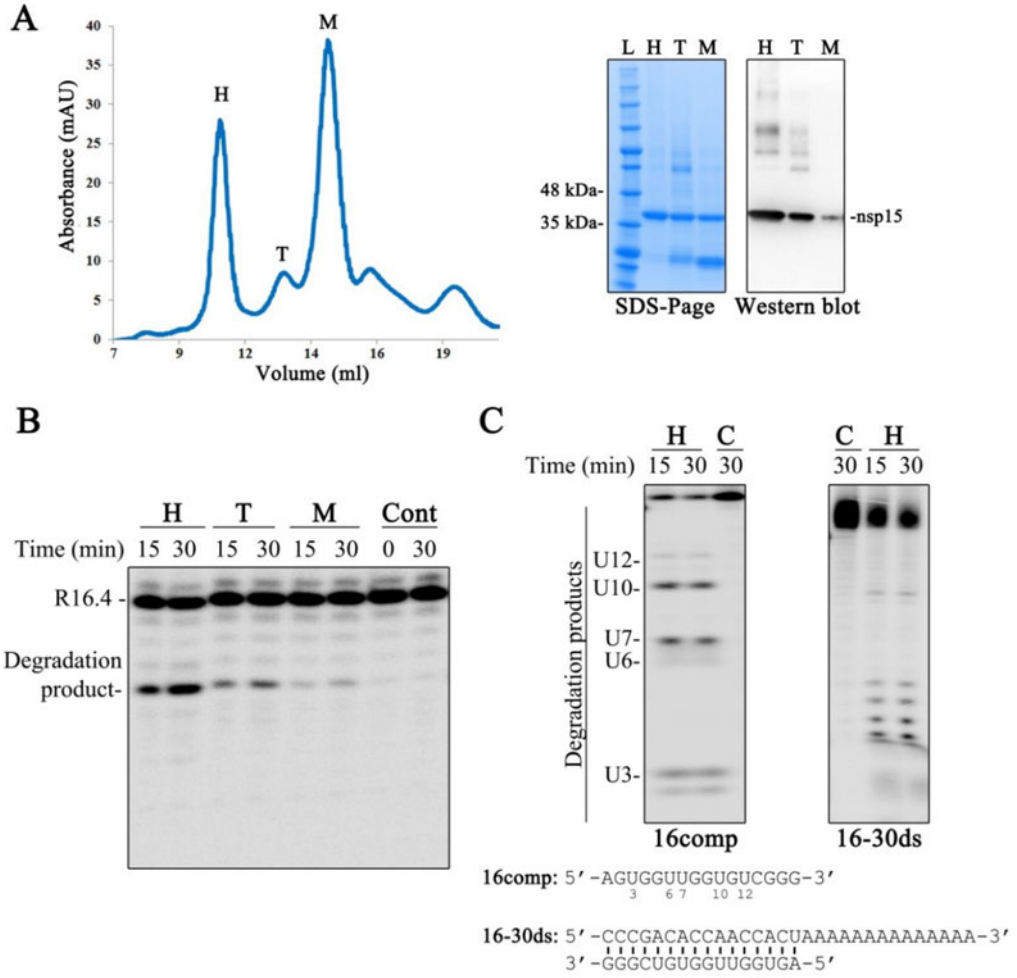

Figure 2. Characterization of SARS-CoV-2 nsp15. (**A**) Left panel: chromatogram obtained during nsp15 size exclusion chromatography; right panels: SDS-PAGE gel with the purified fractions collected during the SEC and the respective Western blot. M, monomer; T, trimer; H, hexamer; L, Protein ladder. (**B**) In vitro activity of the purified fractions H, T and M using 50 nM of R16.4 RNA substrate and 500 nM of protein. (**C**) In vitro activity of nsp15 in the hexamer conformation (500 nM) in the presence of a single-stranded RNA (16comp) and a double-stranded RNA (16–30 ds), which are schematically represented in the bottom. Reactions were analyzed on 7-M urea/20% polyacrylamide gels. C, control reactions; time points are indicated in the top of each panel. All the experiments were performed at least in triplicate.

3.2. nsp15 Activity Is Stimulated in Different Buffer Conditions, with a Marked Preference for Manganese

It was already reported that the activity of nsp15 is highly enhanced in the presence of manganese [13,15,16]. In order to assess the role of other divalent ions over SARS-CoV-2 nsp15 activity, we tested the activity of the enzyme in the presence of Mg^{2+}, Mn^{2+}, Ca^{2+}, Ni^{2+}, Cu^{2+}, Co^{2+} and Zn^{2+} (Figure 3A). Our results clearly illustrated that SARS-CoV-2 nsp15 presents maximum activity in the presence of Mn^{2+} (Figure 3A,C). Interestingly, Ca^{2+} and Cu^{2+} can also stimulate nsp15 activity. In the presence of Ni^{2+} and Co^{2+}, the enzyme retains residual activity, while Zn^{2+} does not influence the activity of this RNase (Figure 3A,C). No degradation was observed in presence of the chelating agent EDTA in these conditions. We also tested if the presence of Mn^{2+} or Mg^{2+} would influence nsp15 oligomerization, which would help explain the increase in nsp15 activity. However, the chromatograms were similar to the one obtained in the absence of divalent ions that is presented in Figure 2A. Altogether, these results confirm the importance of divalent ions, namely Mn^{2+}, for the activity of nsp15 from SARS-CoV-2, similar to what was described

FOI 26-3132 - Document 5

for other counterparts [13,15,16], and exclude the involvement of divalent ions in oligomerization. Studies performed with MERS-CoV and SARS-CoV nsp15 have shown that the presence of Mn^{2+}, but not Mg^{2+}, increases the affinity to the RNA molecule [12,16]. This suggests that Mn^{2+} stimulates nsp15 activity by increasing the ability to bind to RNA substrates and not by binding to its active site. In fact, nsp15 structure suggests that divalent ions may stabilize the protein [18,31]. Next, we tested the nsp15 activity using different Mn^{2+} concentrations, from 1 to 20 mM. The results obtained showed that lower Mn^{2+} concentrations are more effective in stimulating nsp15 activity, with the protein presenting a higher ability to cleave RNA in the presence of 1 mM of Mn^{2+} (Figure 3B,C).

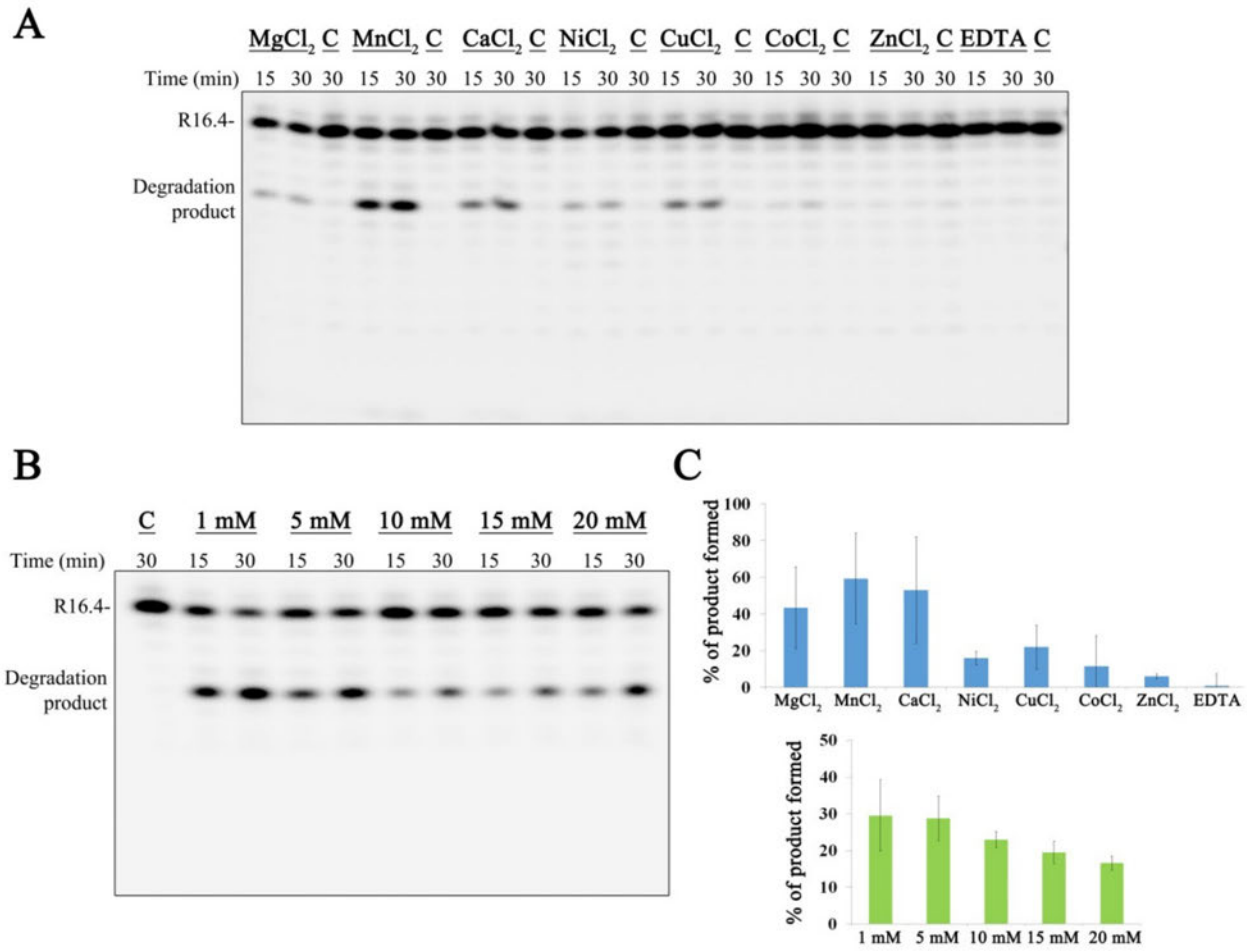

Figure 3. Effect of divalent ions in SARS-CoV-2 nsp15. (**A**) Five hundred nM of nsp15 were incubated with 50 nM of R16.4 RNA substrate in the presence of 10 mM of different divalent ions. (**B**) Five hundred nM of nsp15 were incubated with 50 nM of R16.4 RNA substrate in the presence of different $MnCl_2$ concentrations (1–20 mM). Reactions were analyzed on 7 M urea/20% polyacrylamide gels. C, control reactions; time points are indicated in the top of each panel. All the experiments were performed at least in triplicate. (**C**) Quantification of nsp15 protein activity (% of RNA degradation product generated) in the presence of different divalent ions (on the top) and in a growing range of different $MnCl_2$ concentrations (on the bottom).

Kim et al. reported that nsp15 was crystallized in the presence of a citrate, which was bound to the protein active site [18]. The citrate was shown to make hydrogen bonds with several key and highly conserved residues found in the nsp15 active site, including H235, H250, K290 and T341 (highlighted in Figure 1D). Moreover, it also forms Van der Waals contacts with Tyr343. All these interactions were postulated to stabilize the residues from the active site, thus ordering the NendoU domain [18]. In another study where the nsp15 structure bound to nucleotides was solved, it was possible to observe the presence of

FOI 26-3132 - Document 5

a phosphate ion bound to the active site that also interacted with H235, H250, T341 and K290 residues [31]. It was described that the nsp15 active site is structurally similar to that of RNase A. Sulfate was found to inhibit the ribonucleolytic activity of RNase A [32]. Considering the similarities between both ribonucleases, sulfate could also influence nsp15 activity. In order to determine the role of citrate, phosphate and sulfate over nsp15 activity, we ran activity assays in the presence of these compounds. Our results showed that, in the conditions tested, both phosphate and citrate enhanced nsp15 activity (Figure 4). In contrast, in the presence of sulfate, nsp15 activity was completely blocked (Figure 4). These results indicate that the activity of nsp15 from SARS-CoV-2 is highly influenced by the presence of different chemical groups in the reaction, which can be valuable information when designing compounds to inhibit nsp15 activity.

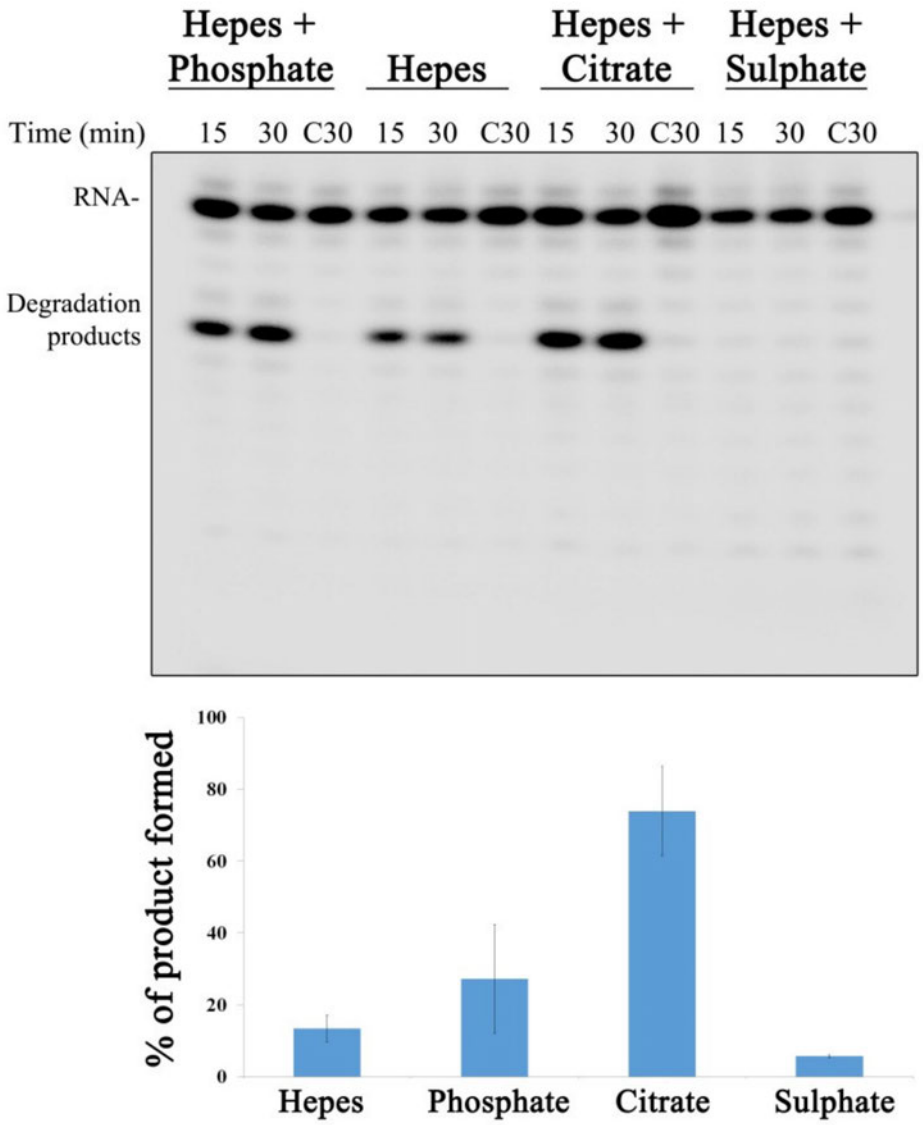

Figure 4. The influence of different buffer compositions in SARS-CoV-2 nsp15 activity. On the top, 500 nM of nsp15 were incubated with 50 nM of R16.4 RNA substrate in the presence of buffers with different compositions, as indicated on the top of each panel. Reactions were analyzed on 7 M urea/20% polyacrylamide gels. C, control reactions; time points are indicated in the top of each panel. All the experiments were performed at least in triplicate. On the bottom, quantification of nsp15 protein activity (% of RNA degradation product generated) in the presence of buffers with different compositions.

FOI 26-3132 - Document 5

3.3. A Residue from ND from SARS-CoV-2 nsp15 Is Important for Hexamer Formation While Residues in NendoU Are Crucial for the Activity of the Protein

nsp15 from different coronaviruses presents a high degree of sequence identity and similarity. SARS-CoV-2 nsp15 shares 88.7% sequence identity and 94.8% of similarity with the SARS-CoV homolog, and 50.1% sequence identity and 63.9% similarity with the homolog from MERS-CoV. The nsp15 active site is constituted by three highly conserved residues (H235, H250 and K290) (Figure 1D) that were postulated to be important for the activity of the enzyme [14,16,18]. Moreover, residues S294, T341 and Y343 were described as important for uridine specificity [16,24,33]. Studies conducted with nsp15 from MERS-CoV have shown that amino acids from the N-terminal portion of the protein (N38, Y58 and N157 in MERS-CoV nsp15 protein) are crucial for hexamer formation [16]. From these, N164 (corresponding to N157 in MERS-CoV) is the only one found in SARS-CoV-2 nsp15 (Figure 1D). Considering the conservation of these amino acids among the three coronaviruses (Figure 1D), and in order to address their role in the activity of SARS-CoV-2 nsp15, we constructed the N164A, H235A, H250A, K290A, S294A, T341A and Y343A point mutants; the S294A_T341A, S294_Y343A and T341A_Y342A double mutants, and the triple mutant S294A_T341A_Y343A. All the mutants were expressed and purified in the same conditions as the wild-type. Size exclusion chromatography showed that the majority of the purified mutants had an elution profile similar to that of the wild-type nsp15, with most of the proteins in hexameric and monomeric forms (Supplementary Figure S1). Interestingly, most of the N164A mutant protein was found in a monomeric form, and only a small peak was detected in the hexameric form (Figure 5A, middle panel). This result showed that N164 residue, which is located in the interface between the N-terminal and NendoU portions of adjacent monomers of nsp15, is crucial for the formation of stable hexamers. This is in agreement with studies performed with MERS-CoV nsp15, where the corresponding residue was also shown to be critical for the formation of the hexamer [16]. In contrast, the K290A mutant presents most of the proteins in the hexameric form (Figure 5A, right panel). This indicates that this residue, which is in the interface between monomers but whose side chain is located in the active site of nsp15, plays a role in the formation of the hexamer. The same behavior was already described for the corresponding residue in SARS-CoV [20]. Taking into consideration that the hexamer is the active form, we analyzed the activity of the fractions corresponding to the hexameric form of all the mutants. For this, we concentrated the samples of each peak corresponding to the hexamer (in order to have enough protein for the activity assays, especially for the N164A mutant) and used two different RNA substrates, R16.4 and the 16comp. As already described above, SARS-CoV-2 nsp15 only cleaves the R16.4 substrate in one place, rendering it a single degradation product (Figure 2B). In contrast, the 16comp substrate has five uridines in its composition, which originates five different degradation products (Figure 2C). We observed that the nsp15 N164A mutant degrades both RNA substrates near the 3′ end and not at the uridine bases as the wild-type protein (Figure 5B,C). This may suggest that mutations in the N-terminal region of the protein may affect its overall folding, compromising the integrity of the active site (NendoU domain). A folding effect is further supported by the unlikelihood of N164 being part of the important interactions between monomers. In fact, the only favorable interaction between N164 and the adjacent monomers are hydrogen bonds with T282. Furthermore, the mutation N164A would represent a decrease of less than 5% in the total contact surface area between monomers. Taking this into account, it is more likely that the predominance of the monomeric form was caused by folding problems and not by the direct absence of hexamer-stabilizing interactions. Although the formation of the hexamer has been severely compromised, N164A still retains a similar activity to the wild-type in terms of substrate consumption (Figure 5B).

FOI 26-3132 - Document 5

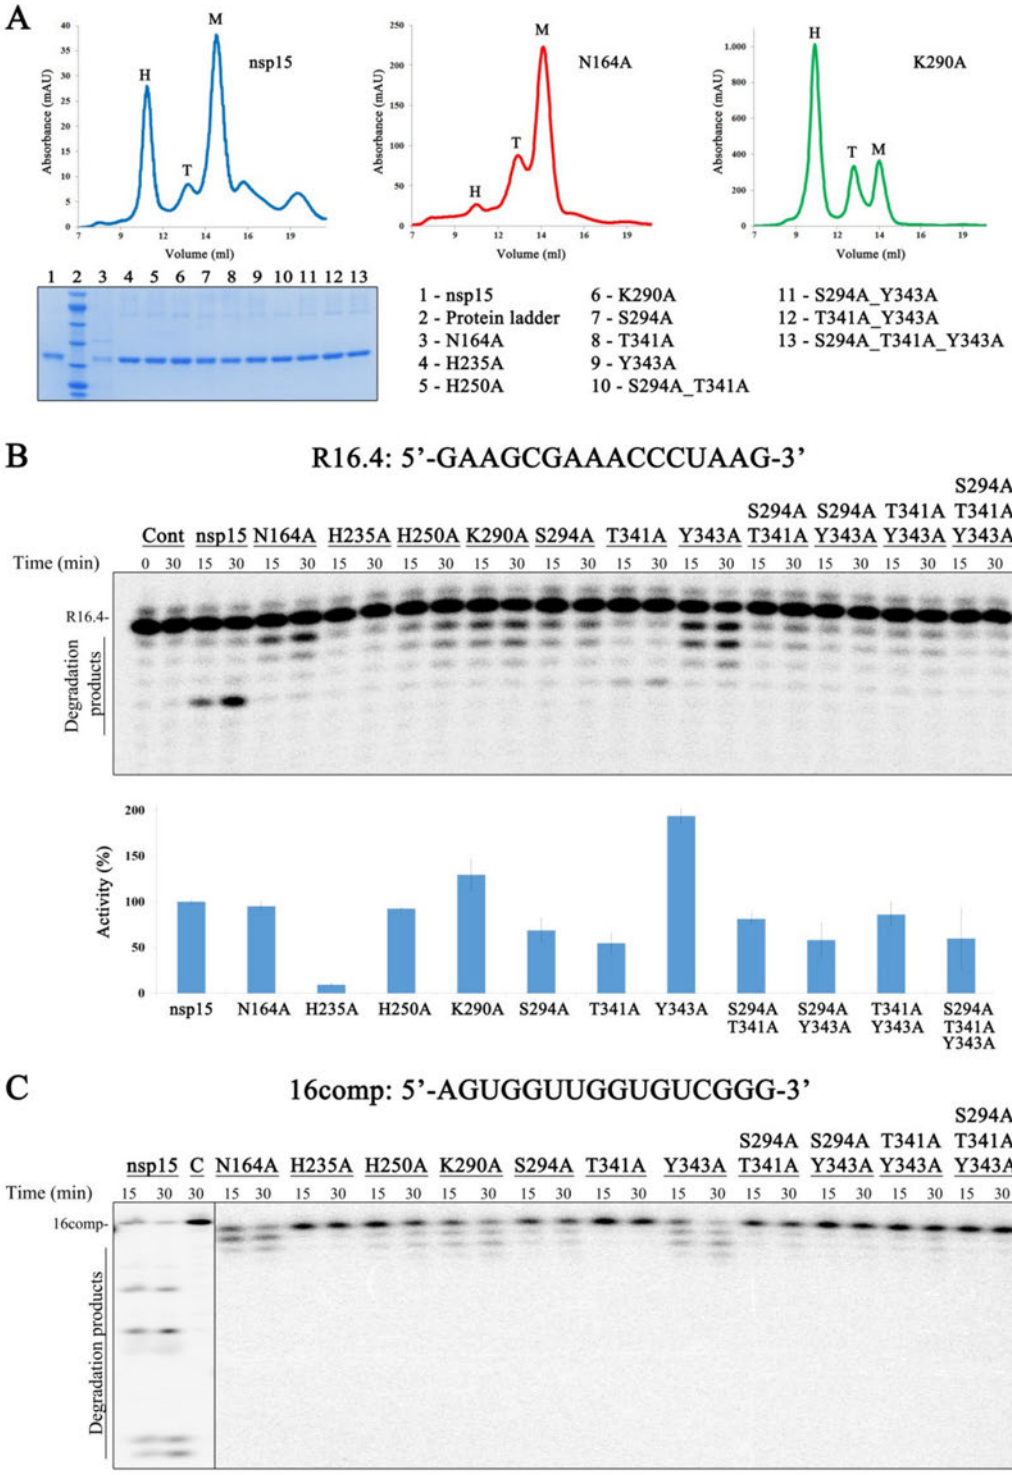

Figure 5. Effect of nsp15 mutations on its endonucleolytic activity. (**A**) On the top, chromatograms obtained during nsp15 wt, N164A and K290A size exclusion chromatographies; M, monomer; T, trimer; H, hexamer; on the bottom, a SDS-PAGE gel with all hexameric fractions of the purified proteins. (**B**) On the top, 800 nM of either nsp15 wt or nsp15 mutant versions were incubated with 50 nM of R16.4 RNA substrate; on the bottom, quantification of nsp15 wt and mutants activity in the presence of R16.4 RNA (% of RNA substrate degraded). The activity of nsp15 wt was considered as 100%. (**C**) 800 nM of nsp15 wt or each mutant version were incubated with 50 nM of 16comp RNA substrate. Reactions were analyzed on 7 M urea/20% polyacrylamide gels. C, control reactions; time points are indicated in the top of each panel. All the experiments were performed at least in triplicate.

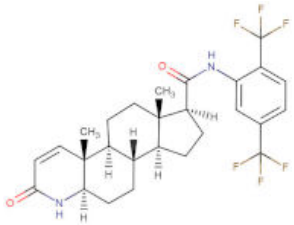
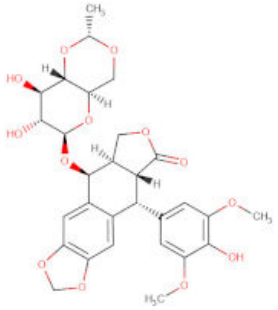
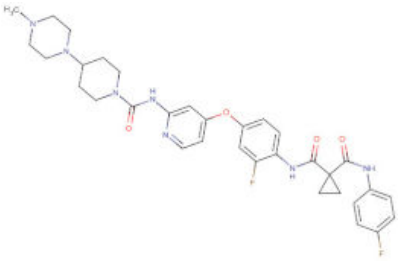
FOI 26-3132 - Document 5

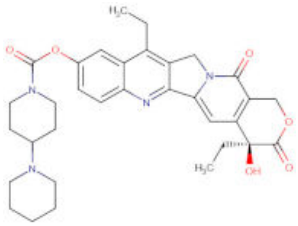
nsp15 His235, His250 and Lys290 residues constitute the catalytic triad. Mutating these residues into alanines rendered different results, indicating that they play distinct roles in catalysis. The H235A mutant is almost inactive, while H250A and K290A still retain unspecific activity, similarly to what was observed for the N164A mutant (Figure 5B,C). These results contrast with the ones obtained with MERS-CoV and SARS-CoV nsp15, where changing these residues into alanine rendered a protein with no detectable activity [16,20]. It was already postulated that S294, T341 and Y343 are important for the uridine specificity demonstrated by nsp15 [16,33]. In fact, S294A and Y343A mutants present an unspecific pattern of degradation for both RNA substrates (Figure 5B,C). By quantifying the disappearance of the substrate, we verified that S294A retains ~70% of the activity when compared to the wild-type, whereas the Y343A mutant has twice more activity (Figure 5B). These results confirm that residues S294 and Y343 are, in fact, important for uridine specificity but not for the ability of nsp15 to cleave RNA. Although T341 was also postulated to be involved in this preference of cleavage, our results show that the nsp15 T341A mutant version maintains the specificity for U residues (Figure 5B). However, this substitution affects the ability of nsp15 to efficiently cleave RNA substrates, rendering a protein with half of the activity when compared to the wild-type (Figure 5B). The double mutants (S294A_T341A, T341A_Y343 and S294A_Y343A) exhibited reduced activity and a similar degradation pattern to that observed in the corresponding single mutants, while the triple mutant (S294_T341A_Y343) presented residual activity (Figure 5B,C). These results confirm the importance of these amino acids for nsp15 activity. Altogether, our biochemical analysis points to the importance of several conserved amino acids for nsp15 activity, sequence specificity and oligomerization.

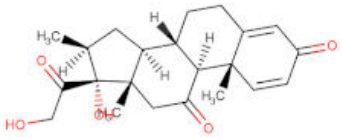
This information is highly valuable to discover compounds that may affect NendoU activity that can be used for the treatment of viral infections provoked by a coronavirus.

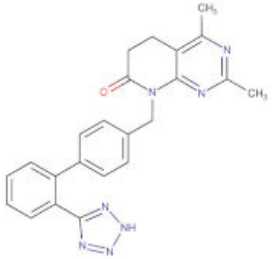












3.4. Searching for SARS-CoV-2 nsp15 Inhibitors

Considering the important role that nsp15 plays in coronavirus pathogenesis, we performed a search for predicted drug candidates that could block the activity of this crucial viral enzyme. We conducted a virtual screening to find inhibitors of nsp15 among 8346 drugs from the Drugbank database that are either approved for clinical use or that are under investigation [27]. Given that the nsp15 activity is increased when incubated in a phosphate-containing buffer, and based on the findings of Kim et al. [31] where nsp15 was co-crystalized with a repurposed drug together with a phosphate ion in the active site, we decided to perform the docking calculations in the presence of a phosphate ion. The drugs with the lowest binding energies from our screening were compared with the ones found by Xu et al. [34]. Six drugs were chosen for further analysis, namely Dutasteride, Irinotecan, Meprednisone, Etoposide, Golvatinib and Tasosartan. The binding affinities ranged from −7.5 kcal/mol up to −9.2 kcal/mol (Table 1). Two binding patterns were observed among the selected drugs. Dutasteride, Golvatinib, Irinotecan and Tasosartan were flexible and long enough to cover the phosphate ion inside the active site (Figure 6A,C,D,F). The extremities of these molecules were located in two regions: one near H235 and another near Y343 and S294. Dutasteride and Golvatinib have fluorinated groups that interact with S294. Together with these halogenated groups, there are aromatic rings that may form pi-stacking interactions with Y343 (Figure 6A,C). Both S294 and Y343 were shown in this study to be important for uridine specificity. Golvatinib is further stabilized by a pi-stacking interaction between another fluorinated aromatic ring with W333. Taken together, these intermolecular interactions may account for the high binding affinity predicted for Golvatinib. Tasosartan also has an aromatic ring near Y343, but it is not well-aligned to form pi-stacking. No specific strong interactions were formed in the case of Irinotecan. Contrary to the first group of molecules, Etoposide and Meprednisone were located only at the top of the active site, interacting with H235 and partially interacting with the phosphate ion (Figure 6B,E). These two molecules did not have specific interactions with nsp15 and were largely exposed to the solvent, which may explain their low binding affinities. The binding modes observed

FOI 26-3132 - Document 5

for the selected drugs are compatible with a scenario of competitive inhibition of nsp15 by occupying the space where the RNA substrate would be bound around the active site.

Table 1. Compounds predicted to bind to nsp15 ribonuclease.

Compound	Category	Binding ΔG (kcal/mol)	Chemical Formula (https://go.drugbank.com, Accessed on 5 of November 2021)
Dutasteride	Approved	−7.8	
Etoposide	Approved	−7.50	
Golvatinib	Investigated	−9.2	
Irinotecan	Approved	−9.0	
Meprednisone	Approved	−7.6	
Tasosartan	Experimental	−8.3	

FOI 26-3132 - Document 5

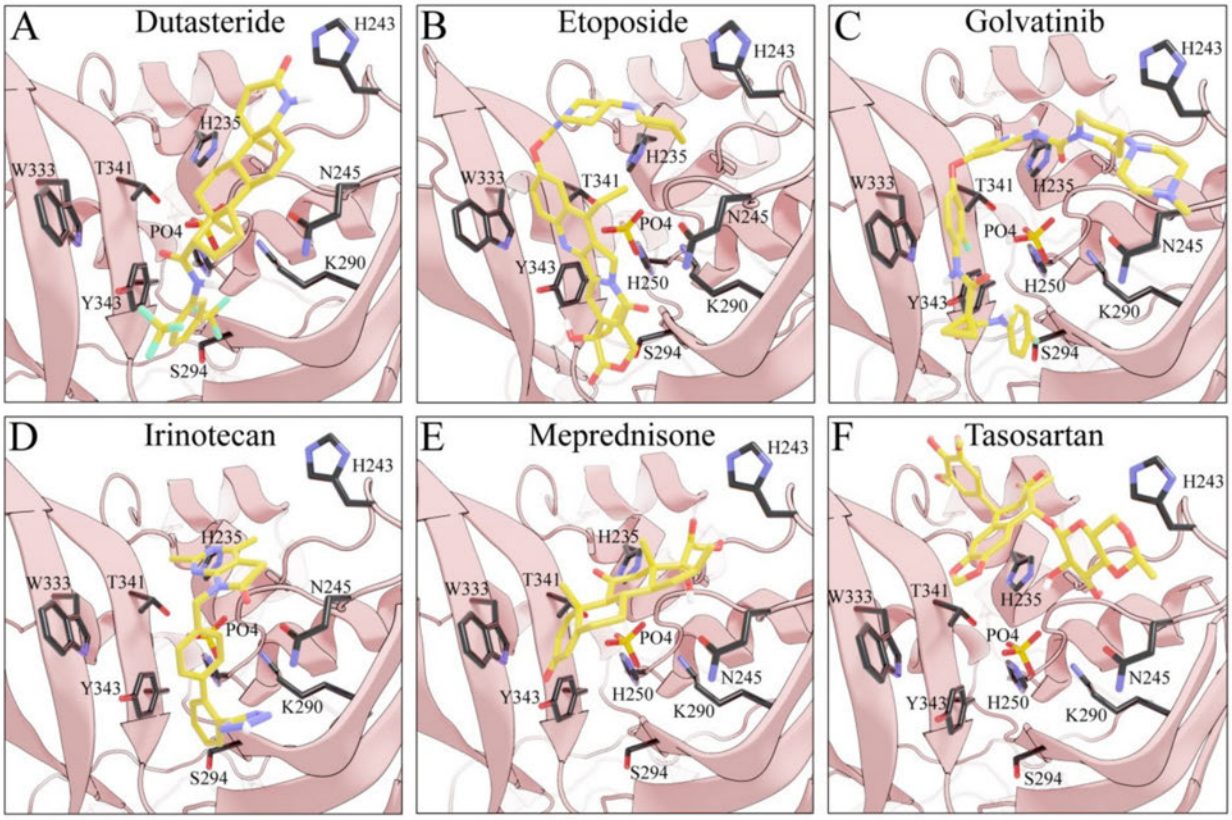


Figure 6. Docking solutions for the six selected drugs (**A**) Dutasteride, (**B**) Etoposide, (**C**) Golvatinib, (**D**) Irinotecan, (**E**) Meprednisone and (**F**) Tasosartan are shown with the carbon atoms in yellow. Key residues of the nsp15 active site are depicted with the carbon atoms in black. The active site and the phosphate ion (PO_4) are covered by Dutasteride, Irinotecan, Golvatinib and Tasosartan. Meprednisone and Etoposide bind only to the top portion of the nsp15 active site.

The selected compounds were tested regarding their ability to inhibit nsp15 activity. In vitro RNA cleavage assays were performed using the R16.4 RNA substrate in the presence or absence of the selected compounds. The RNA and nsp15 concentrations were kept constant. Reaction controls were performed in the absence of the enzymes, with a buffer supplemented with DMSO, since this solvent was used to solubilize all the chemical compounds. To evaluate the biochemical inhibitory effect of the drugs over SARS-CoV-2 nsp15, 1000 µM of each compound were tested. Etoposide, Golvatinib and Irinotecan seemed not to significantly influence the activity of the enzyme in the conditions tested (Figure 7A). However, Dutasteride, Meprednisone and Tasosartan showed ability to inhibit the endoribonuclease activity of nsp15 (Figure 7A). Considering the inibitory effect of these last drugs, we quantified the activity of nsp15 protein in the presence of 600 and 1000 µM of each of the compounds (Figure 7B). In the presence of 600 µM of Dutasteride or Tasosartan, nsp15 retained only ~40% of its activity, while the same concentration of Meprednisone had no effect on the nsp15 activity (Figure 7B). Increasing the concentration of Dutasteride to 1000 µM caused a drastic effect on nsp15 activity, since it almost abolished the ability of the enzyme to cleave the RNA substrate (Figure 7B). 1000 µM of Meprednisone considerably reduced nsp15 activity (Figure 7B). For Tasosartan, the increase in drug concentration had no effect, since the activity was similar to the one detected in the presence of 600 µM (Figure 7B). These results confirmed that nsp15 activity is blocked or significantly reduced in the presence of Dutasteride, Meprednisone and Tasosartan, being Dutasteride the most effective one. These experiments provided important insight into chemical compounds that may be further developed and tested for COVID-19 treatment.

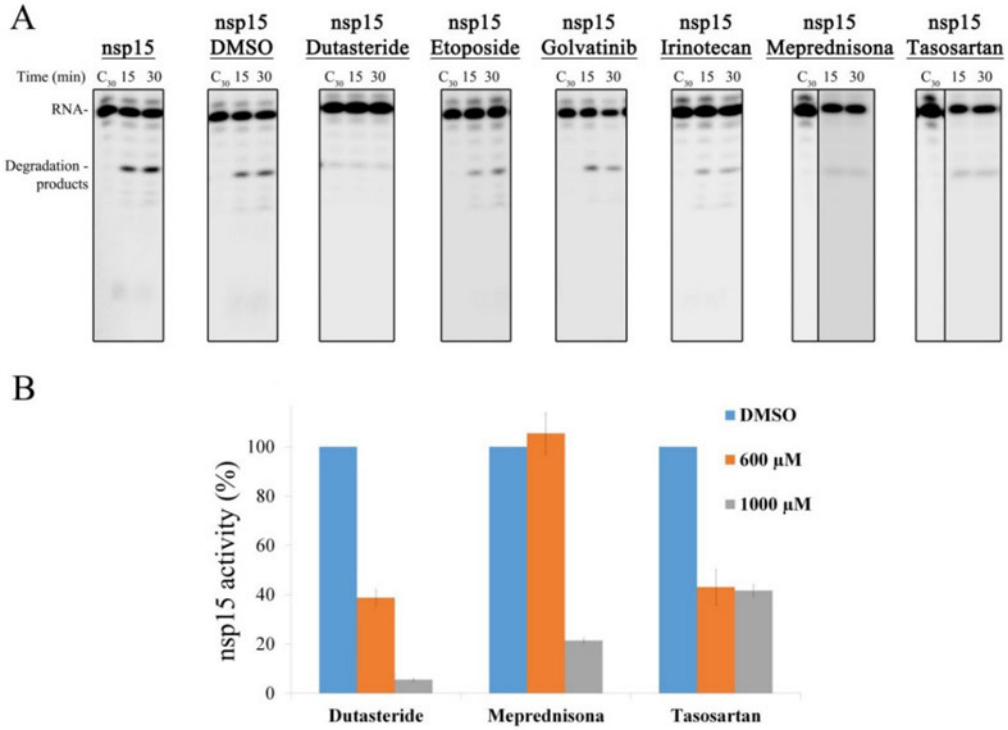

Figure 7. Effect of different drugs in SARS-CoV-2 nsp15 activity. (**A**) 500 nM of nsp15 were incubated with 50 nM of R16.4 RNA substrate in the presence of 1 mM of each drug indicated on the top of the respective panel. Reactions were analyzed on 7-M urea/20% polyacrylamide gels. C, control reactions; time points are indicated in the top of each panel. All the experiments were performed at least in triplicate. (**B**) Quantification of nsp15 activity in the presence of different concentrations of Dutasteride, Meprednisone and Tasosartan. The activity of nsp15 in the presence of DMSO was considered 100%.

4. Discussion

nsp15 is an uridylate-specific endoribonuclease that is highly conserved and present in all coronaviruses [8,11,13,18,35]. This RNase plays a critical role in CoV replication and host immune system evasion, which makes it a very attractive target for drug design [22,36].

In this work, we performed the biochemical characterization of SARS-CoV-2 nsp15 and confirmed its endoribonucleolytic activity [8,13,18,19,30,31,37]. Additionally, we showed different contributions of divalent metal ions for SARS-CoV-2 nsp15 endoribonucleolytic activity. The enzyme showed a preference for Mn^{2+} over Mg^{2+}, Ca^{2+} and Cu^{2+}, while Ni^{2+} and Co^{2+} supported residual activity, and Zn^{2+} inhibited the catalysis. We previously reported that the RNase activity of SARS-CoV-2 nsp14 is also affected by the presence of different metal cofactors [7]. Additionally, Viswanathan et al. described the dependence and preference of SARS-CoV-2 2′-*O*-methyltransferase nsp16 for distinct divalent metal ions [38]. The three enzymes nsp14, nsp15 and nsp16 have a crucial role in innate immune system evasion [22,39,40]. It is tempting to speculate that the surrounding environment could influence the viral response to the host immune system through the modulation of protein activity. Interestingly, Zn^{2+} was shown to inhibit SARS-CoV replication in vitro [41], which is in agreement with our results that demonstrated the inhibition of SARS-CoV-2 nsp15 activity by Zn^{2+}. Moreover, different concentrations of metal ions in blood of patients have been associated with severe illness and the fatal outcome of COVID-19 [42]. This evidence opens the door to explore the biological role of metals in the course of SARS-CoV-2 infection.

nsp15 activity and cleavage specificity have been shown to play important roles in coronavirus life cycles. Our results demonstrated the ability of SARS-CoV-2 nsp15 to cleave single- and double-stranded RNA substrates, with a marked preference for U residues. During CoV replication, the generation of dsRNA intermediates and the

FOI 26-3132 - Document 5

5′-polyuridine (PUN) RNAs produced at the 5′ end of the negative strand are known to trigger type I interferon (IFN-I) [24,43,44]. The endoribonucleolytic activity of nsp15 was found to destroy these intermediate RNAs, hindering the activation of the host innate immune response [22,23,25]. Indeed, nsp15 has been reported as one of the major interferon antagonists from SARS-CoV-2. Thus, it plays a very important role in viral RNA replication and pathogenesis [22,23,25]. Indeed, Nguyen et al. [45] observed that the deletion or inactivation of nsp15 significantly reduced SARS-CoV-2 genome replication. Additionally, in the human Coronavirus HCoV-229E, a nsp15 mutant was found to abolish viral RNA synthesis [8]. In murine hepatitis virus (MHV), nsp15 mutant viruses were defective for viral infection, and deleting parts of the equine arteritis virus (EAV) counterpart rendered a nonviable virus [46,47].

It is known that the biological unit of coronavirus nsp15 homologs is a hexamer, which is crucial for enzymatic activity and RNA binding [16,18–20]. Here, we show that oligomerization is critical for SARS-CoV-2 nsp15 enzymatic activity, being the hexamer of the active form. We also found that the residue N164 is important for nsp15 oligomerization but still retains the ability to cleave RNA; moreover, the oligomeric state seems to impact the U discrimination in SARS-CoV-2 nsp15. In fact, the nsp15 hexamer might be necessary for the stability and organization of the catalytic site and engagement of the RNA molecule. This is the first time that nsp15 oligomerization has been related with its cleavage specificity. Indeed, impacting the efficiency of the enzyme to cleave uridines could be an effective approach to affect viral pathogenesis, since it might have serious consequences in terms of host innate evasion. We also demonstrated that substitution of the residues from the catalytic triad have different outcomes, suggesting a more important role of H235 in catalysis, while the H250A and K290A mutants still retain unspecific activity. This was not observed in the SARS-CoV and MERS counterparts, where these mutations abrogated the activity of nsp15 [16,20]. Thus, our work revealed differences on the functionality of the enzyme that might be related to SARS-CoV-2 pathogenesis. We also demonstrated that the S294 and Y343 residues, which were postulated as responsible for uridine discrimination [16], are, in fact, important for the ability of nsp15 to recognize and cleave U residues but are not critical for the ability of the protein to cleave RNA, as previously described [16,24,33]. Our results indicated that attacking critical nsp15 residues, alone or in combination, could result in an inactive enzyme and, as consequence, a decreased SARS-CoV-2 infectivity. Supporting this, a SARS-CoV-2 replicon system (developed to avoid working with infectious SARS-CoV-2 virus) with a nsp15 H235A_H250A double mutation was shown to have its replication ability highly impaired [45].

Viral infections are known to dramatically alter the host cell metabolism for its replication and spread. SARS-CoV-2 infection was reported to change the metabolic profile in cell lines and lung air–liquid interface cultures [48]. Thus, understanding the influence of metabolites in the course of a viral infection would be extremely valuable. Citrate is a metabolite that plays a key role in pro- and anti-inflammatory homeostasis, contributing to both the antiviral immune response and virus-induced inflammation [49]. In this work, we found that citrate enhances the activity of SARS-CoV-2 nsp15. This finding opens a link between the host cell metabolism and viral RNA degradation pathways. Interestingly, this metabolite was found to co-crystalize with SARS-CoV-2 nsp15 [18]. Citrate binds to the protein active site, promoting its stabilization through Van der Waals contacts with Y343 and hydrogen bonds with the residues H235, H250, K290 and T341 [18], explaining the increase of the endoribonucleolytic activity here observed. It is not the first time that citrate has been reported to modulate the activity of an RNase. The activity of the phosphorolytic ribonuclease PNPase has previously been shown to be inhibited by citrate in the bacteria *E. coli* [50] and *Campylobacter jejuni* (Matos et al., unpublished results). Recently, a structure of SARS-CoV-2 nsp15 bound to Tipiracil was solved, and a phosphate ion was detected in the catalytic pocket [31], which led us to investigate the influence of phosphate over nsp15 activity. Our results demonstrated that phosphate also increases the NendoU activity of SARS-CoV-2 nsp15. It was already described that more than half of the known proteins

FOI 26-3132 - Document 5

interact with phosphate [51]. Additionally, the metabolism of phosphate was suggested to play a critical role in SARS-CoV-2 pathogenesis. For instance, SARS-CoV-2 can induce the depletion of cellular ATP, which consequently interferes with IFN-1 production and induces a cytokine storm [52]. We also discovered that sulfate is capable of inhibiting the endonucleolytic activity of SARS-CoV-2 nsp15. Sulfate ions mimic the phosphate group of RNA and have been used to map enzyme-binding sites [53]. The activity of RNase A, whose active site is structurally similar to that of nsp15, was also found to be inhibited by sulfate [32]. This finding is a significant breakthrough that can be used to rationally design drugs to inhibit nsp15 activity.

Despite the extensive research, the new possible therapies and the already existing vaccines, the worldwide response to the COVID-19 pandemics is still insufficient, and we are lagging behind the virus. In this manuscript, we performed a virtual screening of drugs that could bind the nsp15 active site and block its activity. From the results obtained, we selected the best six drugs to perform in vitro activity assays. Our results demonstrated that Meprednisone, Tasosartan and Dutasteride significantly reduced nsp15 activity, Dutasteride being the most effective compound. Many empirical therapeutic options have been used to treat COVID-19 patients based on the disease progression. Patients with severe COVID-19 can develop a systemic inflammatory response that can lead to lung injury and multisystem organ dysfunction. There are indications that corticosteroids (such as dexamethasone) and other immunosuppressive agents might prevent or mitigate these deleterious effects [54]. Meprednisone is a glucocorticoid and a methylated derivative of prednisone. Prednisone is converted by liver enzymes to the active form prednisolone. Prednisolone is already used to treat a wide range of health problems, such as allergies, blood disorders, skin diseases, infections, cancer, etc. A smaller randomized controlled trial evaluated the effect of methylprednisolone in patients with COVID-19. Although the trial had a low sample size, it showed that the methylated form of prednisolone reduces mortality in hospitalized patients older than 60 years with COVID-19 [55]. Our observation that meprednisone (the methylated and nonmetabolized form of prednisone) has the ability to inhibit the activity of SARS-CoV-2 nsp15 is a good indicator that this drug may exert an antiviral effect. Additionally, its anti-inflammatory properties may also be advantageous to suppress cytokine dysregulation. Tasosartan is used to treat patients with hypertension by blocking the angiotensin II (AT1) receptor and causing vasodilation. It was already reported that tasosartan could be a potential candidate to block the interaction of viral RBD from the spike protein to the ACE2 receptor [56], thus preventing the entry of the virus into the cells. Our work shows that this compound may also prevent viral endoribonucleolytic activity, which is crucial for SARS-CoV-2 replication, being a good candidate to treat COVID-19. Dutasteride is another medication that is primarily used to treat the symptoms of an enlarged prostate. It blocks the conversion of testosterone into dihydrotestosterone, which binds to androgen receptors with a much higher affinity, leading to a poor induction of androgen receptor signaling and to a decrease in human transmembrane protease serine 2 (TMPRSS2) expression. TMPRSS2 was also shown to be necessary for the proteolytic priming of the viral S protein to allow the fusion of SARS-CoV-2 to the cellular membranes. As such, the blocking of the conversion of testosterone into dihydrotestosterone could decrease SARS-CoV-2 entry into human cells [57]. In fact, a double-blinded, placebo-controlled randomized clinical trial (EAT-DUTA AndroCoV) showed that Dutasteride has a beneficial effect in the treatment of COVID-19. Indeed, our results show that this compound has the potential to inhibit the activity of SARS-CoV-2 nsp15. This property might contribute to the reduced viral shedding observed in the trial [58]. However, we should note that Dutasteride is indicated for men and should not be used by women during pregnancy, as it can cause birth defects [59].

One of the great challenges of de novo drug design is to find compounds with desirable pharmacological properties. Therefore, the design of molecules based on scaffolds as the core structures is a way of overcoming this challenge and obtaining potential good drug candidates. Taking this into account, we consider that Meprednisone, Tasosartan and

FOI 26-3132 - Document 5

Dutasteride are excellent scaffolds, due to their effectiveness against nsp15. Two of them are FDA-approved and are being used in patients to treat other diseases, which supports their potential use as drugs. Molecular docking also revealed common features between the selected drugs, namely the interactions with nsp15 S294, Y343 and H235 amino acids, together with their ability to bind to the protein active site in the presence of a phosphate ion. Future designs of efficient drugs could ideally comprise molecules with similar scaffolds to the studied drugs in order to retain most of these features. Additionally, the discovery that sulphate groups are able to inactivate SARS-CoV-2 nsp15 reveals new features to improve or to design new scaffolds.

5. Conclusions

nsp15 has been demonstrating to play an important role in coronavirus pathogenesis. Moreover, there are no closely related homologues to nsp15 in human cells, which makes this ribonuclease a pertinent target for developing CoV inhibitors. nsp15 inhibition may also contribute to revert viral evasion from host cell immunity. Here, we extensively characterized the mechanism of action of SARS-CoV-2 nsp15 activity and added new and useful information for the design/development of therapeutic strategies. Additionally, effective drugs with high therapeutic potential were identified in this work. By using a repurposing approach, in which we tested only drugs that are already approved or under investigation, we may accelerate the use of these compounds as part of a strategy to fight COVID-19 in the very near future. Due to the high homology with other viruses of the family, these results can also be important to fight viruses that may emerge in the future.

ABSTRACT

Objective: To describe outcomes of patients with coronavirus disease 2019 (COVID-19) in the outpatient setting after early treatment with zinc, low dose hydroxychloroquine, and azithromycin (the triple therapy) dependent on risk stratification.

Design: Retrospective case series study.

Setting: General practice.

Participants: 141 COVID-19 patients with laboratory confirmed severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infections in the year 2020.

Main outcome measures: Risk-stratified treatment decision, rate of hospitalization and all-cause death.

Results: Of 335 positively PCR-tested COVID-19 patients, 127 were treated with the triple therapy. 104 of 127 met the defined risk stratification criteria and were included in the analysis. In addition, 37 treated and eligible patients who were confirmed by IgG tests were included in the treatment group (total N=141). 208 of the 335 patients did not meet the risk stratification criteria and were not treated. After 4 days (median, IQR 3-6, available for N=66/141) of onset of symptoms, 141 patients (median age 58 years, IQR 40-67; 73% male) got a prescription for the triple therapy for 5 days. Independent public reference data from 377 confirmed COVID-19 patients of the same community were used as untreated control. 4 of 141 treated patients (2.8%) were hospitalized, which was significantly less ($p<0.001$) compared with 58 of 377 untreated patients (15.4%) (odds ratio 0.16, 95% CI 0.06-0.5). Therefore, the odds of hospitalization of treated patients were 84% less than in the untreated group. One patient (0.7%) died in the treatment group versus 13 patients (3.5%) in the untreated group (odds ratio 0.2, 95% CI 0.03-1.5; $p=0.16$). There were no cardiac side effects.

Conclusions: Risk stratification-based treatment of COVID-19 outpatients as early as possible after symptom onset with the used triple therapy, including the combination of zinc with low dose hydroxychloroquine, was associated with significantly less hospitalizations and 5 times less all-cause deaths.

Keywords: SARS-CoV-2, COVID-19, outpatients, treatment, zinc, hydroxychloroquine, azithromycin

ARTICLE SUMMARY

Strength and limitations of this study

- The first COVID-19 outpatient risk stratification and treatment study
- Repurposed antimalarial drug hydroxychloroquine at low dose in combination with zinc and azithromycin as a therapeutic approach early in the course of COVID-19 until specific drugs or vaccines are available
- Retrospective case series study with findings that have to be validated in prospective controlled clinical trials
- Only outcome data of the untreated control group of the same community based on public reference was available but no other patient characteristics, clinical symptoms, etc.
- No conclusion on the efficacy and safety of the used triple therapy related to severely ill hospitalized patients

INTRODUCTION

In December 2019, the new severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) started as an outbreak in Wuhan, China. This coronavirus has spread rapidly as a pandemic around the world,[1] causing coronavirus disease 19 (COVID-19) pneumonia, acute respiratory distress syndrome (ARDS), cardiac injury, liver and renal injury, thrombosis, and death.[2]

As of June, 2020, diagnosis and treatment of COVID-19 have been almost exclusively studied from an inpatient perspective, including intensive care with mechanical ventilation. Only one study has described characteristics and key health outcomes of COVID-19 diagnosed patients in an outpatient setting.[3] This is surprising as primary care physicians see COVID-19 patients often first. They could play a critical role in early diagnosis, treatment, and management of disease progression and virus spread. This assumption is supported by the established principle in medicine that speed of eradication is linked to the outcome of life-threatening infections.[4]

The early clinical phase of COVID-19 has not been the focus of research until today even though timing of antiviral treatment seems to be critical.[5] The more optimal window for therapeutic intervention is before the infection spreads from upper to lower respiratory tract and before the severe inflammatory reactions.[6] Therefore, diagnosis and treatment of COVID-19 outpatients as early as possible, even based on clinical diagnosis only, may have been an underestimated first step to slow down or even stop the pandemic more effectively. Based on clinical application principles of antiviral therapies, as demonstrated in the case of influenza A,[7] antiviral treatments should be used early in the course of infection.

Due to the lack of vaccines as well as SARS-CoV-2 specific therapies, the proposed use of repurposed antiviral drugs remains a valid practical consideration.[8] One of the most controversial drugs during the current SARS-CoV-2 pandemic is the well-known oral antimalarial drug hydroxychloroquine (HCQ), routinely used in the treatment of autoimmune diseases like rheumatoid arthritis or lupus.[9] [10] HCQ is currently listed as an essential medication for lupus by the World Health Organization (WHO)[11]. With more than 5.6 million prescriptions in the United States, HCQ was the 128th most commonly prescribed medication in 2017.[12] In the meantime, first observational studies concluding beneficial therapeutic effects of HCQ as monotherapy or in combination with the antibiotic azithromycin were reported just a few weeks after the start of the

SARS-CoV-2 outbreak.[13] All studies that used HCQ with rather contradictory results were done with hospitalized and often sicker patients[13-16] and one publication was recently withdrawn.[17 18] As of June 2020, no studies with COVID-19 outpatients treated with HCQ at an early stage of the disease have been reported.

Antiviral effects of HCQ are well-documented.[19] It is also known that chloroquine and probably HCQ have zinc ionophore characteristics, increasing intracellular zinc concentrations.[20] Zinc itself is able to inhibit coronavirus RNA-dependent RNA polymerase activity (RdRp).[21] It has been hypothesized that zinc may enhance the efficacy of HCQ in treating COVID-19 patients.[22] The first clinical trial results confirming this hypothesis were recently published as preprint.[23] Nevertheless, many studies with HCQ in monotherapy or in combination with the antibiotic azithromycin have been inconclusive so far.[13-16] In all of these studies, HCQ was used later than 5 days after onset of symptoms when hospitalized patients most likely had already progressed to stage II or III of the disease.[6] Regardless of the established antiviral effects of zinc and that many COVID-19 patients are prone to zinc deficiencies, dependent on comorbidities and drug treatments,[22] none of these studies were designed to include zinc supplementation as combination treatment.

This first retrospective case series study with COVID-19 outpatients was done to show whether a) a simple to perform outpatient risk stratification might allow for rapid treatment decision shortly after onset of symptoms, and b) whether the triple 5-day therapy with zinc, low dose HCQ, and azithromycin might result in less hospitalizations and less fatalities compared with relevant public reference data of untreated patients.

METHODS

SETTING

This retrospective case series study analysed data from COVID-19 outpatients with confirmed severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection in a community in New York State, USA. Outcome of patients who were treated with a specific triple therapy was compared to public reference data of patients in the same community who were not treated with this therapy.

CONFIRMATION OF COVID-19 DIAGNOSIS

COVID-19 diagnosis was confirmed if patients were positively tested for SARS-CoV-2 by means of PCR of nasal or pharyngeal swab specimens (majority of tests by Roche, Basel; 99,1% sensitivity and 99,7% specificity; other tests used with lower frequency included: Diasorin: 500 copies/mL; ThermoFisher: 10 genomic copy equivalents/reaction; Seegene: 1,250 copies/mL; Hologic: TCID50/mL: 1X10-2) or retrospectively by IgG detection tests (DiaSorin: Sensitivity 97.6% (≥ 15 days after diagnosis), specificity 99.3%; Diazyme: Sensitivity 91.2%, specificity 97.3%). Only patients who did have a record of a positive test result were included in the analysis. The PCR assays were authorized by the Food and Drug Administration (FDA) without clinical sensitivity/specificity data due to the urgent nature of the pandemic. Only one positive test was necessary for the patient to be included in the retrospective analysis.

PATIENTS

Sequentially consecutive COVID-19 outpatients older than 18 years at diagnosis were included in the analysis as treatment group. All patients were white. Patients received a prescription for the triple therapy only if they met one of the following risk stratification requirements during a medical office-based or telehealth consultation:

Group A: age >60 years; with or without clinical symptoms;

Group B: age ≤60 years and shortness of breath (SOB);

Group C: age ≤60 years, clinically symptomatic and with at least one of the following comorbidities: hypertension, hyperlipidemia, diabetes, obesity (body mass index ≥ 30 kg/m^2), cardiovascular disease, heart failure, history of stroke, history of deep vein

thrombosis or pulmonary embolism, asthma, chronic obstructive pulmonary disease (COPD), other lung disease, kidney disease, liver disease, autoimmune disease, or history of cancer. Pregnant women, if any, were to be included in this group as well.

Laboratory confirmed COVID-19 patients of the same community who were not treated with the described triple therapy and related outcome data represented the untreated control group (public reference data).

PROCEDURE AND TREATMENT

Data of treated patients was collected from electronic health records in the year 2020. Demographics, as reported by the patient, and a current medical history of hypertension, hyperlipidemia, diabetes, obesity (body mass index ≥ 30 kg/m^2), cardiovascular disease, heart failure, stroke, asthma, COPD, other lung disease, kidney disease, liver disease, autoimmune disease, history of cancer, thyroid disease psychiatric disorder, or pregnancy were collected.

The presence of the following clinical symptoms of treated patients were documented: cough/dry cough, fever, SOB, changes of or no smell or taste, sore throat, headache, runny nose/clear rhinorrea, sinus congestion, diarrhea/vomiting, cold symptoms, feeling sick, weakness, and low back pain. If reported, number of days since onset of symptoms was documented.

The following vital signs, if available, were collected and documented: heart rate (beats per minute), breaths per minute (BPM), systolic and diastolic blood pressure (mmHg), body temperature (°C), oxygen saturation measured by pulse oximetry (O_2 %), body weight (kg), and/or body mass index (BMI).

Main co-medications were characterised based on primary care prescriptions active at the time of diagnosis, were documented as categorical variables and included: beta-blockers, angiotensin-converting enzyme inhibitors, angiotensin-2 antagonists, calcium channel blockers, hydrochlorothiazide, statins, bronchodilators, antidiabetics, and insulin.

Only diagnosed COVID-19 patients who met the defined risk stratification requirements of group A, B, or C got a prescription for the following triple therapy for 5 consecutive days in addition to standard supportive care: zinc sulfate (220 mg capsule once daily, containing 50 mg elemental zinc), HCQ (200 mg twice daily), and azithromycin (500

mg once daily). No loading dose was used. Patients who did not meet the risk stratification requirements received standard of care to treat common upper respiratory infection. Patients were not treated with HCQ if they had known contraindications, including QT prolongation, retinopathy, or glucose-6-phosphate dehydrogenase (G6PD) deficiency. As usual and following best practice patients were informed about possible drug related side effects. Reported events, if any, were documented as required.

The selection of the used zinc supplement and drugs, dosages and the combination thereof, were based on treatment guidelines, positive reports from other countries like South Korea, emerging first clinical evidence, and based on the discretion of the treating physicians.

OUTCOME

Two outcomes were studied: COVID-19 related hospital admission and all-cause death during time of follow up of at least 28 days in the treatment group and in the untreated control group (public reference). The outcome of COVID-19 patients of the untreated control group was reported by the responsible health department.

STATISTICAL ANALYSES

Only patients of the treatment group who met the defined risk stratification requirements and who received at least a prescription for HCQ, with or without zinc, for 5 days, were included in the retrospective analysis and were categorized accordingly. If the patient’s electronic health record did not include information on a clinical characteristic, it was assumed that the characteristic was not present. In the group of the public reference data only confirmed COVID-19 patients who were not treated in the respective general practice with the triple therapy were included in the analysis. For this untreated control group only outcome data for hospitalization and all-cause death was available and used for the statistical comparison with the treatment group.

No sample-size calculations were performed. Descriptive statistics are presented as median and interquartile range (IQR) for continuous variables and frequencies for categorical variables. For comparison with results of other studies means and standard

deviations were calculated as needed. Normality of distribution for continuous variables was assessed by the Shapiro-Wilk-Test. A 2-tailed Student's t-test was used for parametric analysis, and a Wilcoxon Signed-Rank test was used for nonparametric data analysis. For calculation of correlation the point biserial correlation coefficient was applied if one variable was dichotomous. Associations between two categorical variables were calculated with the Chi-Square test. Odds ratio (OR) were calculated for comparison of the outcome of the treatment group with the untreated control group. The α: 0.05 was considered as a significance level. The data were analysed using Microsoft Excel for Microsoft 365 MSO (32-Bit), the Excel add-on Real Statistics, SigmaStat 4, and Sigma Plot 14.0.

PATIENT AND PUBLIC INVOLVEMENT

In this retrospective case series study no patients were involved in the study design or in setting the research questions or the outcome measures directly. No patients were asked to advise on interpretation or writing of results.

STUDY APPROVAL

The study was approved by the Western Institutional Review Board and it was exempt under 45 CFR § 46.104(d)(4). The analysis was conducted with de-identified patient data, according to the USA Health Insurance Portability and Accountability Act (HIPAA), Safe Harbor. For that reason exact dates and locations are not mentioned in this study.

RESULTS

PATIENTS

In accordance with available public reference data, 712 confirmed SARS-CoV-2 PCR positively tested COVID-19 patients were reported for the respective community at the defined time point of the analysis. Of these 712 patients, 335 presented as outpatients at a general practice and 127 were treated with the triple combination therapy. Of these 127 patients, 104 met the risk stratification criteria and were included in the analysis (table 1). 208 patients of the 335 did not meet the defined risk stratification criteria were treated with standard of care and recovered at home. The SARS-CoV-2 infection of 37 additional patients who met the risk stratification criteria and who were also treated with the triple therapy was later confirmed by IgG tests (table 1). These patients were included additionally in the analysis resulting in a total number of 141 patients, all with a confirmed SARS-CoV-2 infection by PCR or IgG tests. None of these patients were lost to follow-up for the defined outcome. The outcome of the remaining N=377 positively tested but not treated COVID-19 patients, e.g. from other practices of the community, served as public reference (fig 1). Analysis of the 141 patients in the treatment group showed that all of these patients (100%) got a prescription of HCQ, 136 (96.5%) of zinc sulfate, and 133 (94.3%) of azithromycin, while 1 patient (0.7%) got doxycycline instead.

BASELINE CHARACTERISTICS OF THE PATIENTS

Table 2 shows the baseline demographics and clinical characteristics of all 141 patients in the treatment group and for the risk stratification groups A, B, and C. 69 patients (49%) belonged to group A, 48 (34%) to group B, and 24 (17%) to group C. Age ranged from 18 to 80 years and the median age was 58 years with an interquartile range (IQR) of 40-67. The median age of group A, B, and C was 67, 39, and 45 years. A total of 103 patients (73.1%) were male with a male-to-female ratio of 2.71. Most common comorbidities included hypertension (28%), obesity (28%), hyperlipidemia (23%), and diabetes (18%), whilst least common ones were liver disease (2%), heart failure (1%), and stroke (1%). One patient was pregnant (1%) at initiation of treatment. There was a positive and significant correlation between age and hypertension ($r=0.3309$, $p=0.001$), hyperlipidemia ($r=0.26306$, $p<0.001$), and cardiovascular disease

(r=0.16757, p<0.05), while asthma was negatively correlated with age (r=-0.30867, p<0.001).

Median time between onset of clinical symptoms and medical consultation was 4 days (IQR 3-6; available for 66/141 patients, mean 4.8 days ± 2.7) (table 3). There was no significant correlation between age and days of onset of clinical symptoms to consultation (p>0.05). Days from onset of symptoms to consultation were not significantly different between groups (p>0.05).

Most common clinical symptoms included cough (87.2%), fever (77.3%), SOB (46.1%), and changes of or no smell or taste (30%), whilst least common ones were sinus congestion (16%), diarrhea/vomiting (5%), and low back pain (3%). Table 4 shows symptoms of all patients and stratified by groups A, B, and C. There was a significant negative correlation between age and changes of smell or taste (r=-0.43, p<0.001). No patient had a clinical diagnosis of pneumonia.

Table 5 shows vital signs, as they were available, for all patients and by group A, B, and C. Many patients consulted the general practice during the COVID-19 crisis via telehealth so vital signs were not available for all of these patients. The highest proportion of patients had available measurements for heart rate (63%) and pulse oximetry (60%). Vital signs were not significantly different between risk stratification groups (p>0.05) except for systolic blood pressure of group A and B (p<0.05).

Table 6 summarizes most important co-medications. 16% of patients were taking angiotensin-converting enzyme inhibitors, angiotensin-2-antagonists, hydrochlorothiazide or a combination thereof. The most common long-term therapies at the time of COVID-19 diagnosis were statins (20%), beta-blockers (12%), and insulin (18%).

HOSPITALIZATIONS AND ALL-CAUSE DEATH

In the treatment group 4 of 141 patients were hospitalized, which was significantly less than in the untreated group with 58 of 377 patients (15.4%), (fig 2.), (OR 0.16; [95% CI, 0.06 to 0.5]; p<0.001), (table 7, fig 4). Therefore, the odds of hospitalization of treated patients were 84% less than in the untreated patients. All hospitalized patients were male, one in his twenties, two in their forties, and one in his seventies. Three of the 4 hospitalized patients (75%) belonged to risk stratification group B and one to

group A (25%). All patients (100%) reported SOB at time of consultation. Median days from onset of symptoms to consultation were 4 days. Of the treatment group 1 patient had to stay only one day in hospital, 2 other patients were discharged as cured, and 1 patient died (s. below). No patient was on a ventilator.

One of the 141 patients (0.71%) who belonged to treatment group A died after being hospitalized. This patient had a history of cancer and did only take one daily dose of the triple therapy before hospital admission. With 13 of 377 patients (3.5%, fig 3) more patients died in the untreated group (OR 0.2; [95% CI, 0.03 to 1.5]) (table 7, fig 4). The odds of all-cause death of treated patients were 80% less (p=0.16) than in the untreated group.

The 208 patients presenting at the general practice who did not meet the risk stratification requirements and who were not treated with the triple therapy recovered at home and no hospital admissions or deaths were reported.

SAFETY

In general, the triple therapy with zinc, low dose HCQ, and azithromycin was well tolerated. After initiation of treatment 30 of 141 patients (21%) reported weakness, 20 (14%) nausea, 15 (11%) diarrhea, and 2 (1%) rash (table 8). No patient reported palpitations or any cardiac side effect.

DISCUSSION

This first retrospective case series study with COVID-19 outpatients in primary care setting showed that risk-stratified treatment early after onset of clinical symptoms, with the triple therapy zinc, low dose HCQ, and azithromycin was associated with significantly less hospitalizations (odds ratio 0.16; p<0.001) and less all-cause deaths (odds ratio 0.2; p=0.16) in comparison to untreated patients (public reference data) of the same community. Based on the performed risk stratification prevalence of the comorbidities hypertension, hyperlipidemia, and diabetes were the highest in group A (>60 years and clinical symptoms), asthma and other lung diseases were the highest in group B (<60 years and SOB), and obesity and autoimmune disease were the highest in group C (<60 years, clinical symptoms, and defined comorbidities). Most frequent symptoms of these COVID-19 patients were cough followed by fever while available median body temperature measurements were in a normal range. Almost 50% of risk-stratified and treated patients were suffering from SOB while breaths per minute and blood oxygen saturation were still in the normal range. Median time from onset of symptoms to first medical consultation was 4 days (IQR 3-6). Approximately 16% of patients received co-medications known to be associated with zinc deficiency, such as antihypertensive drugs. No patient experienced any known severe adverse events that were considered drug related during treatment or follow up.

STRENGTHS AND WEAKNESSES OF THE STUDY

At the time of this manuscript submission, only one peer-reviewed study had analyzed the key health outcomes of COVID-19 patients diagnosed in primary care setting.[3] Because of this gap in data, the value of this study is multifold. It provides much needed recommendations for risk stratification and a treatment regimen to prevent hospitalization and death of COVID-19 patients. Diagnosis of COVID-19 for all patients in this analysis was confirmed by PCR or IgG tests compared with a recent study in which less than 3% had a diagnosis confirmed by laboratory tests.[24] To start the triple therapy as early as possible after symptom onset is critical for treatment success, because SARS-CoV-2 viral load seems to peak at day 5 to 6 after symptom onset[25-27] and severe cases progress to acute respiratory distress syndrome (ARDS) after only 8 to 9 days.[28 29] Early antiviral treatment is an established protocol to manage severe disease progression, as was shown, for example, by a cumulative case control study

during the 2009 H1N1 influenza pandemic in Canada.[30] For patients at high risk for severe viral disease progression, it is recommended to start antiviral therapy as early as possible.[31 32] Early treatment might be also critically important to effectively reduce SARS-CoV-2 viral load,[5] and this underscores the role of early intervention by primary care physicians as reported herein.

Further strength of this approach was the simple risk stratification of symptomatic outpatients to determine the need for therapy, a strategy not yet applied in COVID-19 primary care,[33] but routinely implemented in primary care for other diseases.[34] Underlying assumptions of the risk stratification used in this setting are different than other recommendations.[35] Here, age stratified high risk was defined as >60 years (typically defined as >65 years) to encompass the common increase of comorbidity incidences in this age group.[36] Patients ≤60 years with SOB, even without reduced pulse oximetry values, were treated because it was assumed virus will likely spread from upper to lower respiratory tract.[37] Also treated were patients ≤60 years with clinical symptoms and prognostically relevant comorbidities.[35] By applying this risk stratification approach, respective care was tailored to patients with a higher likelihood for hospitalizations or fatalities, which ensured that the medical principles of “patient first” and “doing no harm” were maintained.[38] As a result, 62% of COVID-19 patients were treated with standard of care only and recovered at home, and only 38% needed treatment with the triple therapy.

The antiviral potential of HCQ was broadly described *in vitro* and *in vivo*.[39-41] HCQ has a long terminal elimination half-life of 32 days in plasma and 50 days in blood.[42] Therefore, the treatment approach was conservative, with starting dose being the same as maintenance dose and with a short treatment duration of only 5 days, being even more conservative than other recommendations.[40] HCQ-dependent intracellular increases in pH might directly interfere with pH-dependent SARS-CoV-2 replication.[19] Also, chloroquine and probably HCQ have characteristics of a zinc ionophore resulting in increasing intracellular zinc concentrations.[20] The dose of elementary zinc in this study was similar to doses previously studied to successfully prevent infections in the elderly.[43] Antiviral effects of zinc against a variety of viruses have been demonstrated during the last decades.[44] Zinc, in addition to its role as a general stimulant of antiviral immunity, is known to specifically inhibit coronavirus RNA-dependent RNA polymerase.[21] Based on HCQ’s ionophore properties, it has been hypothesized that zinc may enhance the efficacy of HCQ in treating COVID-19 patients.[22] In addition,

zinc might inhibit the serine protease furin.[45] Furin is expressed on endothelial cells, monocytes/macrophages, and smooth muscle cells in human atherosclerotic plaques[46] and therefore might play a critical role for the severe cardiovascular complications of COVID-19. As furin might be responsible to favor SARS-CoV-2 spreading compared with other beta coronaviruses[47 48] and as furin-inhibition protects from certain viral-dependent infections[49], it may be important to evaluate the potential role of zinc in inhibiting this pathway.

Azithromycin was added to the treatment regimen as preliminary data provides evidence for more efficient or synergic virus elimination in conjunction with bacterial superinfection.[13 50] Although there is a synergistic antiviral effect between zinc, HCQ, and azithromycin, zinc supplementation may be instrumental for the outcome of patient populations with severe clinical courses. Zinc deficiency was confirmed in a large number of healthy elderly[51] and in diabetic patients.[52] In addition, it has been documented that the antihypertensive drugs hydrochlorothiazide, angiotensin-converting-enzyme inhibitors, and angiotensin 2 receptor antagonists can result in an increased urinary excretion of zinc with subsequent systemic zinc deficiency.[53] Age, comorbidities, and relevant co-medications align well with the majority of described COVID-19 patients at high risk, including the risk-stratified population of this analysis. Zinc deficiency might explain why certain patient groups seem not to benefit from HCQ in monotherapy. During the 5-day treatment with the triple therapy and during follow up, no severe adverse events were observed and no cases of cardiac arrhythmia were reported in this general practice, which is in accordance with available safety data of more than 300,000 patients.[54]

Inherent to all retrospective analyses, our study has certain limitations such as non-randomization and blinding of treatment. Also, only the outcome data of the untreated control group based on the public reference was available but no other patient characteristics or clinical symptoms and so no risk adjustment was possible. Therefore, confounding factors and selection bias, among other issues, do exist. The demographic composition of the treatment group might have also had an influence on our findings. Because many physician appointments had to be managed by telehealth, vital parameters were not available for the majority of patients. Viral load and ECG data were not analyzed. Treatment with the triple therapy resulted in a numerically lower rate of all-cause deaths. In the absence of clinical details about the untreated patient group, the lower rate of all-cause death in the treated group was not statistically

significant. However, the patients in the treated group were all positively risk-stratified while the risk of the untreated group was obviously lower as this group included high- and low-risk patients.

STRENGTHS AND WEAKNESSES IN RELATION TO OTHER STUDIES, DISCUSSING IMPORTANT DIFFERENCES IN RESULTS

In this study, the ratio of males and average age was comparable with a relevant number of other studies, but distribution of comorbidities was not.[55] The latter was expected because outpatients usually have a different distribution of age and especially of comorbidities than critically ill inpatients. As expected the prevalence of hypertension, hyperlipidemia, and cardiovascular disease correlated positively with age while asthma correlated negatively. Approximately 50% of risk-stratified and treated patients presented with SOB while the parameters breaths per minute and blood oxygen saturation were still within the normal range. These patients would usually not be considered for hospital admission, although SOB might be considered an alarming early sign of disease progression. Based on the implemented risk stratification, these patients were identified and treated immediately.

In contrast to many other studies, the most frequent symptom was cough and not fever.[56 57] Changes in smell or taste in one third of patients and a negative correlation with age were similar to findings from other groups.[58] While mean time from onset of symptoms to treatment was only 4.8 days (median 4 days), previously reported time spans range from 6.3 days,[59] to 8 days,[16] up to 16.6 days,[14], or was often even not reported.[60] In most of these studies, COVID-19 disease had most likely already progressed at the time of presentation to stages II or even stage III of the disease.[6] In many studies, often only limited information is provided about co-medications and specifically about clinical symptoms at admission.[60] The latter would be very important to better understand the differences of clinical presentation between inpatients and outpatients, and thus the urgency for early anti-COVID-19 treatment in outpatient setting.[61] The potential of zinc to enhance the antiviral efficacy of HCQ was already described in detail elsewhere.[22] This hypothesis was recently confirmed by a study using a similar triple therapy and treatment duration.[23] Zinc added to HCQ and azithromycin resulted in a significantly increased number of patients being discharged, a reduction in mortality, or transfer to hospice. In another study, when a lower dose of

200 mg HCQ twice daily was added to basic treatment, mortality of even critically ill patients was significantly reduced.[62] These and our findings indicate that proper dosing of HCQ with its long half-life might be key for the favourable outcome of COVID-19 patients. In critical care, drugs with short half-lives are usually preferred. Especially in critically ill COVID-19 patients, higher doses of HCQ may have unforeseeable effects, for example, on insulin sensitivity in obese patients[63] and glucose levels in diabetics.[64] [65] Besides glucose levels, it is important to closely monitor renal function which is increasingly affected during progression of COVID-19.[66] Because HCQ is substantially excreted by the kidneys, the risk of toxic reactions is greater in patients with impaired renal function.[67]

POTENTIAL IMPLICATIONS FOR CLINICIANS AND POLICY MAKERS

Clinical experience from severely ill inpatients with pneumonia who were treated with high dose HCQ are not readily transferable to the outpatient setting with upper respiratory disease only. For outpatients with a median of only 4 days after onset of symptoms, COVID-19 represents a totally different disease and needs to be managed and treated differently.[61] A simple to perform outpatient risk stratification, as shown here, allows rapid treatment decisions and treatment with the triple therapy zinc, low dose HCQ, and azithromycin and may prevent a large number of hospitalizations and probably deaths during the SARS-CoV-2 pandemic. This might also help to avoid overwhelming of the health care systems.

UNANSWERED QUESTIONS AND FUTURE RESEARCH

Almost no general clinical data of COVID-19 outpatients exists and hence responsible experts and stakeholders should ensure a common effort to close this gap by designing studies specifically for primary care setting. Ongoing studies with HCQ should be amended to include combination with zinc. Based on our and others preliminary data, the triple therapy zinc, low dose HCQ, and azithromycin should be used and tested to generate prospective data as soon as possible. As zinc deficiency may play an important role during infection, development, and the clinical course of COVID-19, zinc supplementation in accordance with defined recommended dietary allowances should be evaluated as a simple option for primary prevention. Zinc has a high safety margin

and it would be physiologically already available if for example treatment with HCQ is initiated.

Tables and Figures

Table 1. COVID-19 Diagnostics by PCR and IgG tests of Patients in the Treatment Group				
COVID-19 Diagnostics – no. (%)	**Risk Stratified Group A (N=69)**	**Risk Stratified Group B (N=48)**	**Risk Stratified Group C (N=24)**	**All Patients Treatment Group (N=141)**
SARS-CoV-2 – PCR Test	51 (74)	39 (81)	14 (58)	104 (74)
SARS-CoV-2 – IgG Test	18 (26)	9 (19)	10 (42)	37 (26)

Table 2. Baseline Demographics and Clinical Characteristics of Patients in the Treatment Group*				
Characteristics	**Risk Stratified Group A (N=69)**	**Risk Stratified Group B (N=48)**	**Risk Stratified Group C (N=24)**	**All Patients Treatment Group (N=141)**
Median age (IQR) – years	67 (64-69)	39 (24-47)	45 (36-50)	58 (40-67)
Male sex – no. (%)	46 (67)	40 (83)	17 (71)	103 (73)
Coexisting conditions – no. (%)				
Any condition	44 (64)	31 (65)	24 (100)	99 (70)
Hypertension	27 (39)	4 (8)	8 (33)	39 (28)
Hyperlipidemia	21 (30)	7 (15)	5 (21)	33 (23)
Diabetes	16 (23)	4 (8)	5 (21)	25 (18)
Obesity	20 (29)	10 (21)	10 (42)	40 (28)
Cardiovascular Disease	9 (13)	1 (2)	3 (13)	13 (9)
Heart Failure	2 (3)	0 (0)	0 (0)	2 (1)
Stroke	1 (2)	0 (0)	0 (0)	1 (1)
Asthma	2 (3)	9 (19)	2 (8)	13 (9)
COPD	0 (0)	0 (0)	0 (0)	0 (0)
Other Lung Disease	6 (9)	5 (10)	4 (17)	15 (11)
Kidney Disease	1 (2)	3 (6)	2 (8)	6 (4)
Liver Disease	1 (2)	2 (4)	0 (0)	3 (2)
Autoimmune Disease	2 (3)	4 (8)	4 (17)	10 (7)
History of Cancer	6 (9)	2 (4)	1 (4)	9 (6)
Thyroid Disease	7 (10)	4 (8)	2(8)	13 (9)
Psychiatric Disorder	7 (10)	4 (8)	5 (21)	16 (11)
Pregnancy	-	-	1 (4)	1 (1)

*IQR interquartile range

Table 3. Patients with Reported Days Since Onset of Symptoms in the Treatment Group				
Characteristics	**Risk Stratified Group A (N=69)**	**Risk Stratified Group B (N=48)**	**Risk Stratified Group C (N=24)**	**All Patients Treatment Group (N=141)**
Patients with reported days – no. (%)	32 (46)	25 (48)	9 (38)	66 (47)
Median days since onset of symptoms – (IQR)	4 (3-6)	3 (3-6.5)	4 (3-5.5)	4 (3-6)

Table 4. COVID-19 Diagnostics and Baseline Reported Clinical Symptoms of Patients in the Treatment Group				
Clinical Symptoms – no. (%)	**Risk Stratified Group A (N=69)**	**Risk Stratified Group B (N=48)**	**Risk Stratified Group C (N=24)**	**All Patients Treatment Group (N=141)**
Cough/Dry Cough	60 (87)	39 (81)	24 (100)	123 (87)
Fever	53 (77)	38 (79)	18 (75)	109 (77)
Shortness of Breath (SOB)	17 (25)	48 (100)	0 (0)	65 (46)
Changes of or no smell or taste	21 (30)	19 (40)	2 (8)	42 (30)
Sore Throat	19 (28)	8 (17)	7 (29)	34 (24)
Headache	19 (28)	6 (13)	7 (29)	32 (23)
Runny Nose/Clear Rhinorrhea	16 (23)	8 (17)	4 (17)	28 (20)
Sinus Congestion	10 (15)	9 (19)	4 (17)	23 (16)
Diarrhea/Vomiting	1 (2)	5 (10)	1 (4)	7 (5)
Cold Symptoms	31 (45)	16 (33)	12 (50)	59 (42)
Feels Sick	40 (58)	38 (79)	17 (71)	95 (67)
Weakness	44 (64)	22 (46)	11 (46)	77 (55)
Low Back Pain	3 (4)	0 (0)	1 (4)	4 (3)

Table 5. Physical Examination – Vital Signs of Patients in the Treatment Group		
Parameter		**Patients with available Parameters – no. (%) of N=141**
Median Heart Rate – beats per minute – (IQR)	86 (80-94)	89 (63)
Median Breaths per Minute [BPM] – (IQR)	16 (15-18)	43 (31)
Median Systolic Blood Pressure [mmHg] – (IQR)	126 (120-139)	66 (47)
Median Diastolic Blood Pressure [mmHg] – (IQR)	80 (74-85.5)	66 (47)
Median Body Temperature [°C] – (IQR)	37.2 (37-37.8)	79 (56)
Median Pulse Oximetry [O2 %] – (IQR)	97 (96-98)	85 (60)
Median Body Weight [kg] – (IQR)	88 (72.6-98.4)	43 (31)
Median Body Mass Index [kg/m^2] – (IQR)	32.2 (28.5-36.3)	30 (21)

Table 6. Co-Medications of Patients in the Treatment Group	
Drug Class	**Patients – no. (%) of N=141**
Betablockers	17 (12)
Angiotensin-converting enzyme inhibitors	8 (6)
Angiotensin-2 Antagonists	13 (9)
Calcium channel blockers	8 (6)
Hydrochlorothiazide	6 (4)
Statins	28 (20)
Bronchodilators	10 (7)
Antidiabetics	11 (8)
Insulin	26 (18)

Table 7. Clinical Outcome in the Treated Patient Group versus the Untreated Patient Group					
Outcome	**Treated Group – no. (%) of N=141**	**Untreated Group – no. (%) of N=377**	**Odds Ratio**	**95% CI**	**P-value**
Hospitalization	4 (2.8)	58 (15.4)	0.16	0.06-0.5	<0.001
All-cause death	1 (0.71)	13 (3.5)	0.2	0.03-1.5	0.16

CI=Confidence Interval

Table 8. Summary of Adverse Events	
Event	**Patients – no. (%) of N=141**
Any adverse event	67 (48)
Weakness	30 (21)
Nausea	20 (14)

Abstract

Background

The common cold is one of the most widespread illnesses and is a leading cause of visits to the doctor and absence from school and work. Trials conducted in high-income countries since 1984 investigating the role of zinc for the common cold symptoms have had mixed results. Inadequate treatment masking and reduced bioavailability of zinc from some formulations have been cited as influencing results.

Objectives

To assess whether zinc (irrespective of the zinc salt or formulation used) is efficacious in reducing the incidence, severity and duration of common cold symptoms. In addition, we aimed to identify potential sources of heterogeneity in results obtained and to assess their clinical significance.

Search methods

In this updated review, we searched CENTRAL (2012, Issue 12), MEDLINE (1966 to January week 2, 2013), EMBASE (1974 to January 2013), CINAHL (1981 to January 2013), Web of Science (1985 to January 2013), LILACS (1982 to January 2013), WHO ICTRP and clinicaltrials.gov.

Selection criteria

Randomised, double-blind, placebo-controlled trials using zinc for at least five consecutive days to treat, or for at least five months to prevent the common cold.

Data collection and analysis

Two review authors independently extracted data and assessed trial quality.

Main results

FOI 26-3132 - Document 5

Five trials were identified in the updated searches in January 2013 and two of them did not meet our inclusion criteria. We included 16 therapeutic trials (1387 participants) and two preventive trials (394 participants). Intake of zinc was associated with a significant reduction in the duration (days) (mean difference (MD) -1.03, 95% confidence interval (CI) -1.72 to -0.34) (P = 0.003) (I^2 statistic = 89%) but not the severity of common cold symptoms (MD -1.06, 95% CI -2.36 to 0.23) (P = 0.11) (I^2 statistic = 84%). The proportion of participants who were symptomatic after seven days of treatment was significantly smaller (odds ratio (OR) 0.45, 95% CI 0.20 to 1.00) (P = 0.05) than those in the control, (I^2 statistic = 75%). The incidence rate ratio (IRR) of developing a cold (IRR 0.64, 95% CI 0.47 to 0.88) (P = 0.006) (I^2 statistic = 88%), school absence (P = 0.0003) and prescription of antibiotics (P < 0.00001) was lower in the zinc group. Overall adverse events (OR 1.58, 95% CI 1.19 to 2.09) (P = 0.002), bad taste (OR 2.31, 95% CI 1.71 to 3.11) (P < 0.00001) and nausea (OR 2.15, 95% CI 1.44 to 3.23) (P = 0.002) were higher in the zinc group. The very high heterogeneity means that the averaged estimates must be viewed with caution.

Authors' conclusions

Zinc administered within 24 hours of onset of symptoms reduces the duration of common cold symptoms in healthy people but some caution is needed due to the heterogeneity of the data. As the zinc lozenges formulation has been widely studied and there is a significant reduction in the duration of cold at a dose of ≥ 75 mg/day, for those considering using zinc it would be best to use it at this dose throughout the cold. Regarding prophylactic zinc supplementation, currently no firm recommendation can be made because of insufficient data. When using zinc lozenges (not as syrup or tablets) the likely benefit has to be balanced against side effects, notably a bad taste and nausea.

Zinc for the common cold

The common cold is often caused by the rhinovirus. It is one of the most widespread illnesses and is a leading cause of visits to the doctor and absence from school and work. Complications of the common cold include ear infection, sinusitis and exacerbations of reactive airway diseases. There is no proven treatment for the common cold. However, an even partially effective treatment for treating and preventing the common cold could markedly reduce the health problems and economic losses associated with it.

Zinc inhibits replication of the virus and has been tested in trials for treatment of the common cold. This review identified 18 randomised controlled trials, enrolling 1781 participants of all age groups, comparing zinc with placebo (no zinc). We found that zinc (lozenges or syrup) reduces the average duration of the common cold in healthy people, when taken within 24 hours of onset of symptoms. In people taking zinc their cold symptoms are also less likely to persist beyond seven days of treatment. Prophylactic zinc supplementation for at least five months reduces incidence, school absences and prescription of antibiotics for children with the common cold, although antibiotics are not required for the common cold. People in whom common cold symptoms might be troublesome (for example, those with underlying chronic illness, immunodeficiency, asthma, etc.) have not been studied, so the use of zinc cannot currently be recommended for them. Given the variability in the dose, formulation and duration of zinc use in the included studies, more research is needed to address these before zinc use can be generally recommended for the common cold. However, as the zinc lozenges formulation has been widely studied, and there is a significant reduction in the duration of cold at a dose of ≥ 75 mg/day, for those considering using zinc it would be best to use it at this dose throughout the cold. When using zinc lozenges (not as syrup or tablets) the likely benefit has to be balanced against side effects, notably a bad taste and nausea. Regarding prophylactic zinc supplementation, currently no firm recommendation can be made because of insufficient data.

Summary of findings for the main comparison

Zinc compared with placebo for the common cold

Patient or population: patients with common cold

Settings: outpatient

Intervention: zinc lozenges or syrup

Comparison: usual care

Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)	Comments
	Assumed risk	Corresponding risk				
	Placebo	Zinc				
Duration of cold symptoms (days)	The mean duration of cold symptoms ranged across control groups from 5.1 to 9.38 days	The mean duration of cold symptoms ranged across control groups from 4 to 12.1 days		1656 (14 studies[1])	++O low[2,3-5]	
Severity of symptom score	The mean severity of symptom score ranged across control groups from 0.4 to 5.61	The mean severity of symptom score ranged across control groups from 0.2 to 3.45		513 (5 studies[6])	++O low[3,5,7,8]	
Incidence of common cold	618 per 1000	382 per 1000 (354 to 431)	RR 0.64 (0.47 to 0.88)	394 (2 studies[9])	+OO very low[3,10-12]	
Number of participants symptomatic after 7 days of treatment	563 per 1000	373 per 1000 (143 to 508)	OR 0.45 (0.2 to 1.0)	476 (5 studies[13])	++OO very low[14-16]	
School absence (number of days)	The mean days of school absence ranged across control	The mean days of school absence in the intervention groups was 0.37		394 (2 studies[9])	+OO very low[10,17,18]	

Open in a separate window

[1]No serious study limitations: all the studies had adequately concealed allocation and blinded both participants and study staff to be considered at low risk of bias. Whether free of other bias was unclear in Macknin 1998; Petrus 1998; Turner 2000a; Turner 2000b; Turner 2000c. Petrus 1998 did not adequately describe the sequence generation. Blinding was inadequate in Turner 2000a; Turner 2000b; Turner 2000c.

[2]Serious inconsistency: there was high statistical heterogeneity. I^2 statistic = 89%. The heterogeneity was due to differences in the nature of the different interventions (zinc gluconate versus acetate lozenges, zinc lozenges versus zinc syrup), wide dose ranges, varied duration of symptoms prior to administration of zinc (varying from 24 to 48 hours) and characteristics of the study population (children versus adults).

[3]No serious indirectness: studies both from low-income and high-income regions have assessed this comparison. Therefore, the result can be confidently generalised to all situations.

FOI 26-3132 - Document 5

[4]No serious imprecision: though the 95% CI around the pooled effect is narrow, the lower limit does not suggest a clinically important reduction in the duration of cold (a decrease in duration of ≤ 1 day is not shown to be important to patients).

[5]Publication bias cannot be ruled out.

[6]No serious study limitation: all the studies had adequately concealed allocation and blinded both participants and study staff to be considered at low risk of bias. Whether free of other bias was unclear and adequate sequence was not generated in one study (Petrus 1998).

[7]Serious imprecision: the 95% CI around the pooled effect is wide, the lower limit is crossing the point of no effect.

[8]Serious inconsistency: there was high statistical heterogeneity. I^2 statistic = 84%. The heterogeneity may be due to differences in the nature of the different interventions (zinc gluconate or acetate lozenges, zinc sulphate syrup) and dose range (30 to 160 mg/day) as well as mean duration of symptoms prior to administration of zinc (varying from 24 to 48 hours), as well as the characteristics of the study population (children versus adults). However, subgroup analysis was not possible as there were not enough studies for each variable.

[9],Kurugol 2006b is a community-based intervention including 200 healthy school children and studying the effect of daily administration of 15 mg zinc sulphate syrup over a period of seven months. Vakili 2009 is also a community-based intervention including 200 healthy school children and studying the effect of daily administration of 10 mg zinc sulfate tablets over a period of seven months.

[10]Serious study limitation: though the study by Kurugol 2006b was of high quality, that by Vakili 2009 was of poor methodological quality.

[11]Serious inconsistency: there is substantial heterogeneity between the two trials: I^2 statistic for heterogeneity = 88%. Both trials showed a benefit with zinc, however the size of this effect was much larger in Vakili 2009. The heterogeneity was due to differences in the trial methodology and the nature of the interventions.

[12]No serious imprecision: the 95% CI around the pooled effect is narrow. Even the lower limit suggests a clinically important reduction in the incidence rate ratio of cold which is shown to be important to patients.

[13]No serious study limitations: allocation concealment was unclear in two studies, i.e. Smith 1989 and Weismann 1990, though both the studies blinded both participants and study staff.

[14]Serious inconsistency: there was high statistical heterogeneity. I^2 statistic = 75%. The heterogeneity may be due to differences in the nature of the different interventions (zinc gluconate or acetate lozenges) and dose range (30 to 160 mg/day) as well as mean duration of symptoms prior to administration of zinc (varying from 24 to 48 hours, as well as the characteristics of the study population (children versus adults). However, subgroup analysis was not possible as there were not enough studies for each variable.

[15]Serious indirectness: only studies from high-income regions have assessed this comparison. Therefore, the result cannot be generalised to all situations.

[16]No serious imprecision: both limits of the 95% CI suggest a clinically important reduction in proportion of participants given the intervention symptomatic after seven days of treatment.

[17]Serious inconsistency: there is substantial heterogeneity between the two trials: I^2 statistic test for heterogeneity = 64%. Both trials showed reduced days of school absence with intervention, however, the size of this effect was much larger in Kurugol 2006b. The heterogeneity was due to differences in the trial methodology and the nature of the interventions.

[18]No serious imprecision: though the 95% CI around the pooled effect is narrow, the lower limit does not suggests a clinically important reduction in the duration of school absence (a decrease in duration of ≤ 1 day is not shown to be important to patients).

[19]No serious inconsistency: there was no statistical heterogeneity. I^2 statistic = 0%.

[20]No serious imprecision: both limits of the 95% CI suggest a clinically important reduction in the rate of antibiotic use with intervention.

[21]No serious study limitations: all the studies had adequately concealed allocation (except Weismann 1990, in which allocation concealment is unclear) and blinded both participants and study staff to be considered at low risk of bias. Whether free of other bias was unclear in Macknin 1998 and Weismann 1990. Weismann 1990 did not adequately describe the sequence generation.

[22]No serious inconsistency: there is no statistical heterogeneity. I^2 statistic = 21%. Both the lozenges and syrup preparation trials were pooled.

[23]No serious imprecision: the 95% CI around the pooled effect is narrow. The resulting adverse events from use of zinc are higher and this is significant.

FOI 26-3132 - Document 5

Background

Description of the condition

The common cold is one of the most widespread illnesses, with adults having two to four episodes annually (Garibaldi 1985). Children may have six to 10 colds a year (and up to 12 colds a year for school children) (Simasek 2007). In the United States, the common cold leads to 75 to 100 million physician visits annually at a conservative cost estimate of USD 7.7 billion per year. Americans spend USD 2.9 billion on over-the-counter drugs and another USD 400 million on prescription medicines for symptomatic relief (Garibaldi 1985; Simasek 2007). More than one-third of patients who saw a doctor received an antibiotic prescription, which has implications for antibiotic resistance from overuse of such drugs (Fendrick 2003). An estimated 22 to 189 million school days are missed annually due to a cold. As a result, parents missed 126 million workdays to stay home to care for their children. When added to the 150 million work days missed by employees suffering from a cold, the total economic impact of cold-related work loss exceeds USD 20 billion per year (Fendrick 2003; Garibaldi 1985). This accounts for 40% of time lost from work (Kirkpatrick 1996). The complications of the common cold include otitis media, sinusitis and exacerbations of reactive airway diseases (Couch 1984; Gwaltney 1966; Turner 2001). Rhinoviruses are the most frequent cause and may account for nearly 80% of common colds during autumn (Turner 2001). There is no proven treatment for the common cold. However, even a medication that is only partially effective in the treatment and prevention of the common cold could markedly reduce morbidity and economic losses due to this illness.

Description of the intervention

The effect of zinc lozenges on the incidence, duration or severity of common cold symptoms has been examined in different studies since 1984. In 1984, Eby et al (Eby 1984) reported for the first time on the efficacy of zinc gluconate lozenges for treatment of the common cold. However, later trials have given variable results. It has been hypothesised that there is a direct correlation between reductions in the duration of common cold symptoms and the daily dosage of all positively charged zinc species released from lozenges at physiologic pH (Eby 1995). The re-analysis of 10 double-blind, placebo-controlled zinc trials by solution chemistry methods showed a significant correlation between total daily dosages of positively charged zinc species and a reduction in the mean duration of common colds (Eby 2004). Zinc gluconate and zinc acetate have very low chemical stability and mainly release positively charged zinc ions in aqueous solutions at physiologic pH, but stronger complexes do not (Eby 2004). Adding a strong zinc binding ligand, such as glycine or citric acid, to a solution containing a zinc complex that is weakly bonded results in the sequestration of zinc to the stronger ligand, reducing or eliminating the benefits of zinc lozenges (Eby 2004). In the review by Marshall it was concluded that zinc gluconate lozenges were effective in reducing the symptoms and duration of the common cold but the side effects and particularly bad taste might limit patient compliance (Marshall 1998). However, results from three trials (Kurugol 2006a; Kurugol 2006b; Kurugol 2007) using zinc sulfate syrup and one trial using zinc sulfate tablet (Vakili 2009) suggested that both the syrup and tablet form are well tolerated and an easy to administer therapy. Adverse effects were mild and had no significant association with the use of zinc sulfate syrup or tablet. The increased incidence of adverse effects noted in the zinc group in various trials may have been related to the use of different ligands (gluconate, acetate) rather than to zinc itself.

How the intervention might work

Interest in the use of zinc for the common cold grew following the results of a randomised controlled trial (RCT) conducted by Eby 1984. Results suggested that if treatment of a cold commenced within three days of the development of cold symptoms and consisted of one 23 mg zinc lozenge dissolved in the mouth every second waking hour, the average duration of cold symptoms was reduced by about seven days. This result was consistent with the earlier observation by Eby (Eby 1984) that a three-year old girl diagnosed with acute lymphocytic leukaemia who had been treated with a 50 mg zinc tablet to improve her zinc status and to stimulate T-cell lymphocyte responsiveness recovered from a cold

FOI 26-3132 - Document 5

within several hours of receiving treatment. In addition, this effect was claimed to be reproducible in other children and adults. Later trials gave inconclusive results (Turner 2001). Results of trials in which no effect of zinc was demonstrated were criticised for having inadequate sample sizes or formulations that reduced the release of zinc ions from the lozenge (Eby 1995).

In-vitro assays indicate that zinc possesses antiviral properties (concentrations of 0.1 mM zinc inhibited growth of eight of nine strains of rhinoviruses) and although such activity suggests Eby's results are biologically plausible, only a handful of RCTs have been able to duplicate his findings. Of the 18 trials conducted since 1984, 11 trials have shown zinc may be useful in the treatment of the common cold and seven have shown no benefit. Most trials showing beneficial effects have been criticised for failing to mask treatment adequately due to the occurrence of side effects, while trials showing no benefit have been criticised for using formulations that reduced the bioavailability of zinc.

Although several possibilities have been suggested, the mechanisms of the efficacy of zinc on the common cold are still unexplained. One possibility is that the interaction of zinc with the host's immune function may have a beneficial effect on common cold symptoms (Macknin 1999). Besides this there is a local mechanism of action: the mouth–nose biologically closed electric circuit (BCEC) which appears to explain the rapid therapeutic response to zinc lozenges (Eby 2010). It moves electrons from the nose into the mouth and, in response to the electron flow, it moves positively charged metal ions, such as ionic zinc, from the mouth into the nose. Human rhinoviruses attaching to the nasal epithelium via the intracellular adhesion molecule-1 (ICAM-1) receptor cause most colds. The zinc ion, based on its electrical charge, has an affinity for ICAM-1 receptor sites and may exert an antiviral effect by attaching to the ICAM-1 receptors in the rhinovirus structure and nasal epithelial cells (Novick 1996). In addition, zinc inhibits viral replication by preventing the formation of viral capsid proteins (Geist 1987; Korant 1976). It has also been suggested that zinc stabilises cell membranes (Pasternak 1987), prevents histamine release (Harisch 1987) and inhibits prostaglandin metabolism (Kelly 1983).

Why it is important to do this review

There is no proven method of prevention or treatment for the common cold. However, any medication that is only partially effective in the treatment and prevention of the common cold could markedly reduce morbidity and economic losses due to this illness. There have been many clinical trials describing the effect of zinc (lozenges and syrup) on common cold symptoms; therefore it is important to know the effect of zinc on the common cold. The last review of all available RCTs of zinc for the common cold was published in 1999. Since then, several new studies (Eby 2006; Kartasurya 2012; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; McElroy 2003; Petrus 1998; Prasad 2000; Prasad 2008; Turner 2000a; Turner 2000b; Turner 2000c; Vakili 2009; Veverka 2009) have been published. It is therefore important to update the information and include all new clinical trials. We undertook the review to assess the overall effectiveness of zinc (lozenges or syrup) in treating the common cold and to provide some guidance with respect to future research.

Objectives

To assess whether zinc (irrespective of the zinc salt or formulation used) is efficacious in reducing the incidence, severity and duration of common cold symptoms. In addition, we aimed to identify potential sources of heterogeneity in results obtained and to assess their clinical significance.

Methods

Criteria for considering studies for this review

Types of studies Double-blind, placebo-controlled randomised controlled trials (RCTs).

Types of participants Trial participants were of either gender and of any age.

Types of interventions Therapeutic trials: interventions commenced within three days of participants developing common cold symptoms and consisted of 1.5 to 2-hourly treatments with a zinc or placebo lozenge during waking hours, for more than six hours a day for a period of five or more consecutive

days.

Prophylactic trials: intervention commenced and continued throughout the cold season for at least five months.

We considered all formulations of zinc (irrespective of the type of salt, formulation and concentration of zinc).

Types of outcome measures Outcome measures frequently used to determine the clinical efficacy of any common cold treatment are the incidence, severity and duration of cold symptoms. Accordingly, for inclusion in this review, the incidence and severity of at least throat and nasal symptoms and cough needed to be assessed.

Primary outcomes

1. Duration of symptoms.
2. Severity of symptoms.
3. Incidence of the common cold.

Secondary outcomes

1. Proportion of participants symptomatic after three, five or seven days of treatment.
2. Time to resolution of individual symptoms: cough, nasal congestion, nasal drainage and sore throat.
3. Change in individual severity symptom scores: cough, nasal score.
4. School absence (days).
5. Antibiotic use.
6. Adverse events.

We defined duration as the number of days to cold resolution from start of treatment. We considered cold resolution to be the resolution of all cold symptoms or resolution of all but one cold symptom, or the participant believed they had recovered from the cold. Severity of cold symptoms needed to be graded: 0 - no symptoms, 1 - mild symptoms, 2 - moderate symptoms and 3 - severe symptoms. We defined incidence as number of colds per study participant during the study period. Adverse events included any or individual adverse events during or after taking the medications.

Search methods for identification of studies

Electronic searches For this 2013 review update we updated the searches in CENTRAL, MEDLINE and EMBASE and in addition searched CINAHL, Web of Science and LILACS.

We searched the Cochrane Central Register of Controlled Trials (CENTRAL) 2012, Issue 12, part of *The Cochrane Library*, www.thecochranelibrary.com (accessed 18 January 2013), which contains the Acute Respiratory Infections Group's Specialised Register, MEDLINE (April 2010 to January week 2, 2013), EMBASE (1974 to January 2013), CINAHL (1981 to January 2013), Web of Science (1985 to January 2013) and LILACS (1982 to January 2013). See details of search strategy in Appendix 1. Details of the previous search strategy are in Appendix 2.

Searching other resources We searched the US National Institutes of Health, Department of Health and Human Services trials registry www.clinicaltrials.gov and the WHO ICTRP trials registry http://www.who.int/ictrp/en/ (18 June 2012). We also searched bibliographies of published papers for unpublished trials. Two review authors (RRD, MS) assessed the studies to ensure appropriate trials were included in the review and to minimise the potential for selection bias.

Data collection and analysis

FOI 26-3132 - Document 5

More information on the statistical methods used in this review can be found in the relevant section of the Cochrane Acute Respiratory Infections Review Group Module. Comparisons were zinc (lozenges or syrup or tablet) with placebo. We compared outcome measures before and after treatment, as well as after day three, five or seven to accommodate trials of different lengths.

Selection of studies Two review authors (RRD, MS) independently reviewed the results for inclusion in the analysis. We resolved differences regarding study quality through discussion.

Data extraction and management We recorded data on a pre-structured data extraction form. The lead review author (MS) entered data directly into Review Manager (RevMan) (RevMan 2012). An independent coder verified accuracy of data entry. We made no attempt to contact investigators. Most trials were conducted over 10 years ago and in view of the information required to be provided by the investigators, we thought that they would be unable to comply.

Assessment of risk of bias in included studies We assessed risk of bias in all included studies using The Cochrane Collaboration's 'Risk of bias' methodology (Higgins 2011). Two review authors (RRD, MS) assessed selection bias (random sequence generation, allocation concealment), performance bias (blinding of participants and personnel), detection bias (blinding of outcome assessment), attrition bias (incomplete outcome data), reporting bias (selective reporting) and other biases, if any. Each item was assessed as high, low or unclear risk of bias along with relevant information reported in the RCT. When the methodological description was unambiguous, one review author entered the methodological description in the 'Risk of bias' table. When the description of methods was ambiguous, the same review author discussed the issue with the co-author to reach a consensus. The methodological descriptions are summarised in Figure 1 and Figure 2.

FOI 26-3132 - Document 5

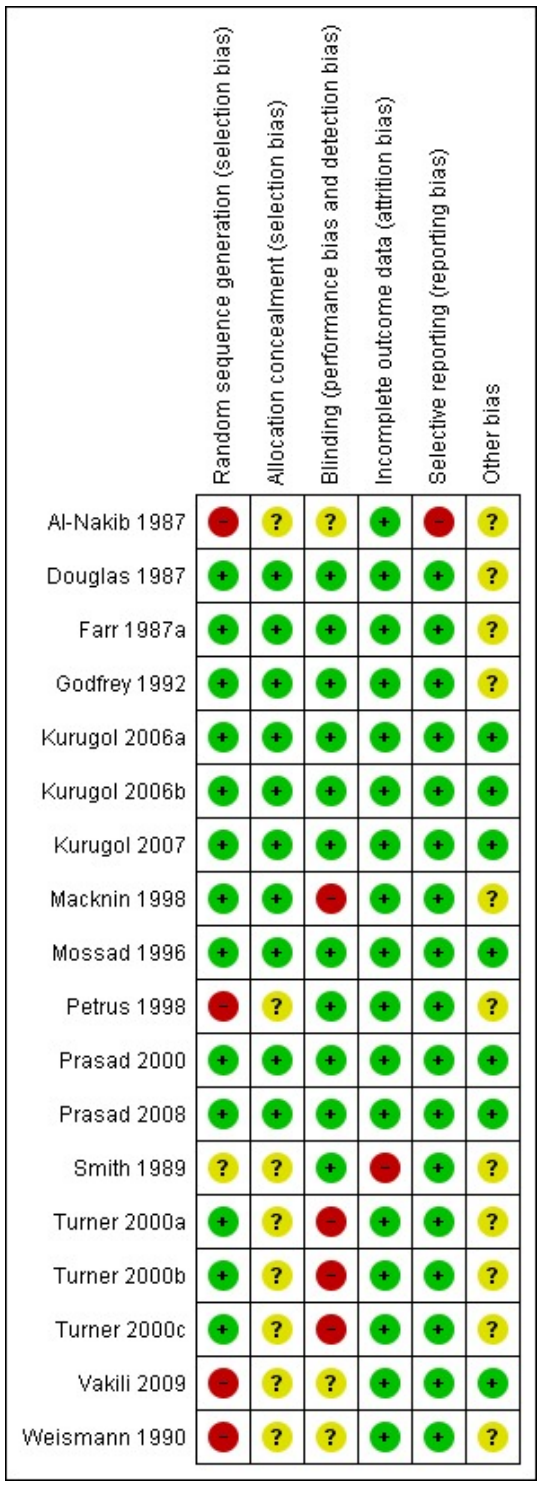

Figure 1

Methodological quality summary: review authors' judgements about each methodological quality item for each included study.

FOI 26-3132 - Document 5

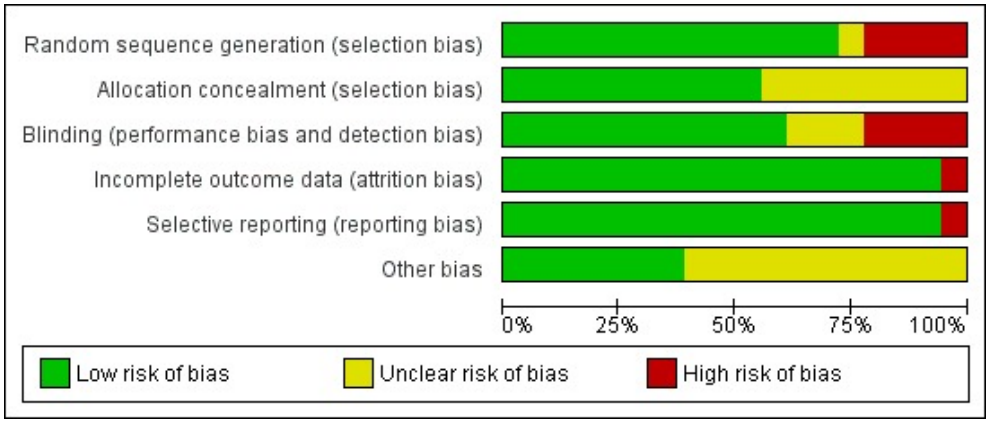

Figure 2

Methodological quality graph: review authors' judgements about each methodological quality item presented as percentages across all included studies.

Measures of treatment effect We extracted outcome data and entered data into RevMan 2012 for statistical analysis. We used the standard methods of the Cochrane Acute Respiratory Infections (ARI) Review Group to synthesise the data. For dichotomous data, we calculated a pooled estimate of the treatment effect for each outcome across trials using the odds ratio (OR). But, for the measurement of incidence of common cold, the incident rate ratio (IRR) was calculated and expressed as RR to match it with the IRR. For continuous outcomes, we recorded both mean post-treatment or post-intervention values and standard deviation (SD). If standard errors (SE) had been reported (and if it were possible) we planned to convert these to standard deviations. We calculated a pooled estimate of treatment effect by calculating either the mean difference (MD) or standardised mean difference (SMD). For both dichotomous and continuous outcomes, we calculated the 95% confidence interval (95% CI) for individual studies. We used fixed-effect models to obtain summary statistics of all types of outcome measures when there was low degree of heterogeneity. When significant heterogeneity was found, we calculated the overall efficacy using random-effects models, which provided more realistic estimates of the CIs under these circumstances (Lau 1997). In this context, a P value < 0.05 indicated significant differences between studies and raised questions as to whether the results could be meaningfully combined. Where it was not possible to perform a meta-analysis, we summarised the data for each trial.

Unit of analysis issues We included only randomised, double-blind, placebo-controlled trials in this review. None of the trials were cross-over or cluster-randomised trials.

Dealing with missing data As many trials were conducted 10 years ago, we thought that the investigators would be unable to compile the missing data, so we did not contact them. For all the outcomes, we considered that incomplete outcome data had been adequately addressed if 80% or more of the participants were included in the analysis, or if less than 80% were included but adequate steps were taken to ensure or demonstrate that this did not bias the results. We performed intention-to-treat (ITT) analysis where the above was not clear. In trials with missing statistics (such as SDs or correlation coefficients), we calculated the data from the available information.

Assessment of heterogeneity We assessed the degree of heterogeneity by using the Chi^2 test and the I^2 statistic (Higgins 2003; Higgins 2011). The Chi^2 test is known to be poor at detecting true heterogeneity among studies; while a statistically significant result indicates heterogeneity, a non-significant result is not evidence of no heterogeneity. The I^2 statistic describes the percentage of total variation across studies that is due to heterogeneity rather than chance. The values of the I^2 statistic lie between 0% and 100%. For the current meta-analysis, we used a simplified categorisation of the I^2 statistic as follows: if significant heterogeneity (I^2 statistic > 50%) was found, we used a random-effects model and if low heterogeneity (I^2 statistic < 50%) was found, we used a fixed-effect model.

FOI 26-3132 - Document 5

Assessment of reporting biases We sought further information from trial authors, although this was not possible for the current meta-analysis as many of the studies were very old. We looked hard for evidence of collection by study investigators of a small number of key outcomes that are routinely measured in the area in question, and reported which studies reported data on these and which did not. We also constructed a matrix indicating which outcomes were recorded in which studies (for example, with rows as studies and columns as outcomes). Complete and incomplete reporting was also indicated. This matrix showed us which studies did not report outcomes reported by most other studies. We assessed risk of bias due to selective reporting of outcomes for the study as a whole as well for each outcome. We also assessed the likelihood of small study effects, such as publication bias, by examining the funnel plot for asymmetry (Egger 1997).

Data synthesis We analysed data using a fixed-effect model in cases of low heterogeneity (I^2 statistic value of < 50%) and a random-effects model in cases of moderate to high heterogeneity between studies (I^2 statistic value of > 50%).

Subgroup analysis and investigation of heterogeneity We considered the following factors as possible explanations for the heterogeneity observed across the results of these studies: dosage and formulations of zinc used, age of participants (children and adults) and the mean duration of symptoms prior to administration of zinc. We plan to investigate these with subgroup analyses when there are sufficient included studies.

Sensitivity analysis We had planned to perform sensitivity analyses based on methodological quality of the trials (with and without quasi-randomised trials), but this was not possible as all were randomised, double-blind, placebo-controlled trials.

Results

Description of studies

Results of the search We retrieved 77 additional studies (MEDLINE = 16, CENTRAL = 11, CINAHL = 41, Web of Science = 77, EMBASE = 15 and LILACS = 4) after removing duplicates in the new searches conducted between June 2010 and January 2013. Two review authors (RRD, MS) screened the new search results. Out of 77 new searches, one trial was screened for potential eligibility after reading the abstract. However, this trial (Kartasurya 2012) did not meet the inclusion criteria and was later excluded.

Included studies We included three additional trials (Turner 2000a; Turner 2000b; Turner 2000c) that were previously excluded, based on unclear methodology. Besides this, no new trials contributed to the data synthesis in this updated review. We included 18 trials (1387 participants in the therapeutic trials and 394 in the preventive trials) in this review.

Location Three trials were conducted in Turkey (Kurugol 2006a; Kurugol 2006b; Kurugol 2007); one trial each in Iran (Vakili 2009), Denmark (Weismann 1990), UK (Al-Nakib 1987) and Australia (Douglas 1987); and 11 trials in the USA (Farr 1987a; Godfrey 1992; Macknin 1998; Mossad 1996; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c).

Participants All the trial participants included in the analysis were both adults and children with age range varying from one to 65 years at the start of the trials. Five trials included children only and among these three trials included children aged one to 10 years (Kurugol 2006a; Kurugol 2006b; Kurugol 2007); one included children and adolescents aged six to 16 years (Macknin 1998) and another included children aged 6.5 to 10 years (Vakili 2009). Two trials recruited participants from volunteers experimentally inoculated with human rhinovirus (Al-Nakib 1987; Farr 1987a). Given that not all participants had cold symptoms at the beginning of the intervention in one trial (Farr 1987a), this trial would be excluded from the statistical overview. In one trial neither the health status of the participants nor the exclusion criteria were stated, while in other trials only healthy subjects from the general population were included. In one trial, participants with cold durations of more than 24 hours (Macknin 1998) and in another trial participants with cold durations of more than 48 hours (Kurugol 2007) were excluded. The trials varied widely in size; two trials had fewer than 50 participants (Prasad 2000;

FOI 26-3132 - Document 5

Prasad 2008), four had more than 50 but fewer than 100 participants (Douglas 1987; Farr 1987a; Godfrey 1992; Mossad 1996), eight had more than 100 but fewer than 200 participants (Al-Nakib 1987; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Petrus 1998; Smith 1989; Weismann 1990; Vakili 2009) and four had more than 200 participants (Macknin 1998; Turner 2000a; Turner 2000b; Turner 2000c).

Interventions Zinc supplements were provided in the form of either syrup, lozenges or tablets. One trial used zinc sulfate tablet (Vakili 2009) and three trials used zinc sulphate syrup (Kurugol 2006a; Kurugol 2006b; Kurugol 2007). Among the trials using lozenge preparations, two different salts were used: zinc gluconate (Al-Nakib 1987; Farr 1987a; Godfrey 1992; Macknin 1998; Mossad 1996; Smith 1989; Weismann 1990; Turner 2000a) and zinc acetate (Douglas 1987; Petrus 1998; Prasad 2000; Prasad 2008; Turner 2000b; Turner 2000c). The supplements were given for different periods of time in all the trials. In the therapeutic trials the duration of supplement was five days (Farr 1987a), six days (Al-Nakib 1987; Douglas 1987), seven days (Farr 1987a; Godfrey 1992; Smith 1989), 10 days (Kurugol 2006a; Kurugol 2007; Weismann 1990), 14 days (Petrus 1998) and no duration mentioned (i.e. participants were given zinc as long as they were symptomatic) (Macknin 1998; Mossad 1996; Prasad 2000; Prasad 2008; Turner 2000a; Turner 2000b; Turner 2000c). In the three trials also studying the prophylactic role of zinc, the duration of supplement was 4.5 days (Al-Nakib 1987), five months (Vakili 2009) and seven months (Kurugol 2006b).

Outcomes

Primary Fourteen trials (Douglas 1987; Godfrey 1992; Kurugol 2006a; Kurugol 2007; Macknin 1998; Mossad 1996; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Weismann 1990; Turner 2000a; Turner 2000b; Turner 2000c) reported the duration of symptoms. Among these, five trials have provided the original data (Kurugol 2006a; Kurugol 2006b; Petrus 1998; Prasad 2000; Prasad 2008). The mean and SD were calculated either from the survival curves (Macknin 1998; Mossad 1996; Prasad 2000; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) or from t/P value (Douglas 1987; Godfrey 1992) reported in other trials. Thirteen trials measured the total severity score of cold symptoms (Al-Nakib 1987; Douglas 1987; Godfrey 1992; Kurugol 2006a; Kurugol 2007; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Weismann 1990; Turner 2000a; Turner 2000b; Turner 2000c) but results from only five trials (Kurugol 2006a; Kurugol 2007; Petrus 1998; Prasad 2000; Prasad 2008) could be pooled, as in eight trials (Al-Nakib 1987; Douglas 1987; Godfrey 1992; Smith 1989; Weismann 1990; Turner 2000a; Turner 2000b; Turner 2000c) the results were not reported in a standard format. The incidence of cold symptoms was measured in two trials (Kurugol 2006b; Vakili 2009).

Secondary The proportion of participants asymptomatic by day three or day five was reported in three trials (Mossad 1996; Smith 1989; Weismann 1990), whereas the proportion of participants asymptomatic by day seven was reported in five trials (Douglas 1987; Godfrey 1992; Mossad 1996; Smith 1989; Weismann 1990). In all these trials, ITT analysis was conducted. Time to resolution of individual cold symptoms was reported as follows: time to resolution of cough in four trials (Kurugol 2006a; Macknin 1998; Prasad 2000; Prasad 2008), time to resolution of nasal congestion in five trials (Kurugol 2006a; Macknin 1998; Petrus 1998; Prasad 2000; Prasad 2008), time to resolution of nasal drainage in five trials (Kurugol 2006a; Macknin 1998; Petrus 1998; Prasad 2000; Prasad 2008) and time to resolution of sore throat in four trials (Kurugol 2006a; Macknin 1998; Prasad 2000; Prasad 2008). Change in individual severity symptom score was reported as follows: change in cough symptom score in two trials (Douglas 1987; Petrus 1998), change in nasal symptom score in four trials (Douglas 1987; Kurugol 2006a; Kurugol 2007; Petrus 1998), change in throat symptom score in two trials (Douglas 1987; Petrus 1998). Standard error of mean (SEM) was not provided in one trial (Douglas 1987). Effect on school absence and antibiotic use were provided in two trials (Kurugol 2006b; Vakili 2009).

Adverse events Fourteen trials (Douglas 1987; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Mossad 1996; Prasad 2000; Prasad 2008; Smith 1989; Weismann 1990; Vakili 2009; Turner 2000a; Turner 2000b; Turner 2000c) reported adverse events. Common adverse events included bad taste, nausea, constipation, diarrhoea, abdominal pain, dry mouth and oral irritation. We reported the adverse events separately for both lozenges and syrup formulations.

FOI 26-3132 - Document 5

Other Six trials using experimentally induced colds with rhinovirus also studied the number of participants shedding the virus, duration of viral shedding, number of virus-positive days, as well as rise in antibody titre. These were not included in the outcome measures as we thought that it would not be of help in drawing conclusions. Three trials reported the effect of zinc supplementation on school absence. Among these, two (Kurugol 2006b; Vakili 2009) reported this outcome during a prophylactic trial, though another (Macknin 1998) was a therapeutic trial.

Excluded studies We excluded five trials.

1. Inclusion criteria not defined, disproportionate number of drop-outs from the zinc group (Eby 1984).
2. Two studies were not RCTs (McElroy 2003).
3. Measured upper respiratory tract infection as a whole (including common cold, seasonal influenza) (Veverka 2009).
4. Used both zinc gluconate nasal spray and zinc orotate lozenges simultaneously (Eby 2006).
5. Studies upper respiratory tract infection as a whole, used zinc supplementation for four months (Kartasurya 2012).

Risk of bias in included studies

Allocation Allocation concealment was adequate in 10 studies (Douglas 1987; Farr 1987a; Godfrey 1992; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Mossad 1996; Prasad 2000; Prasad 2008). It was unclear in seven studies (Al-Nakib 1987; Petrus 1998; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) and not described in one (Vakili 2009).

Adequate sequence generation was described in seven studies (Douglas 1987; Godfrey 1992; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Mossad 1996). However, it was not clear in seven studies (Farr 1987a; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c) and not generated in four studies (Al-Nakib 1987; Petrus 1998; Vakili 2009; Weismann 1990).

Blinding All 18 studies were blinded but placebo blinding was adequately described in 10 trials (Douglas 1987; Godfrey 1992; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Mossad 1996; Prasad 2000; Prasad 2008; Smith 1989). Zinc-treated participants also experienced higher incidences of side effects and/or complaints, and in 12 trials, zinc-treated participants complained of altered, bad or unpalatable taste which suggests that the zinc lozenges were distinct from the placebo lozenges and, in this respect, blinding may have been compromised.

Incomplete outcome data Data were fully detailed in 15 studies and in the remaining three studies (Al-Nakib 1987; Turner 2000a; Turner 2000b; Turner 2000c) details of attrition and exclusions from the analysis were unavailable.

Selective reporting Except two studies (Al-Nakib 1987; Weismann 1990), 16 studies scored 'yes' for being free from selective reporting.

Other potential sources of bias Eleven studies were funded by pharmaceutical companies (Al-Nakib 1987; Douglas 1987; Godfrey 1992; Farr 1987a; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Petrus 1998; Smith 1989; Weismann 1990). Five studies were supported Medical Research Foundation (Godfrey 1992; Mossad 1996; Prasad 2000; Prasad 2008; Vakili 2009) and in addition by National Institute of Health (NIH) (Prasad 2008). Information on clearance by Ethics Committees or Institutional Review Boards was available for all except one study (Smith 1989). In three studies, other sources of bias were not clear (Turner 2000a; Turner 2000b; Turner 2000c).

Effects of interventions

See: Table 1

1. Primary outcomes

(i) Therapeutic effects of zinc

FOI 26-3132 - Document 5

Duration of cold symptoms Fourteen studies (Godfrey 1992; Kurugol 2006a; Kurugol 2007; Macknin 1998; Mossad 1996; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) reported this outcome. Results could be pooled from all the studies and there were 1656 participants including both children and adults (Figure 3; Analysis 1.1). The studies were heterogenous in terms of variable formulations (zinc gluconate or acetate lozenges, zinc sulphate syrup) and dose range (30 mg/day to 160 mg/day) as well as MD of symptoms prior to administration of zinc (varying from 24 to 48 hours). Intake of zinc lozenges or syrup was associated with a significant reduction in the duration (days) of common cold (mean difference (MD) -1.03, 95% confidence interval (CI) -1.72 to -0.34) (P = 0.003) when it was administered within 24 hours of the onset of symptoms. However, there was marked heterogeneity among the included trials. We did subgroup analysis for the following: dose (≥ 75 mg/day versus < 75 mg/day), types of lozenges (gluconate versus acetate), formulation (lozenges versus syrup) and age group (children < 16 years versus adults) (Figure 4; Analysis 1.2).

Comparison 1 Zinc versus placebo, Outcome 1 Duration of cold symptoms.

FOI 26-3132 - Document 5

Analysis 1.2

Comparison 1 Zinc versus placebo, Outcome 2 Subgroup analysis (duration of cold symptoms).

Seven trials (Godfrey 1992; Mossad 1996; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a) used zinc lozenges at a dose of ≥ 75 mg/day, and five trials (Douglas 1987; Macknin 1998; Turner 2000b; Turner 2000c; Weismann 1990) used a dose of < 75 mg/day. Pooled results from the trials using ≥ 75 mg/day of zinc showed a significant reduction in the duration (days) of common cold (MD -1.97, 95% CI -3.09 to -0.85) (P = 0.0006), whereas < 75 mg/day of zinc did not (MD 0.13, 95% CI -0.54 to 0.79) (P = 0.71). However, there was marked heterogeneity among the trials using ≥ 75 mg/day of zinc lozenges. Five trials (Godfrey 1992; Mossad 1996; Macknin 1998; Smith 1989; Turner

FOI 26-3132 - Document 5

2000a) used zinc gluconate lozenges, and six trials (Douglas 1987; Petrus 1998; Prasad 2000; Prasad 2008; Turner 2000b; Turner 2000c) used zinc acetate lozenges. Pooled result from the trials using either zinc gluconate (MD -0.81, 95% CI -1.86 to 0.25) (P = 0.14) or acetate lozenges (MD -1.21, 95% CI -2.69 to 0.28) (P = 0.11) did not show a reduction in the duration (days) of common cold. Again, there was marked heterogeneity among the trials. Twelve trials (Douglas 1987; Godfrey 1992; Mossad 1996; Macknin 1998; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) used zinc lozenges, and two trials (Kurugol 2006a; Kurugol 2007) used zinc syrup formulations. Pooled result from the trials using either zinc lozenges (MD -1.04, 95% CI -2.02 to -0.05) (P = 0.04) or syrup formulations (MD -0.65, 95% CI -0.92 to -0.39) (P < 0.00001) showed a significant reduction in the duration (days) of common cold. There was marked heterogeneity among the trials using lozenges formulations. Eleven trials (Douglas 1987; Godfrey 1992; Mossad 1996; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) studied the effect in adults, and three trials (Kurugol 2006a; Kurugol 2007; Macknin 1998) in children < 16 years age. Pooled results from the trials on adults (MD -1.12, 95% CI -2.17 to -0.06) (P = 0.04) or children (MD -0.62, 95% CI -0.82 to -0.42) (P < 0.00001) showed a significant reduction in the duration (days) of common cold. However, there was marked heterogeneity among the trials involving adult participants.

Severity of cold symptoms Thirteen studies measured the mean severity score of cold symptoms (Al-Nakib 1987; Douglas 1987; Godfrey 1992; Kurugol 2006a; Kurugol 2007; Petrus 1998; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990). Results from five studies (Kurugol 2006a; Kurugol 2007; Petrus 1998; Prasad 2000; Prasad 2008) including a total of 513 participants (Analysis 1.3; Figure 5) could be pooled. The difference was not significant between the intervention and control groups for reduction in the severity of cold symptoms (MD -1.06, 95% CI -2.36 to 0.23) (P = 0.11). In all but two studies, the intervention started within 24 hours of onset of symptoms. In the studies by Douglas 1987 and Kurugol 2007 the intervention started within 24 to 48 hours after the onset of symptoms. In the study by Godfrey 1992 the authors found a significant decrease in the severity of symptoms when treatment was administered within 24 hours, compared to treatment administration within 48 hours. In the trial by Al-Nakib 1987, the zinc group had a significantly lower mean daily clinical score than the placebo group; the difference in scores attaining statistical significance by day four and day five of treatment. However, in the study conducted by Douglas 1987, there were no significant differences between the two groups. Five studies (Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) reported summed severity scores which could not be pooled. One study (Smith 1989) found a reduction in summed severity score in the zinc group, whereas others (Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) did not. Again the dosages, formulations and time of administration of zinc differed among the studies. As insufficient data were available, we could only carry out subgroup analysis for lozenges versus syrup formulation (Analysis 1.4). Three trials (Petrus 1998; Prasad 2000; Prasad 2008) used lozenges and two trials (Kurugol 2006a; Kurugol 2007) used syrup formulations. Pooled results from the trials using either lozenges (MD -1.55, 95% CI -3.62 to 0.52) (P = 0.14) or syrup formulations (MD -0.27, 95% CI -1.51 to 0.97) (P = 0.67) did not show a reduction in the duration of the common cold. There was marked heterogeneity among the trials using the lozenge formulation.

(ii) Prophylactic effects of zinc

Incidence of common cold This was reported in two studies (Kurugol 2006b; Vakili 2009). The two studies used variable dose, formulation and duration of zinc. The follow-up periods of the two studies were different, therefore we based the calculation of the incidence rates on person-years. The person-time incidence rate is an appropriate measure of incidence when follow-up times are unequal (Rothman 1988). Incidence density is defined as the number of incident cases occurring in a susceptible population followed over a given time period; its units are therefore expressed as the number of cases per unit of person-time. The incidence density ratio is defined as the ratio of incidence density of an exposed group to that of an unexposed group. For each study, we calculated the incident rate ratio (IRR) of catching a cold in treated participants compared to the risk in control participants (Analysis 1.5; Figure 6). The IRR of developing a cold in subjects who received the intervention was 0.64 (95% CI 0.47 to 0.88), compared to participants in the control group (P = 0.006).

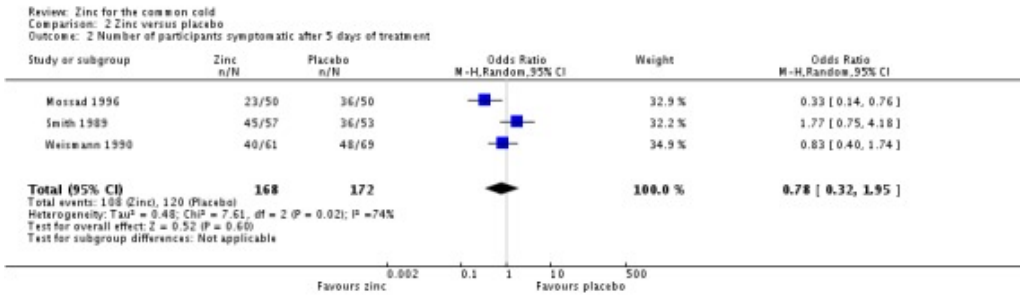
2. Secondary outcomes

(i) Therapeutic effects of zinc

Proportion of participants symptomatic after three, five or seven days of treatment

Proportion of participants symptomatic after three days of treatment Three studies (Mossad 1996; Smith 1989; Weismann 1990) included a total of 340 participants. There was no significant difference between the intervention and control group for the proportion of participants symptomatic after day three of treatment (odds ratio (OR) 0.81, 95% CI 0.27 to 2.42) (P = 0.7) (Analysis 2.1).

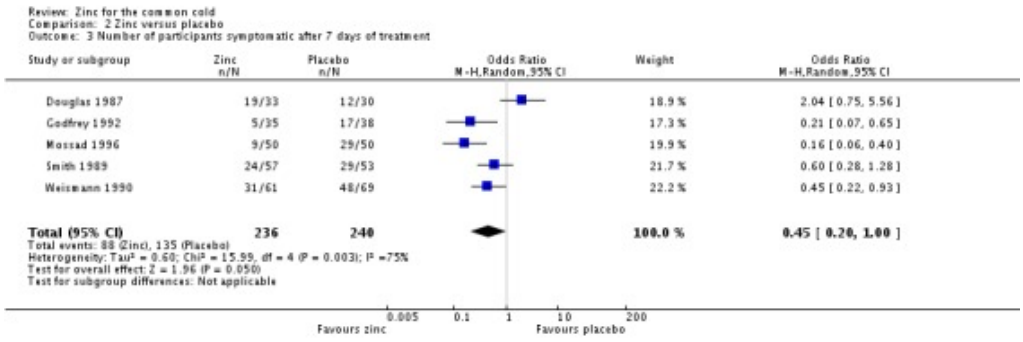


Analysis 2.1

Comparison 2 Zinc versus placebo, Outcome 1 Number of participants symptomatic after 3 days of treatment.

Proportion of participants symptomatic after five days of treatment

FOI 26-3132 - Document 5

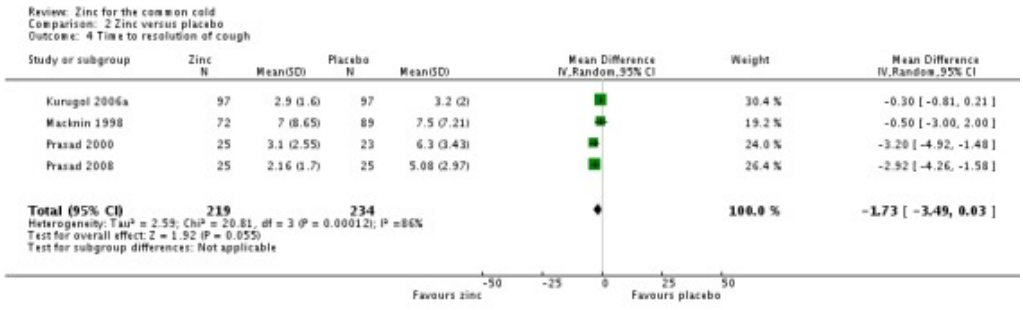


Three studies (Mossad 1996; Smith 1989; Weismann 1990) included a total of 340 participants. There was no significant difference between the intervention and control group for proportion of participants symptomatic after day five of treatment (OR 0.78, 95% CI 0.32 to 1.95) (P = 0.6) (Analysis 2.2).

Analysis 2.2

Comparison 2 Zinc versus placebo, Outcome 2 Number of participants symptomatic after 5 days of treatment.

Proportion of participants symptomatic after seven days of treatment Five studies (Douglas 1987; Godfrey 1992; Mossad 1996; Smith 1989; Weismann 1990) included a total of 476 participants. There was a significant difference between the intervention and control group for proportion of participants symptomatic after day seven of treatment (OR 0.45, 95% CI 0.20 to 1.00) (P = 0.05) (Analysis 2.3).

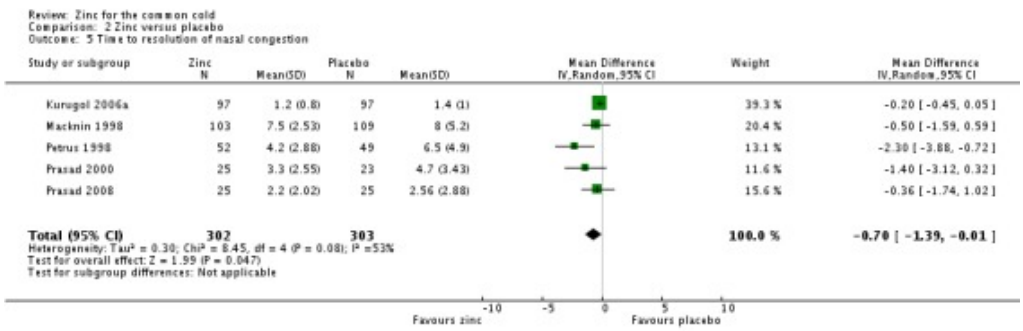


Analysis 2.3

Comparison 2 Zinc versus placebo, Outcome 3 Number of participants symptomatic after 7 days of treatment.

Time to resolution of individual cold symptoms This was reported in days in five studies.

Time to resolution of cough Four studies (Kurugol 2006a; Macknin 1998; Prasad 2000; Prasad 2008) included a total of 453 participants (intervention = 219, control = 234). The time taken for resolution of cough was significantly shorter in the intervention group (MD -1.73, 95% CI -3.49 to 0.03) (P = 0.05) (Analysis 2.4).

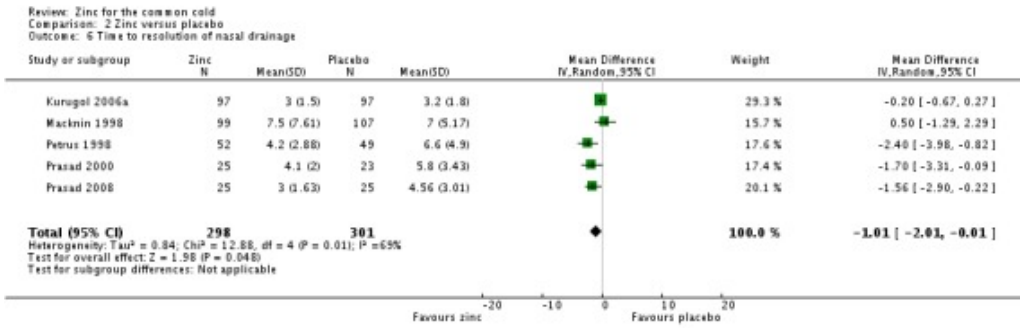


FOI 26-3132 - Document 5

Analysis 2.4

Comparison 2 Zinc versus placebo, Outcome 4 Time to resolution of cough.

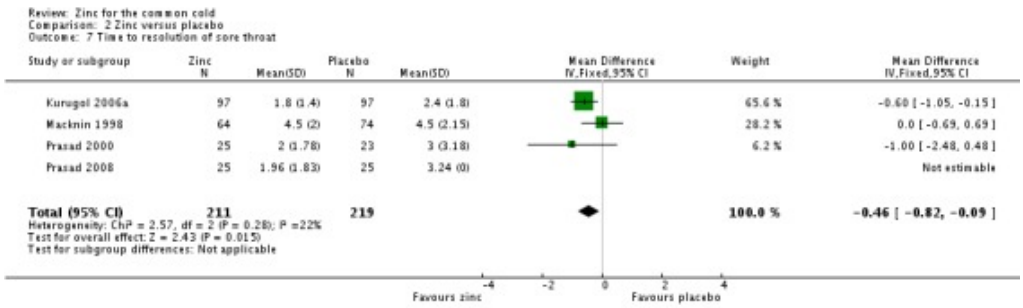
Time to resolution of nasal congestion Five studies (Kurugol 2006a; Macknin 1998; Petrus 1998; Prasad 2000; Prasad 2008) included a total of 605 participants (intervention = 302, control = 303). The time taken for resolution of nasal congestion was significantly shorter in the intervention group (MD -0.7, 95% CI -1.39 to -0.01) (P = 0.02) (Analysis 2.5).



Analysis 2.5

Comparison 2 Zinc versus placebo, Outcome 5 Time to resolution of nasal congestion.

Time to resolution of nasal drainage Five studies (Kurugol 2006a; Macknin 1998; Petrus 1998; Prasad 2000; Prasad 2008) included a total of 599 participants (intervention = 298, control = 301). The time taken for resolution of nasal drainage was significantly shorter in the intervention group (MD -1.01, 95% CI -2.01 to -0.01) (P = 0.05) (Analysis 2.6).

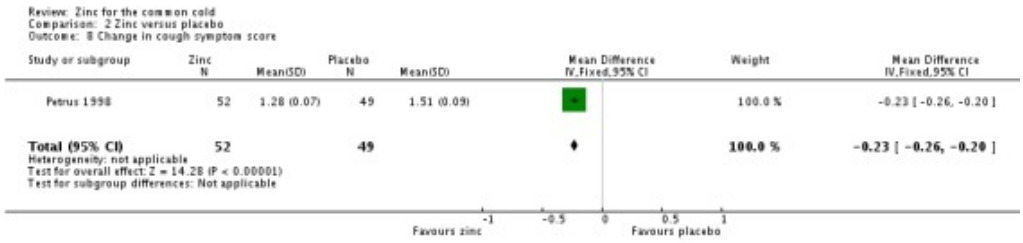


FOI 26-3132 - Document 5

Analysis 2.6

Comparison 2 Zinc versus placebo, Outcome 6 Time to resolution of nasal drainage.

Time to resolution of sore throat Four studies (Kurugol 2006a; Macknin 1998; Prasad 2000; Prasad 2008) included a total of 430 participants (intervention = 211, control = 219). The time taken for resolution of sore throat was significantly shorter in the intervention group (MD -0.46, 95% CI -0.82 to -0.09) (P = 0.02) (Analysis 2.7).

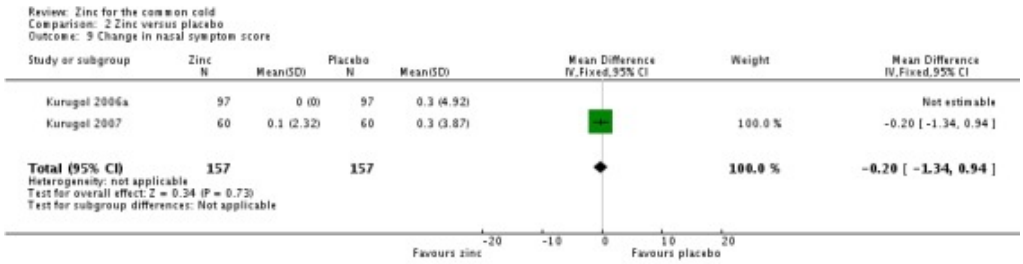


Analysis 2.7

Comparison 2 Zinc versus placebo, Outcome 7 Time to resolution of sore throat.

Change in individual severity symptom scores

Change in cough symptom score This was reported in two studies (Douglas 1987; Petrus 1998). In the study by Douglas 1987, a total of 63 treatment courses were evaluated (intervention = 33, control = 30) and the mean cough score (standard error of mean (SEM) not provided) was lower in the control group (6.3) than in the intervention group (10.6), which was not statistically significant (P = 0.2). In the study by Petrus 1998, a total of 101 participants were included and there was a significant decrease in the mean cough score in the intervention group (MD -0.23, 95% CI -0.26 to -0.2) (P < 0.00001) (Analysis 2.8).



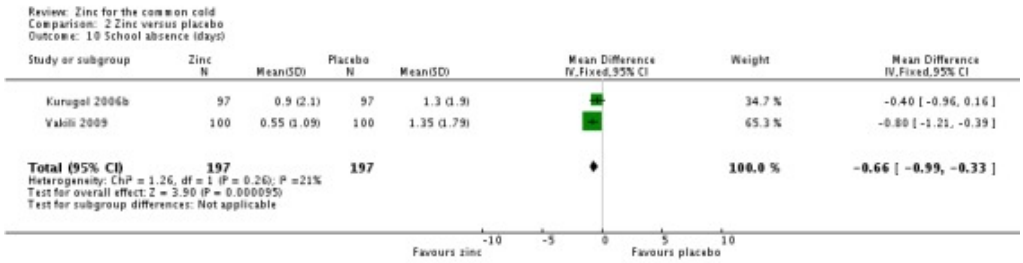
FOI 26-3132 - Document 5

Analysis 2.8

Comparison 2 Zinc versus placebo, Outcome 8 Change in cough symptom score.

Change in nasal symptom score This was reported in four studies (Douglas 1987; Kurugol 2006a; Kurugol 2007; Petrus 1998). In the study by Douglas 1987, a total of 63 treatment courses were evaluated and the mean nasal score (SEM not provided) was lower in the control group (9.8) than in the intervention group (11.7), which was not statistically significant (P = 0.5). In the study by Petrus 1998, a total of 101 participants were included and there was a decrease in the mean nasal score (not significant) in the intervention group (nasal congestion: placebo 1.43 ± 0.05, zinc 1.54 ± 0.08; nasal drainage: placebo 1.61 ± 0.07, zinc 1.45 ± 0.07). In the Kurugol 2006a and Kurugol 2007 studies a total of 314 participants were included and there was no difference between the two groups for the change in nasal symptom score (MD -0.2, 95% CI -1.34 to 0.94) (P = 0.73) (Analysis 2.9).

Analysis 2.9

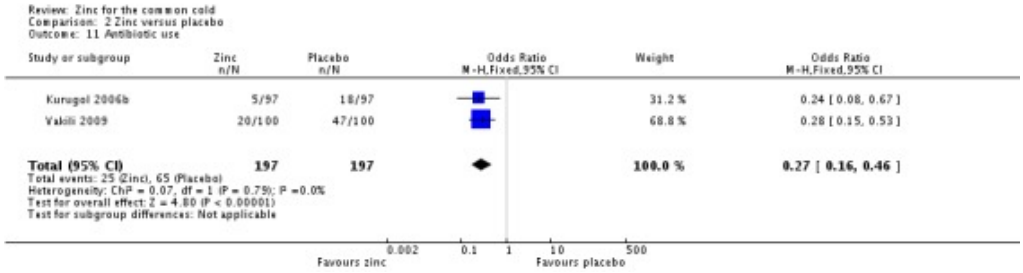


Comparison 2 Zinc versus placebo, Outcome 9 Change in nasal symptom score.

Change in throat symptom score This was reported in two studies (Douglas 1987; Petrus 1998). In one study (Douglas 1987), a total of 63 treatment courses were evaluated and the mean throat score (SEM not provided) was lower in the intervention group (6.1) than in the control group (6.2), which was not statistically significant (P = 0.96). In another study (Petrus 1998), a total of 101 participants were included and there was a decrease in the mean throat score (not significant) in the intervention group (sore throat: placebo 1.34 ± 0.11, zinc 1.26 ± 0.06; scratchy throat: placebo 1.53 ± 0.08, zinc 1.38 ± 0.1).

(ii) Prophylactic effects of zinc

School absence (days) Three trials reported this outcome. The pooled result from the two preventive trials (Kurugol 2006a; Vakili 2009) showed that zinc-supplemented children were absent for fewer days from school (MD -0.66, 95% CI -0.99 to -0.33) (P < 0.0001) (Analysis 2.10). In one of the therapeutic trials (Macknin 1998), children taking zinc were less likely to be absent than children taking placebo (OR 0.60, 95% CI 0.32 to 1.13) (P = 0.12), but the result was not significant.

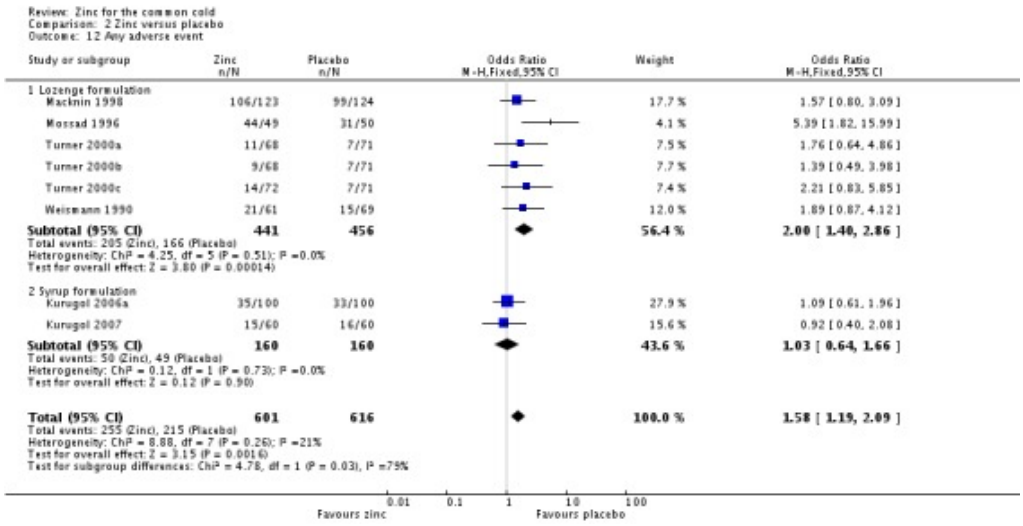


FOI 26-3132 - Document 5

Analysis 2.10

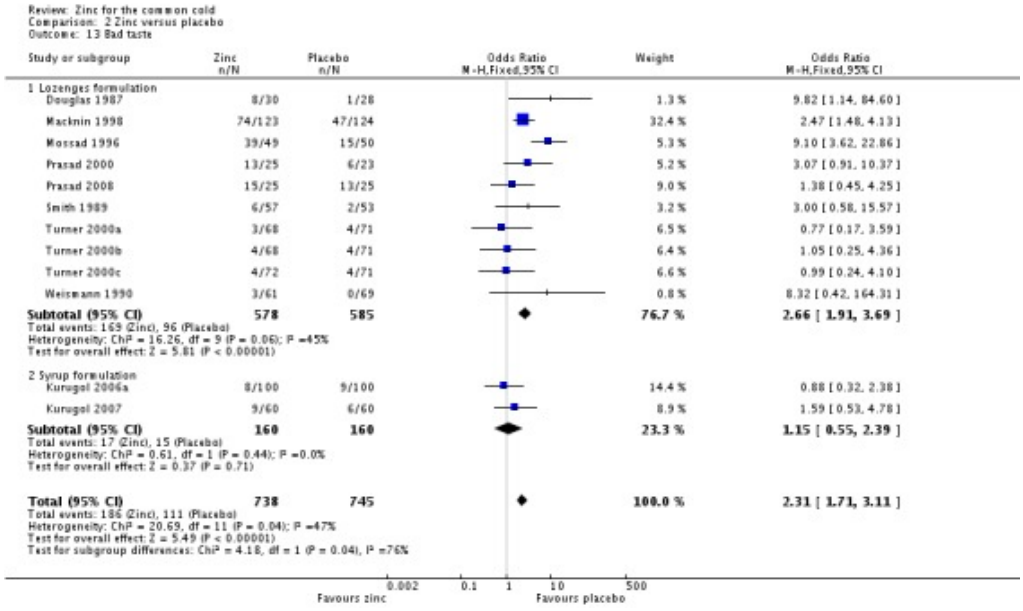
Comparison 2 Zinc versus placebo, Outcome 10 School absence (days).

Antibiotics use Two trials reported this outcome (Kurugol 2006b; Vakili 2009). The antibiotic prescription was more likely in placebo than in zinc-supplemented children (OR 0.27, 95% CI 0.16 to 0.46) (P < 0.00001) (Analysis 2.11).



Analysis 2.11

Comparison 2 Zinc versus placebo, Outcome 11 Antibiotic use.



(iii) Adverse events Thirteen trials (Douglas 1987; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Mossad 1996; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Weismann 1990) reported any or individual adverse events. The incidence of any adverse event was higher in the zinc group (OR 1.58, 95% CI 1.19 to 2.09) (P = 0.002) than in the placebo group. Among the zinc group, the lozenges formulation (OR 2.00, 95% CI 1.40 to 2.86) (P = 0.0001) was more like to produce any adverse events than the syrup formulation (OR 1.03, 95% CI 0.64 to 1.66) (P = 0.9) (Analysis 2.12). Among individual events, bad taste (OR 2.31, 95% CI 1.71 to 3.11) (P < 0.00001) (Analysis 2.13) and nausea (OR 2.15, 95% CI 1.44 to 3.23) (P = 0.002) (Analysis 2.14) had a higher incidence in the zinc group. Among the zinc group, the lozenges formulation (OR 2.66, 95% CI 1.91 to 3.69) (P < 0.00001) was more like to produce bad taste than the syrup formulation (OR 1.15, 95% CI 0.55 to 2.39) (P = 0.71). There was no significant difference between the two groups in the incidence of constipation (P = 0.17) (Analysis 2.15), diarrhoea (P = 0.08) (Analysis 2.16), abdominal pain (P = 0.25) (Analysis 2.17), dry mouth (P = 0.09) (Analysis 2.18) and oral irritation (P = 0.50) (Analysis 2.19).

(iv) Publication bias To assess whether there was a bias in the published literature, we plotted the effect size of each trial versus variance for one of the primary outcome (duration of common cold). The funnel plot generated here shows that most of the precise studies (towards the top of the plots) have effect sizes which are either zero or very close to it (Analysis 1.1). One explanation for such asymmetry might be publication bias.

Discussion

The discussion is divided into two parts: the first will discuss important methodological issues that have emerged from research in this area, and the second part will discuss the results obtained and their clinical significance.

FOI 26-3132 - Document 5

Part 1: methodology

Since Eby's trial in 1984 (Eby 1984), many trials have investigated whether zinc is efficacious in the treatment or prevention of the common cold. Among these 18 trials were included in this 2013 review. We rated the methodological quality of the included trials as good, with two trials excluded because of poor quality. Eby's trial realised a number of limitations which raised concerns regarding the validity of the results. Treatment blinding in the trial has been questioned as zinc lozenges were found to be unpalatable, distorted the taste of participants and caused a higher incidence of side effects. In addition, investigators relied solely on the subjective assessment of cold symptoms; laboratory confirmation of viral infection was not conducted and analyses were only conducted on a subgroup of those originally enrolled in the trial. Eby's trial was nevertheless instructive and highlighted a number of methodological issues.

Like Eby's trial, most trials have relied on community-acquired infections. However, five trials recruited participants from volunteers experimentally inoculated with human rhinovirus (Al-Nakib 1987; Farr 1987a; Turner 2000a; Turner 2000b; Turner 2000c). While high rates of infection with human rhinovirus were attained in the later trials and most participants experienced cold symptoms, in trials relying on community-acquired infection, the infecting agent and the infection rates were generally not determined.

In trials relying on community-acquired infection, investigators relied on trial participants or family members to assess the incidence and severity of cold symptoms. Though in most of the trials information was generally provided on how compliance with the recording of symptoms was assessed, objective periodic assessments of the clinical severity of respiratory symptoms were not conducted. In the trials conducted by Al-Nakib 1987, Farr 1987a, Macknin 1998, Kurugol 2006a, Kurugol 2006b, Kurugol 2007 and Turner 2000a, Turner 2000b and Turner 2000c, symptoms were assessed by trial personnel thus providing some assurance as to the validity of clinical severity scores and estimates based on such scores. Assessment of response to treatment also depended on objective measurements such as nasal mucus weight or tissue counts, which was measured in one study (Al-Nakib 1987) and the authors found that zinc gluconate reduced both of these parameters. However, as in most studies children were involved, this was not practical.

Research by Farr 1987b suggested that in most trials the size of the placebo-blinding study used to determine whether zinc and placebo lozenges were indistinguishable was not sufficiently large to detect a significant difference. In their efforts to find a suitable matching placebo lozenge, Farr showed that a false negative result may occur if a small subject population (i.e. fewer than 20) is used. Given that placebo-blinding studies were only conducted in six of the 18 trials, and with the exception of three trials (Farr 1987a; Prasad 2000; Prasad 2008) the size of the placebo-matching studies in two of the remaining three trials (no information was provided on the size of placebo study conducted by Weismann 1990) ranged from eight to 20, the adequacy of blinding in most trials is questioned. Zinc-treated participants also experienced higher incidences of side effects, complaints or both, and in seven trials zinc-treated participants complained of altered, bad or unpalatable taste, which suggests that zinc lozenges were distinct from placebo lozenges and, in this respect, blinding may have been compromised. However, the increased incidence of bad taste and nausea found by Mossad 1996; constipation and mouth dryness found by Prasad 2000; and bad taste, nausea, mouth, tongue or throat discomfort and diarrhoea found by Macknin 1998, may have been related to the use of different ligands (gluconate, acetate) rather than to zinc itself.

Much of the controversy surrounding the use of zinc lozenges in the treatment of the common cold has concerned whether formulations used in trials showing no benefit failed to release sufficient zinc ions to be effective. It has been hypothesised that there is a direct correlation between reductions in the duration of common cold symptoms and the daily dosage of all positively charged zinc species released from lozenges at physiologic pH (Eby 1995). The reanalysis of 10 double-blind, placebo-controlled zinc trials by solution chemistry methods showed a significant correlation between total daily dosages of positively charged zinc species and a reduction in the mean duration of common colds (Eby 2004). Zinc gluconate and zinc acetate have very low chemical stability and mainly release positively charged zinc ions in aqueous solutions at physiologic pH, but stronger complexes do not (Eby 2004). Adding a strong zinc-binding ligand, such as glycine, citric acid, tartaric acid, mannitol and sorbitol, to a solution

FOI 26-3132 - Document 5

containing a zinc complex that is weakly bonded results in the sequestration of zinc to the stronger ligand, reducing or eliminating the benefits of zinc lozenges (Eby 2004). The extent to which the zinc ion was released from formulations reporting no benefit is not known. However, experimental evidence suggests that in saliva the ionisation of zinc to free zinc for some formulations may have been completely (Zarembo 1992) or partially (Farr 1988) suppressed. A formulation developed by Godfrey (Godfrey 1992) that incorporates glycine has been shown to release more than 50% of the zinc from zinc gluconate as the zinc ion. Results from trials conducted by Godfrey (Godfrey 1992) and Mossad (Mossad 1996) suggest this formulation reduced the duration and severity of respiratory symptoms; whereas the trials conducted by Macknin (Macknin 1998) and Turner (Turner 2000a; Turner 2000b; Turner 2000c) suggest no effect of this formulation. The placebo-matching was inadequate; consequently the adequacy of blinding in all these trials is questioned. Hatch et al (Hatch 1987) reported that zinc acetate releases essentially 100% of its zinc as Zn^{2+} ions at a physiological pH. Thus, use of zinc lozenges may be advantageous. Results from trials conducted by Petrus (Petrus 1998) and Prasad (Prasad 2000; Prasad 2008) suggest this formulation reduced the duration and severity of respiratory symptoms. These studies used compressed lozenges designed by George Eby that were identical in composition. In addition to zinc acetate, they contained directly compressible (agglomerated) dextrose as the tablet base, glycerol monostearate (2.5% of tablet weight) as the tablet lubricant, stevia for added sweetness, and peppermint oil for flavour, with the composition compressed to near maximal hardness for slowest dissolution. These ingredients were specifically chosen because they do not react with ionic zinc. The trials conducted by Douglas (Douglas 1987) and Turner (Turner 2000a; Turner 2000b; Turner 2000c) using zinc acetate suggest no effect of this formulation. Among these, the placebo-matching and blinding were stated to be adequate in all except the trial by Turner. Three trials (Kurugol 2006a; Kurugol 2006b; Kurugol 2007) used syrup preparation of zinc (zinc sulphate) and found reduced duration and severity of respiratory symptoms without any increase in adverse effects in the zinc group. Placebo-matching and adequacy of blinding was not stated in these trials. Another trial (Vakili 2009) used tablet preparation (zinc sulphate) and found decreased incidence, fewer school absences, less antibiotic administration and no adverse effects in zinc-supplemented children. Again placebo-matching and adequacy of blinding was not stated in this trial.

The toxicology of zinc has been well characterised. The potential for elevated blood levels of zinc to disrupt copper metabolism and other nutrients preclude its long-term use in the treatment of the common cold (Pfeiffer 1980). Doses higher than 150 mg/day have also been associated with adverse effects (Chandra 1984). In addition, the higher incidence of side effects in zinc-treated participants will most likely limit the usefulness of zinc in the treatment of common cold symptoms. In 14 trials (Douglas 1987; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Macknin 1998; Mossad 1996; Prasad 2000; Prasad 2008; Smith 1989; Turner 2000a; Turner 2000b; Turner 2000c; Vakili 2009; Weismann 1990) included for reporting of any or individual adverse events, the overall adverse events were higher in the intervention than in the control group, except in one trial (Vakili 2009).

Viral studies were performed in nine trials (Al-Nakib 1987; Douglas 1987; Farr 1987a; Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Turner 2000a; Turner 2000b; Turner 2000c). While in-vitro studies suggest zinc inhibits viral replication and the concentration of zinc in saliva should be sufficient to induce such an effect, six trials (Al-Nakib 1987; Douglas 1987; Farr 1987a; Turner 2000a; Turner 2000b; Turner 2000c) found no effect of zinc on incidence or shedding of rhinovirus by study participants. In relation to this, trials by Farr and Douglas found no effect of zinc in the treatment of cold, while Al-Nakib found reduction in the clinical symptom score. From the trial by Al-Nakib, it might be suggested that medication may have had an effect on signs and symptoms of the colds rather than on virus replication. If this is the case, it would be interesting to know whether zinc would also have the same effect on corona virus colds or, indeed, on colds caused by other respiratory viruses. This may be the future area of research in zinc and common cold trials. Trials by Kurugol (Kurugol 2006a; Kurugol 2006b; Kurugol 2007) did not study the effect of zinc on rhinovirus cold; rather they excluded colds due to influenza viruses from analysis and found that zinc is effective in the treatment of the common cold.

Part 2: results

FOI 26-3132 - Document 5

Although most investigators required participants to record the clinical severity of symptoms each day and used similar scales against which to rate symptom severity (symptoms were rated as none, mild, moderate or severe), there was little commonality in summary estimates used by investigators to describe the duration, incidence and severity of respiratory symptoms. Consequently for some outcomes it was not possible to pool the results from all the trials that reported the same outcome. In addition, there was insufficient detail provided in most published papers to determine whether trials used similar criteria for rating the severity of each symptom and therefore it was not possible to standardise clinical severity scores across all trials.

Among the trials reporting the duration of cold symptoms, results could be pooled from 14 trials. Intake of zinc lozenges or syrup was associated with a significant reduction in the duration of common cold, but there was marked heterogeneity among the included trials. Among these, two trials (Kurugol 2006a; Kurugol 2007) used syrup preparation at a daily dose of 30 mg, whereas other trials used lozenge preparation at a daily dose varying from 30 mg to 190 mg. In a subgroup analysis, the results were significant for the dose of zinc lozenges ≥ 75 mg/day, any formulation of zinc (lozenges or syrup) and any age group (children or adult). Results were not significant for any formulations of zinc lozenges (gluconate or acetate). However, the heterogeneity persisted for all these subgroups except syrup formulation of zinc. Among the two trials using syrup preparation, one trial (Kurugol 2007) found no significant effect, and the other found significant reduction of the duration of common cold. There has been speculation regarding how zinc cures common cold. The most biologically plausible hypothesis, as well as experimental, was by Eby (Eby 2010; Eby 2012). As described by him, the mouth–nose act as a biologically closed electric circuit (BCEC). It moves electrons from the nose into the mouth and, in response to the electron flow, it moves positively charged metal ions, such as ionic zinc, from the mouth into the nose. This BCEC does not transport neutrally or negatively charged zinc into the nose; so the lozenges made with non-positively charged zinc are supposed not to work in common cold therapy. Considering these properties, the observation that zinc lozenges releasing positively charged ionic zinc shorten colds in a dose–response manner can be seen in a more plausible light. This is also supported by finding of usefulness of ≥ 75 mg/day of zinc lozenges in reducing the duration of common cold in the present review. The BCEC also explains why patients with colds and a history of allergy responded so much faster than patients with colds and no history of allergy, as shown by Petrus (Petrus 1998). Orally ingested forms such as tablets, liquids and syrups do not have these properties and therefore, according to Eby's research, are not effective therapy for the common cold (Eby 2012).

Among 13 trials measuring the severity score of cold symptoms, results from five trials (Kurugol 2006a; Kurugol 2007; Petrus 1998; Prasad 2000; Prasad 2008) could be pooled. There was a significant difference between the intervention and control group for reduction in the severity of cold symptoms. The trials using syrup preparation used a daily dose of 30 mg, whereas the trials using lozenge preparation used daily doses varying from 30 mg to 276 mg. Al-Nakib (Al-Nakib 1987) and Douglas (Douglas 1987) provided estimates of mean clinical scores. However, estimates were not directly comparable. In the trial by Al-Nakib, the zinc group had a significantly lower mean daily clinical score than the placebo group, with the difference in scores attaining statistical significance on days four and five. However, in the trial conducted by Douglas, there were no statistically significant differences between zinc and placebo groups with respect to mean nasal, throat and cough scores. Results of the trial conducted by Godfrey (Godfrey 1992) suggested treatment with zinc reduced the frequency and severity of cold symptoms, which was noticeable by day five and significant by day seven. In the trial conducted by Turner (Turner 2000a; Turner 2000b; Turner 2000c) none of the zinc preparations (neither gluconate nor acetate) had any significant effect on the severity of common cold symptoms in the first three days of treatment, which might be related to the lower dose of zinc used in this trial. Among four trials (Douglas 1987; Kurugol 2006a; Kurugol 2007; Petrus 1998) measuring individual symptom scores there was a significant reduction in the cough score, with nasal and throat score being variably affected. In the trial conducted by Smith 1989, the zinc group had lower symptom severity scores on days four to seven of treatment which was statistically significant (P = 0.02); but in the trial conducted by Weismann 1990, no statistically significant differences between the two groups were found by day six of treatment (P = 0.14).

FOI 26-3132 - Document 5

Among the two preventive trials measuring the incidence of the common cold (Kurugol 2006b; Vakili 2009), the incidence rate ratio (IRR) of developing a cold in participants who received the intervention was lower than in the placebo group. There was marked heterogeneity, therefore we used a random-effects model for analysing this outcome. The second trial, though a randomised controlled trial (RCT), was not of good methodological quality, but this was included in the analysis as it included a large number of participants. Even after excluding this trial from analysis, the result still favoured zinc supplementation. The first trial used zinc sulfate syrup at a daily dose of 15 mg for seven months, whereas the second trial used zinc sulfate tablet at a daily dose of 10 mg for five months.

The proportion of participants who were asymptomatic after three, five and seven days of treatment was reported in the trials conducted by Mossad 1996, Weismann 1990 and Smith 1989, and the proportion asymptomatic after seven days of treatment was reported in all but the trials conducted by Farr 1987a and Al-Nakib 1987. Analyses were conducted on an intention-to-treat (ITT) basis. In the trial conducted by Mossad (Mossad 1996) participants were less likely to have cold symptoms after three and five days of treatment in the zinc-treated group. The odds ratios (ORs) for days three and five were 0.37 (95% confidence interval (CI) 0.14 to 0.92) and 0.35 (95% CI 0.16 to 0.76), respectively. In the trials conducted by Weismann 1990 and Smith 1989, the proportion of participants asymptomatic after three and five days in the zinc and placebo groups was similar. The test for heterogeneity attained statistical significance for day five, but not day three and consequently a combined OR for day five is not appropriate. The combined OR for day three was not significant 0.97 (95% CI 0.62 to 1.5). In three trials (Godfrey 1992; Mossad 1996; Weismann 1990), fewer participants in the zinc group had cold symptoms after seven days. The pooled result (OR 0.53, 95% CI 0.38 to 0.75) obtained from five trials (Douglas 1987; Godfrey 1992; Mossad 1996; Smith 1989; Weismann 1990) indicated fewer participants in the zinc group had cold symptoms after seven days of treatment. However, the test for heterogeneity was statistically significant.

In six trials (Godfrey 1992; Kurugol 2006a; Mossad 1996; Petrus 1998; Prasad 2000; Prasad 2008) with similar study designs, methodologies and efficacy assessments, zinc was found to be effective in reducing the duration and severity of common cold symptoms in healthy children and adults, when it was administered within 24 hours of the onset of symptoms. In another trial (Kurugol 2007) with similar study design, methodology and efficacy assessments, zinc was found to be effective in reducing the severity of common cold symptoms in healthy children (without any change in duration), when it was administered within 24 to 48 hours of the onset of symptoms. In the trial by Godfrey 1992, the authors found a significant decrease in the duration and severity of symptoms when treatment was administered within 24 hours, compared to treatment administration within 48 hours. So, if treatment with zinc is to be used for common cold, it should ideally commence within 24 hours of onset of symptoms.

There are a number of potential sources of heterogeneity in results obtained from trials included in this review. Most trials relied on community-acquired infections in which the infecting agent was not identified and as such different agents may have been involved which may have differed in their sensitivity to zinc. The amount of zinc taken each day by participants varied largely across the trials, and given that some formulations released less zinc ion than others the effective dose of zinc across trials was variable. Blinding of treatment may not have been adequately controlled in some trials, thereby increasing the potential for performance and detection bias to occur. The time from onset of cold symptoms to commencement of treatment ranged from one to three days. Given the beneficial effects noted in trials commencing treatment with zinc within 24 hours, the results from all the trials may not be comparable. Last but not the least is the fact that the lifestyle of the study population in all the trials was different and the results might have been affected to some degree by this factor.

Summary of main results

Studies reporting duration and severity of cold symptoms suggest that the intake of zinc is associated with a significant reduction in the overall duration and severity of common cold symptoms. A higher proportion of participants became asymptomatic by day seven of treatment with zinc. Duration of individual cold symptoms was also significantly reduced in the zinc group, though the individual symptom severity scores were not significantly affected by the intake of zinc. Zinc supplementation led

FOI 26-3132 - Document 5

to reduction in the incidence of common cold, decreased school absence and decreased the risk of antibiotic use when used for at least five months. The incidence of adverse events was significantly higher in the zinc group with the syrup preparation being better tolerated than lozenges.

Overall completeness and applicability of evidence

The trials included in the analysis involved healthy children and adults of all ages (except infants) and both sexes. All except four trials (Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Vakili 2009) were conducted in upper-middle and high-income countries, where zinc deficiency is uncommon (including in young children). Out of four trials (Kurugol 2006a; Kurugol 2006b; Kurugol 2007; Vakili 2009), three were conducted in Turkey and one in Iran, which are low-income countries. These later trials found beneficial effects of zinc when used either in syrup or tablet (not lozenges) form. So, any beneficial effect of zinc lozenges might not be directly extrapolated to children and adults of low-income countries. In all the included trials, the main weakness of the data is that most trials, when presenting data, did not differentiate between cold due to rhinovirus and other viruses (as viral studies were not conducted in most of these trials). So it is unclear whether zinc helps those with rhinoviral cold or even cold due to other viruses. However, as rhinovirus is the most common aetiological agent of the common cold all over the world (in both low-income and high-income countries), it may be predicted that zinc lozenges prepared in the above mentioned formulations might also help people living in low-income countries.

Quality of the evidence

The trial evidence included is generally of good quality, with a low risk of bias. All the studies were blinded, but placebo-blinding was adequately described in only six trials. In 12 trials, zinc-treated participants complained of altered, bad or unpalatable taste which suggests that zinc lozenges were distinct from placebo lozenges and, in this respect, blinding may have been compromised. Allocation concealment was adequate in nine studies and unclear in nine studies. Thirteen trials reported a low rate of loss to follow-up, whereas three trials did not mention any loss to follow-up. This suggests that the studies were of good quality. For all the outcomes, there was more than one study reporting the individual outcome. The majority were carefully conducted community trials, with active mechanisms to promote adherence to the intervention and both active and passive case finding. Last and most importantly, as there was a high degree of heterogeneity among the trials, the result should be interpreted with caution.

Potential biases in the review process

All the included trials, as expected, measured the effect of zinc on the common cold. There was therefore the potential to miss trials which may have measured common cold as upper respiratory tract infection in secondary outcomes which were less publicised or less well indexed within the electronic databases. We tried to avoid this by conducting a wide search and assessing the relevance of each paper identified in that search carefully. We extracted data from survival curves or t/P values given in studies that did not provide original data, which might have overestimated or underestimated the effect size. Lastly, publication bias cannot be ruled out as shown by funnel plot asymmetry.

Agreements and disagreements with other studies or reviews

The important changes in this updated review in comparison to the previous version (Marshall 1999) include the following.

1. Intake of zinc is associated with a significant reduction in the duration and severity of common cold symptoms.
2. Duration of individual cold symptoms was also significantly reduced in the zinc group.
3. The syrup and tablet preparation of zinc is better tolerated than lozenges.
4. Zinc supplementation reduces incidence, school absence and prescription of antibiotics in children with the common cold.

FOI 26-3132 - Document 5

In the review conducted by Marshall (Marshall 1999) the included studies had missing information, due to which it was not possible to pool the results across the studies. For example, although most investigators required participants to record the clinical severity of symptoms each day and used similar scales against which to rate symptom severity (symptoms were rated as none, mild, moderate or severe), there was little commonality in the summary estimates used by investigators to describe the duration, incidence and severity of respiratory symptoms. It was therefore only possible to determine the proportion of participants who were asymptomatic after three and five days of treatment for three trials and after seven days of treatment for five trials. Except for one study (Godfrey 1992), duration of symptoms was not reported in the rest of the studies. Therefore, again it was not possible to pool the results for this outcome.

In the revisit of their previous meta-analysis, Jackson (Jackson 2000) found statistically significant heterogeneity between the zinc trials. They calculated a pooled estimate of the zinc gluconate lozenges in colds using the random-effects model of DerSimonian and Laird from eight trials. The summary OR for the presence of "any cold symptoms" at seven days was 0.52 (95% CI 0.25 to 1.2). They concluded that despite numerous randomised trials, the evidence for the effectiveness of zinc lozenges in reducing the duration of common colds is still lacking. Although, according to them, some of the negative results might be explained by low zinc ion availability, they did not examine the issue. Moreover, they have not looked for the effect of any other formulations, as well as high or low doses of zinc.

A review published in 2004 by Hulisz 2004, which was an overview of published articles through MEDLINE (1980 to 2003), concluded that zinc effectively reduces the duration and severity of common cold symptoms when administered within 24 hours of the onset of symptoms. The author also had some concerns regarding the clinical tests of zinc for the treatment of common colds being inconsistent, primarily because of study design, blinding and lozenge contents; early formulations of lozenges being unpalatable with a higher incidence of side effects.

In a systematic review of trials published between 1966 and 2006, Caruso 2007 used 11 features of experimental design affecting signal quality, chance, bias and blinding to evaluate 14 placebo-controlled trials. They gave one point for each of the 11 quality items if it was satisfied, after which only four trials obtained the maximum of 11 points. Based on this, they suggested that the positive results in the zinc trials might be explained by methodological flaws. However, the use of scales for assessing quality or risk of bias is strongly discouraged in Cochrane systematic reviews. Moreover, such an approach, though simple, is not supported by evidence (Higgins 2011).

In another systematic review by Hemilä (Hemilä 2011), the author included 13 placebo-controlled comparisons. Pooling of trials using a total daily zinc dose of less than 75 mg found no effect, but those using zinc acetate in daily doses of over 75 mg found a 42% reduction, and those using zinc salts other than acetate in daily doses of over 75 mg found a 20% reduction in the duration of colds. The author concluded that there is strong evidence that the zinc lozenge effect on common cold duration is heterogeneous so that benefit is observed with high doses of zinc but not with low doses. However, there were no descriptions of other formulations of zinc (syrup or tablet).

In the latest systematic review (Science 2012), the authors included 17 trials. Compared with patients given placebo, those receiving zinc had a shorter duration of cold symptoms (mean difference (MD) -1.65 days, 95% CI -2.50 to -0.81). However, heterogeneity was high. Zinc shortened the duration of cold symptoms in adults but no significant effect was seen among children. In contrast to this, we found zinc to be effective both in children (< 16 years age) and adults. The reduction in the duration of cold symptoms was greater with high doses of ionic zinc (MD -2.75, 95% CI -3.89 to -1.60) than with lower doses (MD -0.84, 95% CI -1.50 to -0.18). However, we found that only zinc lozenges containing high dose (≥ 75 mg/day) reduced the cold duration significantly.

Authors' conclusions

Evidence shows that zinc is beneficial for the common cold in healthy children and adults living in high-income countries. Pooled results from the trials showed that zinc reduced the duration (not the severity) of common cold symptoms when used therapeutically. However, the effect of zinc

FOI 26-3132 - Document 5

lozenges on common cold duration is heterogeneous so that benefit is observed with high doses but not with low doses of zinc. The effects of zinc lozenges should be further studied to determine the optimal lozenge compositions and treatment strategies. Zinc also reduced the incidence of the common cold, school absence and antibiotic use in healthy children when used prophylactically, although antibiotics are not required for the common cold. All the studies included healthy participants; we could not find any evidence regarding use of zinc in participants at increased risk of developing the common cold. As the zinc lozenges formulation has been widely studied, and there is a significant reduction in the duration (days) of cold at a dose of ≥ 75 mg/day, for those considering using zinc it would be best to use it at this dose throughout the cold. Regarding prophylactic zinc supplementation, currently no firm recommendation can be made because of insufficient data. When using zinc lozenges one should be aware of the side effects.

Morbidity associated with the common cold is not trivial. The median duration of a cold episode is 7.4 days, with 25% of cases continuing for two weeks. The burden of the common cold is even more pronounced in individuals with chronic co-morbidities or clinical risk factors, including those with asthma and chronic obstructive pulmonary disease, the elderly, those with a history of otitis media or sinusitis, and those who are immunocompromised. Asthmatic children experience more cold episodes than non-asthmatic children, which is a common risk factor for acute asthma exacerbations. Future studies should therefore focus on the role of zinc in these populations rather than healthy people, as the results would be more meaningful for them.

Investigators also need to recognise the difficulties that have been encountered, particularly with respect to blinding and bioavailability (with various formulations). More research is needed in this area. Given the potential for zinc lozenges to induce adverse effects, the zinc lozenges preparation which produces minimal adverse effects should be formulated. We also need more trials on syrup and tablet preparations of zinc as well as more preventive trials in order to support or refute the above mentioned beneficial findings with these preparations.

Although laboratory confirmation of infection is desirable, in large community-based trials the costs associated with such investigations limit the extent to which serology can be undertaken. However, unlike trials relying on experimentally induced rhinoviral colds, findings from large community-based trials will address issues relating to the diversity of and generalisability to the common cold.

Feedback

Zinc for the common cold feedback: the Eby 1984 report, flavor and flavor masking issues, and what is next, 23 February 2011

Summary My congratulations are extended to Meenu Singh and Rashmi R Das for a very comprehensive review of the zinc for common cold literature. However, some comments are needed concerning the Eby et al. 1984 report, flavor issues and where we need to go next.

Concerning the original 1984 Eby, Davis and Halcomb article

Our original 1984 article[1] started this line of inquiry by showing that it was possible to shorten common colds by 7 days (P = 0.0005) with 23 mg zinc (zinc gluconate) lozenges when taken each two wakeful hours. These lozenges (unflavored and unsweetened dietary supplement tablets) lasted about 30 minutes in the mouth which provided sufficient time for local absorption into oral tissues. This protocol was developed after observing that 50 mg zinc (zinc gluconate) tablets slowly dissolved in the mouth of a 3-year old child with acute lymphocytic leukemia (T-cell) resulted in her severe common colds disappearing within 2 hours without further treatment and many similar informal observations in the general community. Our report has drawn some criticism, mainly since the taste of the zinc gluconate lozenges was modestly objectionable resulting in more dropouts in the zinc-treated group than in the placebo-treated group. Bias would occur if zinc-treated subjects who received little or no benefit selectively dropped out or failed to return reports. We were concerned about this potential for

FOI 26-3132 - Document 5

bias, and to protect our results we estimated the maximum effect of such bias by assuming that all dropouts and all non-reporters in both zinc and placebo treatment groups received no benefit and responded as if they were on placebo. The effect of zinc in that analysis remained substantial and statistically strong (P = 0.007), and this potential bias was shown to be irrelevant. These modifications to our main results were published in our Discussion section on page 23 right-hand column, but they have been ignored in reviews by others, thus adversely biasing results of several critical reviews. Therefore, I am disappointed that this error was also committed by Singh and Das.

Flavor and flavor-masking issues

Concern about blinding evolved from concern over “bad taste” of zinc lozenges. There is much difference in the taste of zinc lozenges, which should be considered in evaluating bias. Zinc gluconate in tablets with no other soluble ingredients[1] are moderately objectionable tasting, but tolerable, to most people. Zinc gluconate releases 72% of its zinc as ionic zinc at physiologic pH 7.4.[2] Zinc gluconate can be sweetened without bitterness using a fructose tablet base as was done in the Al-Nakib trial at the Great Britain Common Cold Unit.[3] However, mixing zinc gluconate with any other sweetener, especially sucrose and/or dextrose, results in products that age within 30 days to be as bitter as the bitterest substance known, sucrose octaacetate. This unexpected and adverse effect caused researchers to search for alternatives to zinc gluconate and for ways to flavor-mask zinc gluconate. Extreme bitterness likely affected only the results of Weisman et al., although they compensated by using very small amounts of zinc.[4]

Although pure zinc acetate, which releases 100% ionic zinc at physiologic pH 7.4,[2] tastes vastly more vile than pure zinc gluconate, it is easily flavor-masked by a variety of sweeteners in either hard-candy compositions such as the lozenges tested by Prasad et al.[5] or compressed tablets as tested by Prasad et al.[6] and Petrus et al.[7] These zinc acetate lozenges did not contain flavor-masking additives. Zinc acetate tastes and works best when present in a 1:100 ratio with dextrose in very highly compressed tablets which last about 30 minutes when being dissolved in the mouth. One failure occurred in effervescent lozenges containing zinc acetate which were flavor-masked with tartaric acid and sodium bicarbonate, resulting in elimination of ionic zinc.[8],[9]

Citric acid was used to flavor-mask the objectionable taste of zinc gluconate in a corn syrup and sucrose hard candy lozenge.[10] Citric acid has a high affinity for ionic zinc and no zinc ions were available for absorption into oral tissues, resulting in clinical failure.[2] Due to its pleasant taste, this formula is commonly used in commercial zinc lozenges in the United States resulting in no effect against common colds other than nutritional support.

Glycine was used to flavor-mask zinc gluconate in several clinical trials, with two[11],[12] showing efficacy and one[13] showing lack of efficacy. Variability in results may have been caused by glycine since it eliminates about one half (or more) of the ionic zinc from lozenges.[2] NOTE: This formula does not release “over 90% ionic zinc” at physiologic pH 7.4 as portrayed by Sing and Das, but it does release that amount at pH 5.0, a nonsense pH.

Availability of ionic zinc is dependent upon a number of variables including pH, concentration, temperature and compound being tested, and such is a subject of extensive research by solution equilibrium inorganic chemists .[2]

Consequently, to say that effective zinc lozenges have an objectionable taste that can bias clinical trials is not necessarily factual. The worst possible taste and most bias in effective zinc lozenges results from zinc gluconate in a non-fructose carbohydrate hard candy or tablet base, which was found only in the Weisman trial.[4] Zinc gluconate in a non-soluble tablet base is about 1/10th as objectionable,[1] while zinc gluconate in a fructose tablet base,[3] zinc gluconate-glycine[11, 12, 13] and zinc acetate[5,6,7] in a 1:100 dextrose tablet base are each commercially acceptable in taste. However, zinc acetate lozenges are potentially the most effective, use the least zinc, and are the best tasting. Zinc acetate lozenges also had the least potential for bias due to their pleasant taste, although they had an astringent mouth-feel demonstrating release of zinc ions. A perfect placebo would have been astringent in mouth-feel,

FOI 26-3132 - Document 5

perhaps like tannin. Pursuit of a pleasant tasting and effective zinc lozenge has led to both clinical successes and failures, and the large variety of formulations has greatly complicated the analytical picture.

What is next?

As the researcher that originally discovered the effect of ionic zinc from throat lozenges on the duration of common colds, I am very concerned that the statement "zinc is good for colds" released on nearly every U.S. national TV news program, radio station and newspaper (and perhaps also in Europe, Australia and elsewhere) due to loose journalistic interpretation of the Singh and Das report. It is far too broad and too simplistic to be accurate, and it will likely lead to OTC products that will not have the features necessary to shorten colds more than a day, thus 26 years of zinc lozenge research could be lost and perhaps not regained for decades or a century. These features were previously described in my 2009 review.[2] That review showed dose-response linearity of lozenges by their ionic zinc content on the duration of colds. It showed that reductions in the mean (P=0.001) and median (P=0.004) durations of common colds were statistically significant and meaningful.

It also showed that the effects of a compressed dextrose tablet containing 18 mg of zinc (zinc acetate dyhydrate - 60 mg), glycerol monostearate as a tablet lubricant and peppermint oil on silica gel, which happens to be a 2X homeopathic*Zincum aceticum* formula, is expected to shorten common colds by 7 days. These lozenges released the same amount of ionic zinc as did our 23 mg zinc gluconate lozenges tested in 1984.[1] They are 1.9 cm (¾ inch) diameter and 1.27 cm (1/2 inch) thick tablets which are best produced on heavy production machines like a Stokes 328-2 tablet press. Magnesium stearate was not used as a lubricant due to concerns about concentrated magnesium greatly stimulating rhinovirus replication.[14]

These zinc acetate lozenges are pleasant tasting and taste like peppermint candy. If these tablets are compressed to a sufficient hardness, they will dissolve in the mouth in about 30 minutes. Fick's laws of membrane permeability show that the amount of a solute absorbed across a membrane is time and concentration dependent. Thirty minutes is a reasonable time for oral dissolution. Also, the dextrose-based formula does not excessively promote saliva production. I suggest that it is now time to focus on this basic formulation and go forward with research on it. I see no necessity to focus on zinc compounds that do not release 100% of their zinc as ionic zinc, or on products that dissolve too fast for significant oral absorption, or on products that contain too little ionic zinc to be effective. From the time of contact with the oral mucosa aspects of Fick's laws, the use of syrups or orally ingested tablets to treat common colds are not advised if large reductions in their duration are desired.

Perhaps there is also a requirement to consider how ionic zinc works in shortening colds and the work of Merluzzi et al. in showing that ionic zinc, but not bound zinc, inhibits the replication of rhinoviruses should be considered vital,[15] along with the extensive pioneering work of Korant and Butterworth in showing the inhibitor effects of ionic zinc on rhinoviral replication.[16], [17],[18], [19], [20], [21], [22], [23] These articles should give support to the notion that the main effect of ionic zinc in treating common colds is by rhinovirus replication inhibition.

Although I cannot see into the future, I have proposed here what I believe to be the most likely route to successful treatment of common colds, and I hope that new zinc lozenge researchers will follow my advice. If they do follow my advice, they should be able to demonstrate in a coordinated manner the massive benefits of zinc in treating colds in just a few years, rather than in the decades or centuries that I expect from future distortions of the literature if researchers continue to test faulty products and publish those results. Provided with good results, manufactures can follow through with products that will shorten colds by a week in the general public. Then, and only then, can we say that there is a cure for the common cold!

Reply We thank Dr Eby for his comment on the review as well as giving his expert opinion on the future direction of zinc cold research. Addressing the issue of bias that has occurred in their trial (which has also been highlighted in many other reviews), we want to point out that, though the author (Eby et al) have discussed about the bias resulting from increase drop out in their study in the designated paragraph described above, it should be noted that there are many drawbacks in their trial that make the quality score of a trial poor (please refer to the Cochrane handbook on bias before giving good score to a randomized clinical trial and thus qualifying them for inclusion in a review).

Regarding Dr Eby's description of how zinc acts in the treatment of common cold, it is very true that it is the ionic zinc that plays major role and we hope that authors of future trials will take these issues into account before any meaningful conclusion can be drawn from a particular trial (we have also highlighted these facts in the present review). However, this mechanism might not play important role in the preventive act of zinc for the common cold. But, as zinc has been found in clinical trials to have preventive role for the common cold (zinc also has role in prevention of lower respiratory tract

FOI 26-3132 - Document 5

infection/pneumonia, found in a recent Cochrane review), other mechanisms might play role, including enhancement of innate as well as acquired immunity and correction of underlying zinc deficiency. Only future research in this area can answer these questions.

Comment from Ronald Turner, 1 March 2011

Summary The authors of this review state that our paper (Turner RB, Cetnarowski WE. Effect of treatment with zinc gluconate or zinc acetate on experimental and natural colds. Clin Infect Dis 2000;31:1202-1208) was excluded for poor methodology as the study was not randomized. The study was in fact randomized as stated in the methods section of the paper. If there was confusion on this issue, I would have gladly supplied the original study protocol to the authors of this review.

Ronald Turner Submitter agrees with default conflict of interest statement: I certify that I have no affiliations with or involvement in any organization or entity with a financial interest in the subject matter of my feedback.

Reply This paper by Turner et al, though described as a randomized trial, was exclude because of the poor quality score (not because of randomization only, as commented by the author).

Contributors Meenu Singh and Rashmi R Das

Are we really sure zinc is an effective treatment for the common cold?, 3 March 2011

Summary We are concerned regarding a number of aspects of this updated review on the use of Zinc for the treatment and prevention of the common cold[1]. The review concludes that “zinc is beneficial for the common cold in healthy children and adults living in high-income countries.” We are concerned that the threats of potential biases on the review have not been considered carefully enough. Below we include contour enhanced funnel plots[2] of the two primary treatment outcomes of the review – duration of illness and severity of symptoms (see Figure). Figure: Funnel plots for the two primary treatment outcomes in the review (http://dl.dropbox.com/u/21306757/funnel_plot_zinc.jpg)

Although these plots contain relatively small numbers of studies (6 and 5 respectively), there is a concerning trend in both graphs that the smaller the trials the increasingly larger the effect sizes observed. Additionally, the most precise studies (towards the top of the plots) have effect sizes which are either 0 or very close to it. One possible explanation, and we acknowledge this is not the only explanation, for such “small study effects” trends is publication bias, which would imply that outcomes from trials with less beneficial/harmful effects have been suppressed. This could be due to the suppression of whole trials which have never been published, or, it could be due to suppression of particular outcomes from certain trials (outcome reporting bias)[3] or a combination of the two. Outcome reporting bias is perhaps a particular concern because we infer from the review that 13 treatment trials (including 1 trial excluded from the statistical overview[4]) were identified but only 10 studies reported on each of the primary outcomes, with fewer trials still reporting both outcomes. From this initial position of potential outcome reporting bias, further selection occurred to include these trials into each meta-analysis (6 and 5 respectively), because the review authors believe the results were not reported in a compatible format, although we suggest that it may well be possible to include at least one further study [5] reporting a dichotomous version of the outcome using previously described methods[6, 7]. Some of these studies excluded from the meta-analysis are discussed in the results section, with at least one study having no effect (Douglas 1987[8] for severity of symptoms). Unusually for a review with small study effects, the studies identified as being industry-sponsored are the largest, but are also those closer to the null effect suggesting much smaller effects. The smaller studies indicating greater effects are noted as medical research foundation sponsored, which may support an alternative explanation to the one we propose.

The authors identified heterogeneity between studies and thus used random effects models in the meta-analysis. As this model gives more weight to the smaller, imprecise, studies (than the fixed effect one), in the presence of funnel plot asymmetry, this has the effect of producing larger effect sizes than the fixed effect alternative; both estimates with their 95% confidence intervals are included on the figure

FOI 26-3132 - Document 5

(although both approaches will lead to statistically significant benefits of zinc)[9]. With so few studies, alternative formal approaches to unpicking the heterogeneity, such as meta-regression on dose or dose-duration values would be difficult to undertake.

In the methods section, the authors report making an assessment of publication bias “by examining the funnel plot for asymmetry” and reference a highly cited paper on testing for publication bias[10]. Curiously, there is no further mention or discussion of the results of any assessment for publication bias in the paper. While any formal test on the data is likely to have low power due to the relatively small numbers of studies[6], we believe scrutinising the above funnels is helpful, although the asymmetry is so extreme we initially identified the problem simply by looking at the presented forest plots.

Additionally, we do not understand the author’s statement that “we assessed risk of bias due to selective reporting of outcomes for the study as a whole, rather than for each outcome” For the reasons outlined above, we think some outcome specific consideration would be helpful.

The authors conclude their assessment of “Potential biases in the review process”, that although there was the potential that they may have missed studies referring to the common cold as upper respiratory tract infection, “there are no other obvious sources of potential bias”, we urge the authors to reconsider this statement. In light of the above, and particularly considering the data presented on side effects, we would like to suggest that the conclusions of this review are toned down taking into account the threat of potential reporting biases.

A further issue to have come to light in examining this meta-analysis is that the primary outcome – duration of cold symptoms – is stated to be measured in days. However, the meta-analysis is conducted using the standardised mean difference. If all studies measure the outcome on the same scale (days) it is unclear why the outcome needed standardising and the results would be better presented on the (untransformed) mean difference scale where clinical interpretation is much easier and less strong statistical assumptions are required.

Yours sincerely, Jaime L Peters, Santiago G Moreno, Bob Phillips, Alex J Sutton.

Reply Thanks for pointing out some important issues related to the review. We also have the same concern regarding the final conclusion (which we have discussed more or less in the review) and that's why no recommendation could presently be made on use of zinc for the common cold. Regarding the publication bias, we agree with the authors (Jaime L Peters, Santiago G Moreno, Bob Phillips, Alex J Sutton) that publication bias could not be ruled out which might also compromise the findings of the

FOI 26-3132 - Document 5

present review. But what's important is that, though publication bias alerts to the problem, they do not provide a solution to it. Moreover, funnel plots have their own limitations. So, what Eby et al described above regarding the future direction is more important, as they provide a solution to the problems in the zinc common cold research. But in the next updated version, we will add the funnel plot. Regarding the application of random and/or fixed model effect in the meta-analysis, they have their inherent problems. Last concern regarding inclusion of MD instead of SMD, we have replied it below [actually, the MD for the duration of cold is -1.48 (around 2 days)].

Comment from Christopher Cates, 7 March 2011

Summary Dear Sir, I have not personally started taking zinc tablets for the common cold, as I do not think the average answer tells me enough to justify a change in practice (too much heterogeneity and a very wide predictive interval [-4.2 to 1.2 days when analyzed as mean difference]. See method in: Riley RD, Higgins JPT, Deeks JJ. Interpretation of random effects meta-analyses. BMJ. 2011;342:d549). Prasad seems to me to be measuring something different to the other studies, as the mean difference of 3 days in these studies is incompatible with all the other study results? It would be easier for readers to understand these results if they were presented as a mean difference in days (rather than SMD). Surely the overall average result is of limited usefulness when there is such diversity between the study results? Yours faithfully, Chris Cates MA FRCGP

Submitter agrees with default conflict of interest statement: I certify that I have no affiliations with or involvement in any organization or entity with a financial interest in the subject matter of my feedback.

Reply The mean difference (in days) for the duration of cold is -1.48 (around 2 days). We agree with the authors regarding the heterogeneity of results, as a result of which no recommendation was possible about zinc for the common cold (already described in conclusion).

Contributors Meenu Singh and Rashmi R Das

Comment from Catherine McIlwain, 14 March 2011

Summary I'd like to request that one line of text (“Zinc inhibits rhinoviral replication”) in the plain language summary be restated in simpler terms. That phrasing resulted in quite a few comments from consumers who don't understand virus replication.

If you are amenable to a change, I would recommend using the word ‘virus’ instead of ‘rhinoviral’ throughout the plain language summary. In addition, would it be acceptable to change ‘rhinoviral replication’ to ‘the spread of the virus’ only in the plain language summary, of course.

Catherine McIlwain

Submitter agrees with default conflict of interest statement: I certify that I have no affiliations with or involvement in any organization or entity with a financial interest in the subject matter of my feedback.

Reply No. replication and spread of virus does not mean necessarily the same thing. But we can say it as follows: zinc inhibits replication of common cold virus.

Contributors Meenu Singh and Rashmi R Das

The zinc for the common cold review by Singh and Das has a number of problems which should be considered when the review is next time updated, 5 September 2011

Summary 1) Search of the studies: Eby and Halcomb (2006) reported a randomized double-blind placebo-controlled trial on zinc for the common cold [1], which is missing from the review. The trial is included in MEDLINE (PMID: 16454145) and Singh and Das should have found it and listed among the trials requiring an assessment. 2) Extraction of data: Singh and Das describe that “The lead review author (MS) entered data directly into Review Manager. An independent coder verified accuracy of data entry”. However, looking at their Analysis 1.1 led me to wonder how can they claim that the findings of the Petrus (1998) trial were non-significant (the 95% CI covering the “no effect”), given

FOI 26-3132 - Document 5

that Petrus (1998 p. 600) wrote that “t-test showed that the mean duration of all symptoms was significantly lower in the zinc group (3.8±0.2 days) than in the placebo group (5.1±0.4 days) (P=0.008)”. In their Analysis 1.1, Singh and Das give the mean duration of colds in the zinc group as 4.4 days, and not as the 3.8 days reported by Petrus (above). The value of 4.4 days is given in the Petrus (1998) Table II as the overall mean duration of colds, i.e. the mean for all zinc and placebo participants combined, but Table II also gives the 3.8 days for the duration of colds in the zinc group. In their paper, Petrus (1998) gives the accuracy of the mean as the SE (standard error), whereas the Review Manager needs the SD (standard deviation). The SE values reported by Petrus (1998) are highly inaccurate (above), yet Singh and Das calculated the corresponding SD estimates from them. To get the accurate Petrus (1998) trial results, I contacted the statistician of the group and got their results: 3.797 (SD 1.630) days in the zinc group and 5.106 (SD 2.955) in the placebo group (Ken Lawson, email 4 Mar 2009). The Petrus (1998) values in Analysis 1.1 should be replaced with these correct and accurate values.

3) The characteristics of included studies table: In the Characteristics of included studies table, Singh and Das write about the Al-Nakib (1987) trial that there was “unclear risk” for the item “incomplete outcome data addressed?”. However, Singh and Das write that “there were no drop-outs or withdrawals”. Lack of drop-outs does not justify their judgment (“unclear risk”). Furthermore, Singh and Das state that in the Al-Nakib trial there is “high risk” for the item “free of selective reporting?”. The statement that there is “high risk” calls for justification, whereas none is given. Furthermore, Singh and Das list six outcomes for the Al-Nakib (1987) trial, yet only one of them is relevant to the review: “the severity of symptoms”. However, I cannot see this outcome in any of their Analysis tables. The outcome section of the included studies table should list only those outcomes that are used in the review. Furthermore, it would help the reader if the included studies table describes in which Analysis the values of the outcomes are presented. Singh and Das state that in the Smith (1987) trial there is “low risk” for the item “incomplete outcome data addressed?”. Smith started with 176 participants and reported the results for only 110 participants, which means that they reported data for only 62% of the initial participants. In their Methods section, Singh and Das write that “we considered that incomplete outcome data had been adequately addressed if 85% or more of the participants were included in the analysis, or if less than 85% were included but adequate steps were taken to ensure or demonstrate that this did not bias the results.” In their included studies table, Singh and Das do not describe why the analysis of 62% of initial participants is acceptable for the Smith (1987) trial although they give the limit of 85% in their Methods. Stating that the Smith (1987) trial has “low risk” with the 38% drop-out rate, and the Al-Nakib (1987) trial has “unclear risk” with no drop-outs (above) is puzzling. Singh and Das use an inclusion criterion “randomized controlled trials”. Weismann (1990) did not report the method of allocation in their trial report. Nevertheless, Singh and Das describe in their included studies table the Weismann (1990) trial: “Methods: randomized trial”. Since their report did not describe the method of allocation, I contacted Kaare Weismann, who wrote to me “It was a consequetive allocated study with the same number of patient in the two groups” (email 2 Jul 2010). Thus, the Weismann (1990) trial was not randomized. Given their inclusion criteria, Singh and Das should exclude the Weismann trial or they should re-write the inclusion criteria so that they also include pseudo-randomized trials which have used, for example, alternative allocation. Furthermore, Singh and Das state that there is “unclear risk” for the item “allocation concealment?” in the Weismann (1990) trial, even though the trial was double blind. The term double-blind means that both the patients and researchers are unaware of the type of treatment until the trial is concluded. Consequently, neither of them can know to which group a patient had been allocated. Thus, double-blind means that there must have been allocation concealment. Otherwise the patients and researchers could not remain blind after randomization. This same error is seen in the description of the Al-Nakib (1987) and Petrus (1998) trials, which also were double-blind trials. As a consequence of this error, Figure 1 gives an impression that several studies were methodologically less satisfactory than they actually were. More details of the trials should be given in the included studies table. For example, in their “implications for practice”, Singh and Das state that “We could not find any trials conducted in low-income countries, so our results cannot be applied to people living in low-income countries.” However, three trials by Kurugol (2006a, 2006b, 2007) were carried out in Turkey, and one trial by Vakili (2009) was carried out in Iran. These are low-income countries. According to World Bank statistics, the GDP per capita in Turkey and Iran is 80% and 90% lower than in Germany, as an example. Thus, the above statement is

FOI 26-3132 - Document 5

false although there are countries which are much poorer than Turkey and Iran. To help the reader to understand the contexts of the trials, it would be useful to describe the country and the settings of the trials. Such information affects the generalization of the findings. Studies in Turkey and Iran cannot be directly extrapolated, for example, to the western countries.

4) The characteristics of excluded studies table: In the Characteristics of excluded studies table, Singh and Das comment on the Eby (1984) trial: “Intention-to-treat analyses were not conducted; analyses were only conducted on a subset of those originally enrolled in the trial.” However, this is also true for the Smith (1987) trial, which included only 62% of the initial participants in the analysis (above). Eby (1984 p. 20-21) described: “Of 146 original volunteers, 120 subjects returned reports. Initially, to use as much of the data as possible, we analyzed the 80 complete reports from 108 subjects who had been ill for 10 days or less at the start of treatment. ... this report is restricted to those 65 subjects who reported being ill for 3 days or less before starting the experiment.” Singh and Das use an inclusion criterion “interventions commenced within three days of participants developing common cold symptoms”. Given such a criterion, Eby's post-randomization restriction to 65 subjects who were ill for 3 days or less before the treatment started is relevant data. In any case, Singh and Das should treat Eby (1984) and Smith (1987) trials consistently, so that both are included or excluded on the basis of the high rate of participants not included in the analysis. Singh and Das further criticise the Eby (1984) trial: “The trial relied on subjective assessment of symptoms by subjects.” However, this applies to essentially all zinc and common cold studies. In evidence-based medicine, the subjective symptoms are most essential outcomes. Subjective symptoms determine whether a patient goes to work or school, stays at home, or visits a physician. Double-blinding prevents systematic bias in the subjective assessment of symptoms, and therefore “subjective” per se cannot cause bias in a double-blind trial. Furthermore, if Singh and Das consider that “subjective assessment” is a basis to exclude the Eby (1984) trial, they should apply the same criterion to the other trials. Singh and Das also comment on the Eby (1984) trial: “Inclusion criteria were not adequately addressed and therefore there may have been potential for selection bias to occur.” In randomized trials, the primary concern is the comparability of trial arms, so that there are no systematic differences that could lead to bias. All randomized trials use inclusion criteria of some kind, but that has nothing to do with the question whether the trial arms are comparable. Inclusion criteria are relevant when we consider the possibility to generalize the results, but not when considering the internal validity of a trial. Finally, Singh and Das conclude their criticism of the Eby (1984) trial: “In addition, no information was provided on how allocation to treatment groups was concealed, the power of the study was not stated and viral studies were not conducted”. First, in most other zinc and common cold studies there is no information about how allocation was concealed (i.e. how blinding was maintained). Second, statistical power is relevant when planning a trial, but not after the trial is concluded, since the confidence interval gives the same information. Third, given that the primary goal in evidence-based medicine is to find out whether a treatment has clinically important effects, viral studies are not relevant. All these issues are missing in most of the zinc and common cold studies. Thus, if Singh and Das consider that these arguments give a sound basis to exclude the Eby trial, they should apply the same criteria also to the other trials. In the Characteristics of excluded studies table, Singh and Das comment on the Turner (2000) trial: “Poor methodological quality. Not a randomised trial”. However, Turner writes “Subjects who met the criteria for randomization to treatment were randomly assigned to 1 of the 4 treatments in accordance with the drug-randomization code” (p. 1202), [for induced colds:] “Subjects were randomized to receive study medication 24 h after challenge if they had a total daily symptom score ≥ 3” (p. 1203), [for natural colds:] “Subjects who presented to the study sites with a common-cold illness of ≤ 1 calendar day’s duration (effectively 36 h), reported ≥ 2 different symptoms, and had a total symptom score of ≥ 2 were randomized to receive 1 of the 3 treatments” (p. 1203).Thus, the statement by Singh and Das is false, unless they have information that disproves the text of the Turner (2000) report. In such a case, they should present their evidence. The Turner (2000) trial was reported as a randomized placebo-controlled double-blind study, and there is no basis to claim that it was of “poor methodological quality”.

5) Different methods of administering zinc should be analyzed separately: The majority of the zinc trials examined zinc lozenges in the western countries. Three trials by Kurugol (2006a, 2006b, 2007) and one trial by Vakili (2009) administered zinc as syrup or tablets; however, all these trials were carried out in low-income countries, Turkey and Iran. Thus, it is possible that the benefit of zinc

FOI-26-3132 - Document 5

supplementation in these trials is caused by biological mechanisms that are different from the mechanisms of the zinc lozenges, which are intended to be dissolved slowly in the mouth. The daily dose of zinc in the Kurugol and Vakili studies varied from 10 to 30 mg per day, whereas the total daily dose of zinc in the zinc lozenge studies varied from 30 to 207 mg per day [2]. Thus, it is possible, or probable, that the benefits of the low dose zinc supplementation found by Kurugol and Vakili are explained by a sub-optimal dietary intake of zinc by children in Turkey and Iran. In contrast, it is possible that high dose zinc is needed in the lozenges to get benefit from them. Although Singh and Das restrict their systematic review to tablets, syrup and lozenges, they should also take a look at the other zinc literature. A few studies have examined the use of nasal administration of zinc to treat colds and found significant benefit [3,4]. Still, patients should not be exposed to intranasal zinc, since there are cases of anosmia caused by such a therapy [5]. Nevertheless, the benefit of local application of zinc to the nose indicates that the effect of zinc lozenges may be caused by local effects in the mouth-throat region, instead of systemic effects such as those caused by the ingestion of tablets and syrup. Therefore it is inappropriate to pool the tablet and syrup trials with the lozenge trials. This is a good example of the apples and oranges problem.

6) The duration of the common cold should not be dichotomized: Singh and Das present three tables which show “number of participants symptomatic after N days of treatment”, N being 3, 5 and 7. Dichotomization of continuous variables has been criticized [6]. Moreover, there is no need to dichotomize the duration of colds when analyzing the zinc lozenge trials. Although several trials did not report the mean and SD for the duration of colds in the trial arms, all of them reported data that makes it possible to calculate the mean and SD for cold duration [2]. The use of continuous outcome for common cold duration would also simplify the review as three redundant tables can be removed.

7) Duration of the common cold should be normalized so that placebo groups have length 100%: There is substantial variation in the duration of colds in the placebo groups of the zinc lozenge trials, from 5.1 days to 9.0 days and 10.8 days [2]. Although part of this variation is evidently caused by random variation, it is also caused by actual variations in the severity of disease in different patient groups and in differences in outcome definitions. Therefore, the relative effect of zinc on the common cold duration should be calculated in percentages, because the relative effect partly adjusts for the variations between patient groups and outcome definitions. For example, if a 6-day cold is shortened by 1 day, it is not equivalent to a 1-day cold being shortened by the same amount although both differences are equal in absolute units. Consequently, it is much more reasonable to calculate the relative effect of zinc, so that a 6-day cold shortened by 2 days and a 1-day cold shortened by 0.33 days both correspond to an equivalent 33% reduction. Calculating the relative effect corresponds to the normalization of all control groups to an episode duration of one unit or 100%. Therefore, in our Cochrane review on vitamin C and the common cold we calculate the relative effect [7]. The use of relative effect in the analysis of common cold duration corresponds to using the risk ratio in the analysis of binary data. In their Analysis 1.1, Singh and Das pool the results by the SMD method, which means normalizing the duration by the SD (i.e. 1 unit in the scale corresponds to the SD of each study). However, using such a scale (SD units) is very difficult for an ordinary reader to understand. In their abstract,, Singh and Das write: “Intake of zinc is associated with a significant reduction in the duration (standardised mean difference (SMD) -0.97)”. However, reporting should always give the unit of the measurement. In the SMD method, the unit is the SD unit. Thus, the above sentence should be re-written more accurately: “zinc shortened the duration of colds by 0.97 SD units”. Such accurate reporting would reveal the main problem of the SMD procedure: what does the SD-unit mean? I pooled the results of three large-dose zinc acetate lozenge trials and I found that “zinc shortened the duration of colds by 42%” [2], which is easy to understand. Most people can form an opinion whether 42% is small or large, but few people can form an opinion whether 0.97 SD units is small or large, or whether it is more or less than 42%. Thus, a relative scale would make the analysis of zinc trials easier to understand for the ordinary readers compared with the SD scale. The Cochrane Handbook comments (9.2.3.2): “The standardized mean difference [SMD] is used as a summary statistic in meta-analysis when the studies all assess the same outcome but measure it in a variety of ways (for example, all studies measure depression but they use different psychometric scales).” Thus, the SMD can be useful, for example, in psychiatry. In the case of common cold duration, the relative effect in percentages is much easier for readers.

FOI 26-3132 - Document 5

8) Subgroup analysis should be carried out: Singh and Das write in the Background section that a "significant correlation between total daily dosages of positively charged zinc species and a reduction in the mean duration of common colds" has been reported. Therefore, the daily dose of zinc should be considered in the statistical analysis. However, in their Result section Singh and Das claim that "subgroup analysis was not possible as there were not enough studies for each variable." This is not correct. As noted above, there is a 6-fold variation in the total zinc dose (30 to 207 mg per day [2]) in the zinc lozenge studies. Given that the results of the zinc lozenge trials diverge so that some found no effect whereas some others found highly significant benefit, the relation between the dose and effect should be analyzed. Dose-response relation is a basic concept in pharmacology. I analyzed 13 zinc lozenge trials and divided them into three subgroups on the basis of the total daily dose of zinc and the type of lozenge [2]. None of five trials with the lowest doses of zinc found benefit of the lozenge, suggesting that they may have been using too low a dose. In the high-dose trials, greater benefit was seen in three trials with zinc acetate, and smaller benefit in five non-acetate trials [2]. Further research should focus, in particular, on high doses of zinc acetate (providing 80-90 mg/day of zinc) [2]. Thus, subgroup analysis is possible and it indicates a path to research that is needed. The syrup and tablet studies with children in the low-income countries should be presented as a separate group, on a separate Analysis table.

9) Pooling the adverse effects of all zinc trials is unsound: Eby has pointed out that the adverse effects of zinc lozenges, such as bad taste, can be explained largely by the differences in the composition of the lozenges [8-10]. In their Discussion, Singh and Das acknowledge this possibility: "the increased incidence of bad taste and nausea ... may have been related to the use of different ligands (gluconate, acetate) rather than to zinc itself." In addition, it is obvious that dissolving a high zinc dose lozenge slowly in the mouth causes different adverse effects compared with ingesting a low zinc dose tablet or syrup straight to the stomach. Nevertheless, Singh and Das combine the adverse effects of the tablet and the zinc lozenge trials together as if they could estimate a "universal adverse effect of zinc" in the dose range of 15 to 192 mg per day. Nevertheless, the lack of "mouth irritation" by zinc syrup in the Kurugol studies (Analysis 2.19) is fully uninformative for a reader who is interested in the possible adverse effects of zinc lozenges. Thus, it would be much more informative to summarize the adverse effects as text, instead of pooling the results of such different trials. In the most recent zinc acetate lozenge trial, there were no significant differences between the zinc and placebo groups in the occurrence of adverse effects although the daily dose was 92 mg (Prasad 2008). Thus, it seems possible to formulate zinc lozenges that have minimal adverse effects. Furthermore, a patient suffering from acute adverse effects such as bad taste can simply stop taking the lozenges, whereas those who don't suffer from such adverse effects could benefit from the lozenges. Although Singh and Das restrict their systematic review to treating the common cold, they should also take a look at other zinc literature for information about zinc safety. For certain patients, zinc has been administered at high doses, 150 mg/day, for therapeutic purposes for months [2,11-12]. On the basis of such long-term studies with high zinc doses, there does not seem to be any basis for assuming that treating the common cold for a week with high doses of zinc (80-90 mg/day) in the form of lozenges might cause unanticipated harm.

10) Credit should be given to earlier work on the same topic: In their Introduction, Singh and Das write "The last review of all available RCTs of zinc for the common cold was published in 1999", which is erroneous. Although it is not reasonable to discuss in detail all the earlier literature on the topic, the main reviews should be cited and briefly commented. Jackson's [13] and Caruso's [14] systematic reviews on zinc and the common cold were published after 1999. In the Discussion section, RevMan proposes a subtitle "Agreements and disagreements with other studies or reviews". Evidently, the same issue can be discussed under some other title. In any case, it would be important for Singh and Das to describe to what extent their review agrees and disagrees with the earlier reviews, such as [13,14]. If the conclusions do not differ from earlier reviews, then a new review does not increase our understanding about the topic. If the conclusions are different, then the reasons for the differences should be briefly discussed.

Submitter agrees with default conflict of interest statement:I certify that I have no affiliations with or involvement in any organization or entity with a financial interest in the subject matter of my feedback.

Reply 1) The Eby and Halcomb (2006) trial has been mentioned under "excluded studies" in the updated review.

2) The Petrus (1998) values in Analysis 1.1 has been replaced with these correct and accurate values in this updated review.

3) About the Al-Nakib (1987) trial, for the item “incomplete outcome data addressed?”, the assessment has been changed into “low risk” in the characterstics of study table. Again, for the Al-Nakib trial, “high risk” for “free of selective reporting?” has been justified in the updated review. Furthermore, regarding the “the severity of symptoms” outcome reported in Al-Nakib (1987) trial, it was not possible to analyse the data, as the same was not avialble and also the trial was conducted almost 26 years back. This might be the reason that, no meta-analysis till date has been able to pool this trial result. Regarding the the Smith (1987) trial, in the updated review it has been changed to “high risk” for the item “incomplete outcome data addressed?”. Regarding the inclusion of Smith (1987) trial in the meta-analysis, please go through the paragraph "dealing with the missing data". Regarding the inclusion of Weismann (1990) trial, it is a randomized trial, and previous meta-analyses (Jackson et al 2000, Hemilä 2011) has handled this as a randomized trial in their analyses. So, there is no point in excluding this trial or lebeling this as a "pseudo-randomized trial". Regarding, contacting the authors, we have already mentioned that we did not try to contact authors of the trials conducted 10 years back. Infact, this trial was conducted almost 20 years back. More details of the Weismann (1990) trial, Al-Nakib (1987) and Petrus (1998) trial have been given in the included studies table in the updated review. The "implications for practice” section has been modified and the sentence “We could not find any trials conducted in low-income countries, so our results cannot be applied to people living in low-income countries” has been removed.

FOI 26-3132 - Document 5

4) Regarding the exclusion of Eby trial (1984), please go through the inclusion criteria and dealing with the missing data section in the updated review. We have remoed the points like “subjective assessment” and "viral studies were not conducted”, as they are not stronger criterion to exclude the Eby (1984) trial. The other points made to exclude the trial are valid and >50% loss to follow up in any trial is not at all acceptable, even if the authors have tried to maintain the integrity of the data. So, we stand on our decision to exclude the Eby trial. Regarding the Turner (2000) trial, it has been included in the updated review.

5) Different methods of administering zinc have been analyzed separately in the updated review.

6) Regarding the duration of the common cold should not be dichotomized, we did not make any change. They are actually not visible, if somone does not really want to visualise them.

7) The duration of the common cold has been normalized so that the placebo group has length 100%. The changes have been made in the updated review.

8) Subgroup analysis has been carried out in the updated review.

9) Though pooling the adverse effects of all zinc trials is unsound, we still reported it as we thought it would be useful and is part of any systematic review. There is no clear cut mechanism postulated and all are assumptions how adverse events occur with zinc lozenges.

10) In the updated version, we have discussed about the earlier reviews by Jackson et al [2000] and Caruso [2007] under the subtitle “Agreements and disagreements with other studies or reviews”. Please go through them.

Zinc for the common cold feedback, 8 April 2014

Summary Were the Hirt and Mossad study that tested intranasal administration excluded from the analysis because of the route of administration? Or were there other reasons as well?

David Riley

I agree with the conflict of interest statement below: I certify that I have no affiliations with or involvement in any organization or entity with a financial interest in the subject matter of my feedback.

Reply We thank David Riley for the feedback on our paper. The Hirt and Mossad study that tested intranasal administration was excluded from the analysis because of the route of administration.

Regards, Dr Rashmi Ranjan and Dr Meenu Singh.

EMBASE (1974 to June 2012), CINAHL (1981 to June 2012), Web of Science (1985 to June 2012) and LILACS (1982 to June 2012).

We used the following search strategy to search CENTRAL and MEDLINE. We combined the MEDLINE search with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision); Ovid format (Lefebvre 2011). We adapted the search strategy to search EMBASE, CINAHL, Web of Science and LILACS (see search strategies below).

Appendix 2. Details of previous search strategy

We searched the Cochrane Central Register of Controlled Trials (CENTRAL) (*The Cochrane Library* 2010, Issue 2) which contains the Acute Respiratory Infections Group's Specialised Register, MEDLINE (1966 to May week 3, 2010) and EMBASE (1974 to June 2010). We combined the MEDLINE search with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision); Ovid format (Lefebvre 2009). See Appendix 2 for the EMBASE search strategy.

FOI 26-3132 - Document 5

Date	Event	Description
17 September 2016	Amended	This Cochrane Review was withdrawn in April 2015, and this withdrawal notice was updated in September 2016. See Published notes.

History

Protocol first published: Issue 1, 1999 Review first published: Issue 2, 1999

Date	Event	Description
30 April 2015	Amended	This review was withdrawn due to concerns raised via the feedback mechanism regarding the calculation and analysis of data in the review in April 2015. Whilst it is not unusual for reviews to be withdrawn, the editorial group took the view that it would be better to take a cautious approach and explore the source and calculation of data used in the analysis in more detail, rather than keep the review on the Cochrane Database of Systematic Reviews for the time being.
29 July 2014	Feedback has been incorporated	Feedback comment added to the review (number 7)
11 December 2013	Amended	Authors have readdressed their reply to the Feedback comment (number 6).
18 October 2013	Amended	Changes made in response to comments received from the Cochrane Editorial Unit
18 January 2013	New citation required but conclusions have not changed	Conclusion regarding the recommendation of zinc for the common cold remains unchanged.
18 January 2013	New search has been performed	Searches updated. Three new trials were included in this updated review (Turner 2000a;Turner 2000b;Turner 2000c) and two new trials were excluded (Eby 2006;Kartasurya 2012).
23 March 2012	Amended	Typographical errors to feedback comment amended.
9 January 2012	Feedback has been incorporated	Feedback incorporated.
7 September 2011	Amended	Authors' replies to Feedback comments added to review.
8 August	Feedback has been	

Characteristics of studies

Characteristics of included studies [ordered by study ID]

FOI 26-3132 - Document 5

Al-Nakib 1987

Methods	Double-blind, placebo-controlled randomised trial
Participants	Healthy adults 18 to 50 years
Interventions	Therapeutic trial: participants took 1 lozenge 2-hourly for 6 days Intervention group: zinc gluconate lozenges containing 23 mg zinc Placebo group: not stated Prophylactic trial: participants took 1 lozenge/2 waking hours for a total of 12 lozenges/day for 4.5 days. On the second day they were challenged with HRV-2 Intervention group: zinc gluconate lozenges containing 23 mg zinc Placebo group: not stated
Outcomes	Severity of symptoms Mean daily nasal secretions Total tissue counts Viral shedding Biochemical and haematological parameters Trial 1: urinary zinc levels
Notes	Although adults were stated to be healthy, no exclusion criteria were stated

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	High risk	Not described. Participants divided into groups balanced by age and sex
Allocation concealment (selection bias)	Unclear risk	The method of concealment was not described in detail to allow a definite judgement
Blinding (performance bias and detection bias) All outcomes	Unclear risk	Insufficient information to permit judgement of ‘low risk’ or ‘high risk’ of bias
Incomplete outcome data (attrition bias) All outcomes	Low risk	There were no drop-outs or withdrawals
Selective reporting (reporting bias)	High risk	1 or more outcomes of interest in the review were insufficiently reported so that they could not be entered in a meta-analysis
Other bias	Unclear risk	The zinc and placebo lozenges were gifted by RBS Pharma, Milan

FOI 26-3132 - Document 5

Douglas 1987

Methods	Double-blind, placebo-controlled randomised trial
Participants	Participants in the trial were healthy adults who had in the previous year participated in a study of interferon prophylaxis against rhinovirus infection
Interventions	Participants took 6 to 8 lozenges/day at 2nd-hourly intervals for a minimum of 3 days and maximum of 6 days if symptoms persisted. New course commenced after 2 weeks if symptoms persisted but type of treatment may differ. Consequently 33 zinc courses and 30 placebo courses Treatment group: zinc acetate lozenges containing 10 mg zinc Placebo group: lozenges contained sodium acetate
Outcomes	Duration and severity of symptoms (nasal, throat or cough) Viral cultures
Notes	The duration of the common cold was ≤ 2 days before starting treatment for 56 of the 58 participants. 2 zinc and 5 placebo treatment courses were excluded because lozenges had not been used for ≥ 3 days and at the rate of ≥ 4 per day. The SD value was not reported and was calculated from P value. The zinc lozenges contained high amount of tartrate; as a result zinc dissociates from acetate and binds instantly to tartrate

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Used sequentially numbered bottles
Allocation concealment (selection bias)	Low risk	Used blocked randomisation in blocks of 4. The code was broken twice (once in middle of study and then at the end of study)
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants and key study personnel ensured. It was unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All		Plausible effect size (difference in means) amongst missing outcomes was

FOI 26-3132 - Document 5

Farr 1987a

Methods	Double-blind, placebo-controlled trial
Participants	Healthy adults
Interventions	Trial 1: treatment consisted of initial loading dose of 2 lozenges 36 hours following inoculation with HRV-39, and thereafter 1 lozenge every 2 hours for a total of 8 lozenges/day for 5 days Intervention group: zinc gluconate lozenges containing 23 mg zinc Placebo group: lozenges contained 0.00125 mg denatonium benzoate Trial 2: treatment consisted of initial loading dose of 2 lozenges 2 hours following inoculation with HRV-13, and thereafter 1 lozenge every 2 hrs for a total of 8 lozenges/day for 7 days Intervention group: zinc gluconate lozenges containing 23 mg zinc Placebo group: 0.0025 mg denatonium benzoate
Outcomes	Severity and duration of symptoms Tissue counts Laboratory tests Infection rates
Notes	Exclusion criteria were symptoms of any respiratory illness in the week before the study, a history of hay fever, any familiarity with the taste of either denatonium benzoate or zinc, a history of any chronic disease, pregnancy, lactation or an unacceptable contraceptive method in women of child-bearing potential, and known abuse of habit-forming drugs

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Computer randomisation
Allocation concealment (selection bias)	Low risk	Each lozenge was wrapped in cellophane and packaged in an opaque polyethylene bottle bearing the study number, the participants' number, the treatment day and dosing instructions
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants and key study personnel ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias)		

FOI 26-3132 - Document 5

Godfrey 1992

Methods	Double-blind, placebo-controlled randomised trial
Participants	Participants were recruited from among Dartmouth College students and staff who spontaneously presented to the cold clinic at the College Health Service. Age ranged from 18 to 40 years. Inclusion required that the cold had lasted ≤ 2 days. Exclusion criteria were positive bacteriological throat culture, pregnancy, lactation and diabetes mellitus
Interventions	Participants took 1 lozenge every 2 hours for up to 8 hours a day Treatment group: zinc gluconate lozenges containing 23.7 mg zinc. Placebo group: lozenges contained tannic acid, glycine and calcium saccharinate in an orange-flavoured, boiled candy base
Outcomes	Frequency and severity of symptoms over 7 days
Notes	The mean duration of the common cold was 1.3 days at entry. 8 zinc and 6 placebo participants withdrew from the trial. The SD value was not reported and was calculated from t-value. The zinc lozenge contained glycine, which binds zinc tightly and therefore the free zinc ion level probably was much lower than suggested by the total zinc dose

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Random numbers table
Allocation concealment (selection bias)	Low risk	A pharmacist, using a randomisation table provided by the study statistician, packaged containers for individual participants with lozenges according to the production run number and subject identification number
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants and key study personnel ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	Low risk	Plausible effect size (difference in means) amongst missing outcomes was insufficient to have a clinically relevant impact on observed effect size
Selective		

FOI 26-3132 - Document 5

Kurugol 2006a

Methods	Double-blind, placebo-controlled trial	
Participants	The study was conducted at Ege University Nursery and Primary School including children aged 2 to 10 years. Children with chronic disease, immunodeficiency disorder, asthma and history of hypersensitivity were excluded	
Interventions	Therapeutic trial: children received syrup preparation of zinc twice daily for 10 days Intervention group: zinc syrup consisted of 1.32 g zinc sulphate in 100 cm^3 (15 mg of zinc in a 5 cm^3 spoonful) and glycerin, glucose, sunset yellow, orange essence, nipajin Placebo group: similar to above, but lacking the zinc component	
Outcomes	Duration and severity of cold symptoms	
Notes	Used zinc sulfate syrup. A total of 6 (3%) subjects discontinued, 4 for non-compliance and 2 for adverse effects due to medication	
Risk of bias		
Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Computer random numbers generator
Allocation concealment (selection bias)	Low risk	A statistical consultant programmed a computer-generated randomisation code and prepared the packages of medication
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	Low risk	Missing outcome data balanced in numbers across intervention groups, with similar reasons for missing data across groups
Selective reporting (reporting bias)	Low risk	The study protocol is not available but it is clear that the published reports include all expected outcomes, including those that were pre-specified
Other bias	Low risk	Berko Ilac Company, Turkey, supplied the active and placebo medications and digital thermometers. The company did not participate in designing the

FOI 26-3132 - Document 5

Kurugol 2006b

Methods	Double-blind, placebo-controlled trial
Participants	The study was conducted at Ege University Nursery and Primary School including children aged 2 to 10 years. Children with chronic disease, immunodeficiency disorder, asthma and history of hypersensitivity were excluded
Interventions	Prophylactic trial: children received syrup preparation of zinc once daily for 7 months. Intervention group: zinc syrup consisted of 1.32 g zinc sulphate in 100 cm^3 (15 mg of zinc in a 5 cm^3 spoonful) and glycerin, glucose, sunset yellow, orange essence, nipajin Placebo group: similar to above, but lacking the zinc component
Outcomes	Number of colds per study child Cold-related school absence Concomitant antibiotic use
Notes	Used zinc sulfate syrup. A total of 6 (3%) participants discontinued, 4 for non-compliance and 2 for adverse effects due to medication

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Computer random numbers generator
Allocation concealment (selection bias)	Low risk	A statistical consultant programmed a computer-generated randomisation code and prepared the packages of medication
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken

FOI 26-3132 - Document 5

Kurugol 2007

Methods	Double-blind, placebo-controlled trial
Participants	The study was conducted at Ege University Nursery and Primary School including children aged 1 to 10 years. The children who developed symptoms of common cold within the first 24 to 48 hours were registered in the study. Exclusion criteria were common cold symptoms for > 48 hours, immunodeficiency disorder, chronic disease, recent acute respiratory disease (diagnosed by a physician in the previous 2 weeks), zinc allergy, allergic disease or non-allergic rhinitis, positive culture for group A *Streptococcus* and a positive cell culture for influenza A or B viruses
Interventions	Participants were asked to take 1 spoonful of syrup twice a day for 10 days Treatment group: zinc syrup consisted of 1.32 g of zinc sulfate in 100 ml (15 mg of zinc in 5 ml spoonful) and glycerin, glucose, sunset yellow, orange essence and nipajin as preservative Placebo group: identical to above, but lacking the zinc component
Outcomes	Duration and severity of cold symptoms
Notes	Used zinc sulfate syrup. 9 children (3 in the zinc group and 6 in the placebo group) dropped out during the study period because of using antibiotics, decongestants or cough medicine

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Computer random numbers generator
Allocation concealment (selection bias)	Low risk	A statistical consultant programmed a computer-generated randomisation code and prepared the packages of medication. The packages were identical in appearance except for the randomisation numbers. The packages were randomly distributed by the study nurse
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition		

FOI 26-3132 - Document 5

Macknin 1998

Methods	Double-masked, placebo-controlled trial
Participants	Students were recruited from 2 school districts in Cleveland, Ohio. They were aged 6 to 16 years in grades 1 through to 12. Inclusion required that the cold had lasted for ≤ 24 hours. Participants were excluded if they had an oral temperature greater than 37.7ºC, had previously taken the zinc preparation, were pregnant, had a known immune deficiency, any acute illness other than common cold (e.g. pneumonia, gastroenteritis) or cold symptoms lasting more than 24 hours
Interventions	Students asked to take zinc lozenges, 10 mg, orally dissolved, 5 times a day (in grades 1 to 6) or 6 times a day (in grades 7 to 12) until their cold symptoms had been completely resolved for 6 hours Treatment group: zinc gluconate lozenges containing 10 mg zinc in a 3.75 g hard candy that also contained sucrose, corn syrup, glycine Placebo group: lozenges contained calcium lactate pentahydrate instead of zinc and had similar composition as above
Outcomes	Duration of resolution and severity of symptoms
Notes	The median percentage of prescribed lozenges taken was 82.5% in the zinc group. 2 students (1 in each group) provided false information at entry and were excluded from analysis. Mean and SD were not reported and were estimated from the figure. The zinc lozenge contained glycine, which binds zinc tightly and therefore the free zinc ion level probably was lower than suggested by the total zinc dose

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Computer random number generator
Allocation concealment (selection bias)	Low risk	A computer-generated randomisation code was provided to the pharmacist, who held the code and prepared the packages of medication
Blinding (performance bias and detection bias) All outcomes	High risk	Blinding of key study participants and personnel attempted, but likely that the blinding could have been broken

FOI 26-3132 - Document 5

Mossad 1996

Methods	Double-blind, placebo-controlled trial
Participants	Participants were recruited from among the Cleveland Clinic staff through announcements in internal clinic publications and by word of mouth. They were older than 18 years of age. Inclusion required that the cold had lasted for ≤ 24 hours. Exclusion criteria were pregnancy, immune deficiency or symptoms of the common cold for > 24 hours prior to interview
Interventions	Participants took 1 lozenge 2-hourly for every waking hour Treatment group: zinc gluconate lozenges containing 13.3 mg zinc Placebo group: lozenges contained 5% calcium lactate
Outcomes	Duration and severity of cold symptoms
Notes	Participants were assessed for non-adherence to treatment; reasons for non-adherence were: participants had taken antibiotics, condition diagnosed by physician to be other than the common cold, participants filled in diaries from memory, or insufficient lozenges were taken (i.e. fewer than 4 per day for the first 4 days). One participant in the zinc group withdrew from the study on the first day because she could not tolerate the lozenges. Mean and SD were not reported and were estimated from the figure. The zinc lozenge contained glycine, which binds zinc tightly and therefore the free zinc ion level probably was lower than suggested by the total zinc dose

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Computer random numbers generator
Allocation concealment (selection bias)	Low risk	A statistical consultant prepared a computer-generated randomisation code and the packages of medication
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data		

FOI 26-3132 - Document 5

Petrus 1998

Methods	Double-blind, placebo-controlled trial
Participants	Participants were recruited from the campus of the University of Texas through posted announcements. They were 18 to 54 years of age. Participants were excluded if they had a serious illnesses, organ transplants or disability (including HIV infection)
Interventions	Participants were instructed to use a lozenge every 1.5 hours while awake during day 0, then 1 lozenge every 2 hours while awake on following days while symptoms were present for 14 days or 6 hours after disappearance of last symptoms Treatment group: zinc acetate lozenges containing 9 mg zinc in a 2.7 g dextrose base Placebo group: lozenges contained sucrose octaacetate (0.169 mg)
Outcomes	Duration and severity of symptoms
Notes	One subject was lost to follow-up

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	High risk	Not described
Allocation concealment (selection bias)	Unclear risk	The method of concealment is not described or not described in sufficient detail to allow a definite judgement
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants and key study personnel ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	Low risk	The effect size among missing outcomes not enough to have a clinically relevant impact on observed effect size
Selective		

FOI 26-3132 - Document 5

Prasad 2000

Methods	Double-blind, placebo-controlled trial
Participants	Participants were students, staff and employees at Wayne State University, Michigan, who were ≥ 18 years. Inclusion required that the cold had lasted for ≤ 24 hours. Exclusion criteria were pregnancy, underlying immunodeficiency, chronic illness, symptoms of common cold for more than 24 hours, or had previously used zinc lozenges to treat common cold
Interventions	Participants were asked to use 1 lozenge every 2 to 3 hours while awake for as long as they had symptoms Treatment group: zinc acetate lozenges containing 12.8 mg zinc Placebo group: lozenges contained 0.25 mg of sucrose octaacetate, 6 mg of peppermint oil, 16 mg silica gel, 3877.75 mg dextrose DC and 100 mg glycerol monostearate
Outcomes	Duration of symptoms Plasma levels of zinc and pro inflammatory cytokines
Notes	Two participants in the placebo group dropped out on day 2

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Used randomisation code
Allocation concealment (selection bias)	Low risk	A research consultant prepared the randomisation code and the packages of medication
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	Low risk	The effect size among missing outcomes not enough to have a clinically relevant impact on observed effect size
Selective		

FOI 26-3132 - Document 5

Prasad 2008

Methods	Double-blind, placebo-controlled trial
Participants	Participants were students, staff and employees at Wayne State University, Michigan, who were ≥ 18 years. Inclusion required that the cold had lasted for ≤ 24 hours. Exclusion criteria were pregnancy, underlying immunodeficiency, chronic illness, symptoms of common cold for more than 24 hours, or had previously used zinc lozenges to treat common cold
Interventions	Participants were asked to use 1 lozenge every 2 to 3 hours while awake for as long as they had symptoms Treatment group: zinc acetate lozenges containing 13.3 mg zinc in a hard candy that contained 3.8 g of sucrose and corn syrup Placebo group: lozenges contained 0.25 mg of sucrose octaacetate
Outcomes	Duration of symptoms Plasma levels of zinc and pro inflammatory cytokines
Notes	No loss to follow-up

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Used randomisation code
Allocation concealment (selection bias)	Low risk	A research consultant prepared the randomisation code and the packages of medication
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	Low risk	The effect size among missing outcomes not enough to have a clinically relevant impact on observed effect size
Selective		

FOI 26-3132 - Document 5

Smith 1989

Methods	Double-blind, placebo-controlled trial
Participants	Participants were recruited from students from 3 colleges and from 1 family practice. They were older than 18 years. Participants were excluded if they had a serious acute or chronic medical condition, seasonal allergies, productive cough, required antibiotic therapy or had taken any treatment for symptoms within 8 hours of baseline assessment
Interventions	Participants took a loading dose of 4 lozenges then took 2 every 2 hours for 7 days or 24 hours after disappearance of last symptoms Treatment group: zinc gluconate lozenges containing 11.5 mg zinc Placebo group: lozenges contained sucrose octaacetate
Outcomes	Duration and severity of symptoms
Notes	Sixty-four subjects were excluded because of insufficient dose (< 10 lozenges on any day) or insufficient duration of therapy, and 2 were lost to follow-up. Mean and SD were not reported and were estimated from the figure

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Unclear risk	Insufficient information about the sequence generation process to permit judgement of ‘low risk’ or ‘high risk’
Allocation concealment (selection bias)	Unclear risk	The method of concealment is not described in sufficient detail to allow a definite judgement
Blinding (performance bias and detection bias) All outcomes	Low risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	High risk	The effect size among missing outcomes enough to induce clinically relevant bias in observed effect size
Selective reporting		

FOI 26-3132 - Document 5

Turner 2000a

Methods	Double-blind, placebo-controlled trial
Participants	Participants were recruited at 4 different study sites: IMTCI (Lenexa, KS), GFI Pharmaceutical Services (Evansville, IN), TKL Research (Paramus, NJ) and Research Across America (RAA; Dallas). They were 18 to 65 years of age Inclusion required that the cold had lasted for ≤ 1 calendar day (effectively < 36 hrs). Exclusions not described
Interventions	Participants took the lozenges every 2 to 3 hours (a total of 6 per day) while awake until cold symptoms resolved Treatment group: zinc gluconate lozenges containing 13.3 mg zinc Placebo group: lozenges contained tannic acid, sucrose octaacetate, quinine
Outcomes	Duration and severity of symptoms
Notes	Loss to follow-up not described. Analysis was based on intention-to-treat principle. Mean and SD were not reported and were estimated from the figure. The zinc gluconate lozenge contained glycine, which effectively binds to zinc and therefore the free zinc ion level probably was lower than suggested by the total zinc dose

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	Used drug randomisation code
Allocation concealment (selection bias)	Unclear risk	The method of concealment is not described in sufficient detail to allow a definite judgement
Blinding (performance bias and detection bias) All outcomes	High risk	Blinding of participants, key study personnel and outcome assessment ensured, and unlikely that the blinding could have been broken
Incomplete outcome data (attrition bias) All outcomes	Low risk	Loss to follow-up not described
Selective

FOI 26-3132 - Document 5

Vakili 2009

Methods	Double-blind, placebo-controlled trial	
Participants	School-aged Iranian children in the suburb of Mashhad. The age range was 6.5 to 10 years. The participants were free from chronic diseases, such as sickle cell disease or protein-energy malnutrition	
Interventions	Participants took tablet daily for 6 days a week for 5 months Treatment group: zinc sulfate tablets containing 10 mg zinc Placebo group: not defined	
Outcomes	Occurrence and duration of common cold	
Notes	Used zinc sulfate tablets. No loss to follow-up	
Risk of bias		
Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	High risk	Not described
Allocation concealment (selection bias)	Unclear risk	The method of concealment is not described in sufficient detail to allow a definite judgement
Blinding (performance bias and detection bias) All outcomes	Unclear risk	Insufficient information to permit judgement of ‘low risk’ or ‘high risk’
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up
Selective reporting (reporting bias)	Low risk	The study protocol is not available but it is clear that the published reports include all expected outcomes, including those that were pre-specified
Other bias	Low risk	This study was supported by grant of vice president for research, Mashhad University of Medical Sciences

FOI 26-3132 - Document 5

Weismann 1990

Methods	Double-blind, placebo-controlled randomised trial
Participants	6 general practitioners residing in the suburban area of Copenhagen conducted the study. Participants were aged 18 to 65 years. Excluded were pregnant and lactating women, diabetics
Interventions	Participants took 1 lozenge at 1 to 1.5-hourly intervals Treatment group: zinc gluconate lozenges (in maltitol syrup) containing 4.5 mg zinc Placebo group: lozenges contained maltitol syrup with natural flavour
Outcomes	Overall assessment of clinical condition assessed by participants using a visual analogue scale
Notes	14 participants were excluded because of a lack of records and 1 because of their young age. Mean and SD were not reported and were estimated from the figure. Consecutive allocation method was used in the study

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	High risk	Not described
Allocation concealment (selection bias)	Unclear risk	The method of concealment is not described in sufficient detail to allow a definite judgement
Blinding (performance bias and detection bias) All outcomes	Unclear risk	Insufficient information to permit judgement of ‘low risk’ or ‘high risk’
Incomplete outcome data (attrition bias) All outcomes	Low risk	The effect size among missing outcomes not enough to have a clinically relevant impact on observed effect size
Selective reporting (reporting bias)	Low risk	The study protocol is not available but it is clear that the published reports include all expected outcomes, including those that were pre-specified
Other bias	Unclear risk	The lozenges were manufactured and supplied by a firm

SD: standard deviation

Characteristics of excluded studies [ordered by study ID]

FOI 26-3132 - Document 5

Study	Reason for exclusion
Eby 1984	The trial was rated of poor methodological quality. A higher incidence of side effects and complaints in the zinc group may have reduced compliance with treatment (no information was provided on whether compliance with treatment was assessed). Intention-to-treat analyses were not conducted; analyses were only conducted on a subset of those originally enrolled in the trial. Inclusion criteria were not adequately addressed and therefore there may have been potential for selection bias to occur. In addition, no information was provided on how allocation to treatment groups was concealed, and the power of the study was not stated.
Eby 2006	Used both zinc gluconate nasal spray and zinc orotate lozenges simultaneously
Kartasurya 2012	Studied upper respiratory tract infection as a whole, used zinc supplementation for 4 months
McElroy 2003	Poor methodological quality. Not a randomised trial
Potter 1993	Poor methodological quality. Not a randomised trial
Veverka 2009	Poor methodological quality. Measured upper respiratory tract infection as a whole (common cold and seasonal flu)

Contributions of authors

Dr Meenu Singh (MS) and Dr Rashmi Ranjan Das (RRD) jointly prepared and edited the review.

None known.

Notes

September 2016 updated withdrawal notice This Cochrane Review was withdrawn in April 2015, and this withdrawal notice was updated in September 2016.

The review was withdrawn as result of comments submitted via the Cochrane Library by Harri Hemilä in February 2015. Hemilä identified multiple errors in this Cochrane Review and made allegations of plagiarism of text and data from a previously published systematic review (Hemilä H. Zinc Lozenges may shorten the duration of colds: a systematic review. *Open Respiratory Medicine Journal* 2011;5:51-58. dx.doi.org/10.2174/1874306401105010051). The comments referred to the version of this review first published in June 2013 (Singh M, Das RR. Zinc for the common cold. *Cochrane Database of Systematic Reviews* 2013;(6):CD001364. http://onlinelibrary.wiley.com/doi/10.1002/14651858.CD001364.pub4/full).

FOI 26-3132 - Document 5

The Cochrane Acute Respiratory Infections Group, which maintains the review, withdrew the review in April 2015, pending an assessment of the errors reported, and the group referred the allegations of plagiarism to the Editor in Chief. The Editor in Chief notified the authors of the concerns, and followed the Committee for Publication Ethics (COPE) guidelines.

Replication of text was identified in the Cochrane Review. This was limited to copying of short phrases and was acknowledged by the authors. The level of text plagiarism was minor and at a level that would be addressed by a correction. The Editor in Chief carried out further investigation into the alleged plagiarism of data, with the co-operation of the review authors, who provided supplementary information in support of their work. The allegations related to the derivation of means and standard deviations of data from some of the included studies. Although the authors acknowledge and cite the Hemilä 2011 review, the Editor in Chief considered that the authors' explanation regarding some similarities in presented data between the two reviews was not conclusive.

This version of the review will therefore remain withdrawn.

April 2015 withdrawal notice This review was withdrawn due to concerns raised via the feedback mechanism regarding the calculation and analysis of data in the review in April 2015. Whilst it is not unusual for reviews to be withdrawn, the editorial group took the view that it would be better to take a cautious approach and explore the source and calculation of data used in the analysis in more detail, rather than keep the review on the Cochrane Database of Systematic Reviews for the time being.

Abstract. In view of the emerging COVID-19 pandemic caused by SARS-CoV-2 virus, the search for potential protective and therapeutic antiviral strategies is of particular and urgent interest. Zinc is known to modulate antiviral and antibacterial immunity and regulate inflammatory response. Despite the lack of clinical data, certain indications suggest that modulation of zinc status may be beneficial in COVID-19. *In vitro* experiments demonstrate that Zn^{2+} possesses antiviral activity through inhibition of SARS-CoV RNA polymerase. This effect may underlie therapeutic efficiency of chloroquine known to act as zinc ionophore. Indirect evidence also indicates that Zn^{2+} may decrease the activity of angiotensin-converting enzyme 2 (ACE2), known to be the receptor for SARS-CoV-2. Improved antiviral immunity by zinc may also occur through up-regulation of interferon α production and increasing its antiviral activity. Zinc possesses anti-inflammatory activity by inhibiting NF-κB signaling and modulation of regulatory T-cell functions that may limit the cytokine storm in COVID-19. Improved Zn status may also reduce the risk of bacterial co-infection by improving mucociliary clearance and barrier function of the respiratory epithelium, as well as direct antibacterial effects against *S. pneumoniae*. Zinc status is also tightly associated with risk factors for severe COVID-19 including ageing, immune deficiency, obesity, diabetes, and atherosclerosis, since these are known risk groups for zinc deficiency. Therefore, Zn may possess protective effect as preventive and adjuvant therapy of COVID-19 through reducing inflammation, improvement of mucociliary clearance, prevention of ventilator-induced lung injury, modulation of antiviral and antibacterial immunity. However, further clinical and experimental studies are required.

1. Introduction

Zinc is an essential metal being involved in a variety of biological processes due to its function as a cofactor, signaling molecule, and structural element. It is involved in the

regulation of carbohydrate and lipid metabolism, as well as the functioning of the reproductive, cardiovascular, and nervous system (1). At the same time, the most critical role of zinc is demonstrated for the immune system. Briefly, zinc regulates proliferation, differentiation, maturation, and functioning of leukocytes and lymphocytes (2). Zinc plays a signaling role involved in the modulation of inflammatory responses (3). It is also a component of nutritional immunity (4). Correspondingly, alteration of zinc status significantly affects immune response resulting in increased susceptibility to inflammatory and infectious diseases including acquired immune deficiency syndrome, measles, malaria, tuberculosis, and pneumonia (5). Earlier data demonstrate that populational Zn status is associated with the prevalence of respiratory tract infections in children and adults (6,7).

In view of the high prevalence of zinc deficiency worldwide (up to 17%), its impact on population health is considered as a significant issue (8). Moreover, certain groups of people, including infants, especially preterm ones, and elderly, are considered to be at high risk of zinc deficiency and its adverse effects (9).

Under zinc deficiency condition, organisms are more susceptible to toxin-producing bacteria or enteroviral pathogens that activate guanylate and adenylate cyclases, stimulating chloride secretion, causing diarrhea and diminishing absorption of nutrients, thus exacerbating an already compromised mineral status. In addition, zinc deficiency may impair the absorption of water and electrolytes, delaying the termination of normally self-limiting gastrointestinal disease episodes (10). During chronic deficiency, the production of pro-inflammatory cytokines increases, influencing the outcome of a large number of inflammatory, metabolic, neurodegenerative and immune diseases (11). Diseases such as rheumatoid arthritis, diabetes (12), atherosclerosis and obesity (13), impaired cognitive function (14), as well as age-related macular degeneration (AMD) may be due to zinc deficiency, worsening chronic inflammation and triggering oxidative stress.

Coronaviridae were considered as the etiological agent in 6-29% of respiratory infections (15,16), although the severity of the disease varies significantly on the particular virus and its virulence (17). The viruses from the *Coronaviridae* family are zoonotic viruses that can be transmitted from animals to humans. The bat is considered the reservoir for these viruses, but other intermediate animals can also transmit the virus to humans (18). COVID-19 is a coronavirus disease caused by the novel 2019-nCoV virus (now called SARS-CoV-2) that appeared for the first time in Wuhan, China at the end of 2019 (19). Despite a close relation other two highly pathogenic coronaviruses, MERS-CoV and SARS-CoV (20), SARS-CoV-2 expanded to the majority of countries (21). On 11 March 2020, WHO characterized COVID-19 as a pandemic (22). Currently, the prevalence of COVID-19 exceeds 1,521,200 cases resulting in 92,700 deaths worldwide (23).

COVID-19 predominantly affects the respiratory system resulting in pneumonia and acute respiratory distress syndrome (24), leading to the requirement of mechanical ventilation (25). In turn, advanced age, acute respiratory distress syndrome (ARDS) and mechanical ventilation are known to be associated with higher COVID-19 mortality (26). The risk is also increased by modern life in which individuals are exposed to a multitude of chemicals, even in low doses that in the long-term predispose to chronic diseases and metabolic disturbances (27-31). Preexisting chronic metabolic diseases including diabetes, cardiovascular diseases (32), and obesity (33) are considered as risk factors for increased COVID-19 susceptibility and mortality. It is proposed that the elderly are at higher risk of COVID-19 due to impaired immune function (34).

Due to the clearly demonstrated role of zinc in immunity (2), and impaired zinc status in ageing (35), metabolic diseases including diabetes, obesity, and cardiovascular diseases (13), it is speculated that zinc compounds may be used as an adjunct therapy in COVID-19 treatment (36) for increasing antiviral resistance (37). Of note, zinc was earlier suggested as the potential agent for immune support and prevention of H1N1 influenza ('swine flu') (38).

In view of lack of clinical data on preventive and/or therapeutic efficiency of zinc in COVID-19, as well as primary involvement of the respiratory system, in this review, we will discuss recent clinical data on the role of zinc in protection against bronchopulmonary infections, as well as the existing indications of the direct impact of zinc on nCoV-2019.

2. Zinc and COVID-19

In view of the global COVID-19 pandemic, potential protective effect of zinc is of particular interest. Zinc is considered as the potential supportive treatment in therapy of COVID-19 infection due to its immune modulatory effect, as well as direct antiviral effect (36). However, the existing data will be only mechanistically discussed in this review, as direct data on anti-COVID-19 effects of zinc are absent to date.

Specifically, Zn^{2+} cations especially in combination with Zn ionophore pyrithione were shown to inhibit SARS-coronavirus RNA polymerase (RNA dependent RNA polymerase, RdRp) activity by decreasing its replication (39). These important findings demonstrate that Zn^{2+} may be considered as the particular antiviral agent in COVID-19 treatment. Of note, recent trials have indicated efficiency of chloroquine antiviral activity as a treatment of COVID-19 (40), although the intimate mechanisms of its antiviral activity require further investigation (41). Earlier findings demonstrate that chloroquine is a zinc ionophore increasing Zn^{2+} flux into the cell (42). Moreover, the authors also propose that chloroquine-mediate zinc influx may underlie anticancer activity of the compound (42). Similarly, it was hypothesized that increasing intracellular Zn^{2+} concentration by chloroquine may also mediate its antiviral effect against SARS-CoV-2. In this view zinc supplementation without chloroquine might have similar positive effects without adverse side-effects of chloroquine treatment (43). Hypothetically, such an effect may be also observed using other zinc ionophores like quercetin and epigallocatechin-gallate (44) with substantially lower toxicity, although clinical trials supported by experimental *in vitro* studies are required to support this hypothesis.

Another Zn-related approach to modulation of COVID-19 may include targeting Zn ions in the structure of viral proteins. Particularly, it has been demonstrated that disulfiram-induced Zn^{2+} release from papain-like protease in MERS-CoV and SARS-CoV resulting in protein destabilization (45). In view of

the presence of similar critical Zn-containing sites, Zn-ejector drugs (e.g., disulfiram) may be considered as potential antiviral agents (46) and components of targeted oxidation strategy in anti-SARS-CoV-2 treatment (47).

SARS-CoV-2 similarly to SARS-CoV requires angiotensin-converting enzyme 2 (ACE2) for entry into target cells (48). Therefore, modulation of ACE2 receptor was considered as the potential therapeutic strategy in COVID-19 treatment (49). Speth *et al* (50) demonstrated that zinc exposure (100 μM) was shown to reduce recombinant human ACE-2 activity in rat lungs. Although this concentration is close to physiological values of total zinc, the modulating effect of zinc on SARS-CoV-2-ACE2 interaction seem to be only hypothetical (51).

Although neither coronavirus HCoV 229E (52) nor HCoV-OC43 (53) infection caused a significant reduction in ciliary beat frequency, HCoV 229E induced ciliary dyskinesia resulting in impaired mucociliary clearance. The latter may not only alter viral particle removal, but also predispose to bacterial co-infection as observed for influenza virus (54). In turn, Zn supplementation was shown to improve ciliary length in bronchial epithelium of Zn-deficient rats (55), as well as increase ciliary beat frequency *in vitro* (56). Therefore, zinc may hypothetically ameliorate nCoV-2019-induced dysfunction of mucociliary clearance. Generally, zinc was shown to be essential for respiratory epithelium due to antioxidant and anti-inflammatory activity (57), as well as regulation of tight junction proteins ZO-1 and Claudin-1 (58), thus increasing its barrier functions. In turn, downregulation of tight junction protein complexes e.g., ZO-1 and Claudin-1 and reduction in barrier function aggravates viral and bacterial inflammatory processes (59). In addition, loss of TJ perm selectivity in the airways results in an un-controlled leakage of high molecular weight proteins and water into the airways, which results in the formation of alveolar edema and ARDS (60).

3. Zn and respiratory viruses

Despite limited data on the direct effect of zinc on SARS-CoV-2 and COVID-19, its antiviral effects were demonstrated in other viral diseases. Zinc was shown to have a significant impact on viral infections through modulation of viral particle entry, fusion, replication, viral protein translation and further release for a number of viruses including those involved in respiratory system pathology (37,61). Specifically, increasing intracellular Zn levels through application of Zn ionophores such as pyrithione and hinokitiol significantly alters replication of picornavirus, the leading cause of common cold (62). These findings generally correspond to the earlier indications of suppressive effect of zinc on rhinovirus replication originating from the early 1970s (63). In addition, Zn treatment was shown to increase interferon α (IFNα) production by leukocytes (64) and potentiate its antiviral activity in rhinovirus-infected cells (65). As antiviral activity of IFNα is mediated through JAK1/STAT1 downstream signaling and up-regulation of antiviral enzymes [e.g., latent ribonuclease (RNaseL) and protein kinase RNA-activated (PKR)] involved in viral RNA degradation and inhibition of viral RNA translation (66), recent findings allow to propose that these mechanisms may be stimulated by Zn^{2+}.

These findings along with the existing data on the role of zinc in immunity raised interest to the potential use of zinc in prevention and/or treatment of common cold. A systematic review by Singh and Das (67) published in Cochrane database revealed a significant reduction in common cold duration, as well as the incidence rate ratio of developing common cold (IRR=0.64 (95% CI: 0.47-0.88), P=0.006) in response to zinc supplementation. The results of meta-analysis demonstrated that Zn supplementation in the dose >75 mg/day significantly reduced duration of common colds (68), with Zn acetate being the most effective form (69).

Certain studies also revealed the association between Zn status and respiratory syncytial virus (RSV) infection. Particularly, it has been demonstrated that whole blood zinc was significantly lower in children with RSV pneumonia (70). Impaired zinc metabolism in perinatal alcohol exposure is associated with immunosuppression and altered alveolar macrophage activity resulting in increased susceptibility to RSV infection (71). In turn, Zn compounds were shown to inhibit respiratory syncytial virus replication and RSV plaque formation with a more than 1,000-fold reduction at 10 μm Zn preincubation (72).

It is also notable that zinc deficiency was associated with higher mortality and adverse long-term outcome in influenza-MRSA bacterial superinfection (73), also underlining the importance of considering the risk of bacterial coinfection.

Despite the presence of experimental findings on the protective effect of zinc supplementation against respiratory virus infections, clinical and epidemiological data are still to be elaborated and systematized.

4. Pneumonia in adults and the elderly

Zinc is essential for the immune system and elderly people have an increased probability for zinc deficiency (74). Low Zn status was considered as the potential risk factor for pneumonia in elderly. Particularly, subjects with high serum Zn (>70 μg/dl, i.e., approx. 10.8 μmol/l) were characterized by reduced incidence of pneumonia [0.52 (0.36, 0.76), P<0.001], as well as lower disease duration and antibiotic administration as compared to low-Zn (<70 μg/ml) group (75), being also related to all-cause mortality (76). Serum Zn levels were 15% lower in cases of community-acquired pneumonia and advanced age, being also associated with pneumonia severity as evaluated by CURB-65 scores (77). The incidence of severe pneumonia was significantly higher in Irani patients with low Zn status, although the mean duration of fever, tachycardia, and tachypnea only tended to be longer, although not significant (78). Correspondingly, serum Zn levels were found deficient at the onset of acute respiratory failure with the lowest values observed in septic shock patients. However, no association between serum Zn values and day-30 mortality or period of stay in intensive care unit was observed (79).

The results of systematic analysis also confirmed the efficiency of intake of at least 75 mg/day Zn in reduction of pneumonia symptom duration but not severity, with the response being more pronounced in adults than in children (80). At the same time, certain studies failed to reveal any improvement in pneumonia when administered along with standard antibiotic treatment, although the period of supplementation was only 4 days (81).

A detailed study by Boudreault *et al* (82) demonstrated that low plasma Zn predisposes to ventilator-induced injury in intensive care, being related to the role of metallothionein system in lung protection. These data corroborate the results of the experimental study demonstrating aggravation of ventilation-induced lung injury in Zn deficient rats (83).

In Indian patients high plasma zinc levels were found to be associated with reduced mortality from sepsis as well as lower 48-h SOFA scores (84). Moreover, persistent low serum Zn levels were associated with increased risk of recurrent sepsis in critically ill patients (85).

Altogether, the existing data demonstrate an association between zinc status and pneumonia in adults and elderly, as well as its complications including respiratory failure, ventilator-induced injury, and sepsis.

5. Pediatric respiratory infections

Initial reports have postulated nearly exceptional susceptibility of elderly to SARS-CoV-2 infection allowing to propose natural resistance to COVID-19 in children (86). However, detailed analysis of the pediatric COVID-19 cases (87) and the emerging Russian experience indicate that children may be also severely affected by SARS-CoV-2. In view of high incidence of Zn deficiency in infants, the existing data on the association between Zn status and pneumonia in children is also discussed.

High incidence of pneumonia in developing countries has been considered as the consequence of zinc deficiency in the population (7). The incidence of low serum zinc in children with severe pneumonia was 80% (88). Correspondingly, a 2-fold lower level of serum Zn was observed in pediatric acute lower respiratory infection patients (89). Significantly lower serum zinc levels were observed in children with pneumonia complicated by sepsis, mechanical ventilation, and cases of lethality (90). Generally, indications of low zinc status in children with pneumonia provide a rationale for preventive Zn supplementation.

Particularly, Zn supplementation in developing countries reduced pneumonia morbidity by 19% (RR=0.81; 95% CI: 0.73, 0.90), whereas a 15% decrease in pneumonia-specific mortality was not significant (91). A recent systematic review and meta-analysis published in Cochrane database demonstrated that Zn supplementation significantly reduced the incidence and prevalence of pneumonia in children by 13 and 41% (92).

In contrast to the demonstrated preventive effects of Zn supplementation, data on the therapeutic effect of zinc in treatment of childhood pneumonia are conflicting (93). Despite the earlier observed reduction of treatment failure risk (94) and case fatality [RR=0.67 (95% CI: 0.24-0.85)] (95) in children with severe pneumonia, a more recent study demonstrated that Zn supplementation in 2-24 months old children with radiologically verified pneumonia did not result in significant improvement of risk reduction of treatment failure (96). Moreover, Zn supplementation in Zn-deficient children with pneumonia until achievement of normal serum Zn levels did not improve clinical appearance of the disease (97).

A number of studies revealed the potential efficiency of Zn supplementation in prevention of non-specified acute lower respiratory infections including bronchitis, bronchiolitis, pneumonitis. Specifically, supplementation with 10 mg zinc gluconate in Zn-deficient children resulted in a nearly twofold reduction of the number of episodes of acute lower respiratory infections as well as the time to recovery (98). In addition, Zn supplementation (30 mg/day) in Thai children significantly reduced severity of acute lower respiratory tract infections resulting in faster disease cessation and shorter hospital stay (99). A detailed meta-analysis demonstrated that Zn supplementation significantly decreased the incidence of acute lower respiratory infection defined according to specific clinical criteria in children aged <5 years (100).

In parallel, the impact of Zn supplementation in relation to upper respiratory tract infections was also demonstrated. Particularly, the number of upper respiratory tract infections in Colombian children was reduced by 73% in response to supplementation with 5 mg Zn in a 12-month randomized clinical trial (101). Certain studies also revealed protective effect of zinc supplementation against both acute upper and lower respiratory diseases in children (102,103).

6. Zinc and lung inflammation

Inflammation plays the key role in COVID-19 pathogenesis both at local (pneumonia) and systemic (cytokine storm) levels, and the search for adequate anti-inflammatory agents is of particular importance (104).

Although the role of zinc in regulation of inflammatory response was discussed in detail in a number of reviews (2,5), certain aspects of the regulatory role of zinc in pneumonia pathogenesis and lung inflammation are still to be elucidated. However, the existing data clearly demonstrate that Zn ions may possess anti-inflammatory effects in pneumonia thus limiting tissue damage and systemic effects.

Specifically, Zn deficiency in rats resulted in a significant increase in proinflammatory TNFα and VCAM-1 expression and lung tissue remodeling, being partially reversed by Zn supplementation (105). Zn deficiency also resulted in a significant alteration of lung epithelial cell barrier function through up-regulation of TNFα, IFNγ, and FasR signaling and cellular apoptosis *in vitro* (106). Zn deficiency was shown to up-regulate acute phase response-related genes through stimulation of JAK-STAT signaling in lungs under septic conditions (107). Zinc and nitric oxide (NO)-metallothioneine (MT)-Zn pathways were shown to mediate lung injury in response to LPS or hyperoxia (108).

In turn, Zn pretreatment significantly reduced LPS-induced pulmonary endothelial cell damage and increased cell viability *in vitro*, as well as improved respiratory function as assessed by blood oxygen pressure and saturation (109). It has been demonstrated that Zn pretreatment significantly decreases LPS-induced neutrophil recruitment to the lungs thus reducing acute lung injury in mice (110).

It is also notable that zinc deficiency is associated with inflammatory alterations of lung extracellular matrix predisposing to fibrosis (111). This finding is of particular interest in view of the presence of interstitial pulmonary fibrosis in COVID-19 patients (112).

Certain studies revealed protective effect of zinc against lung injury in systemic inflammation including sepsis.

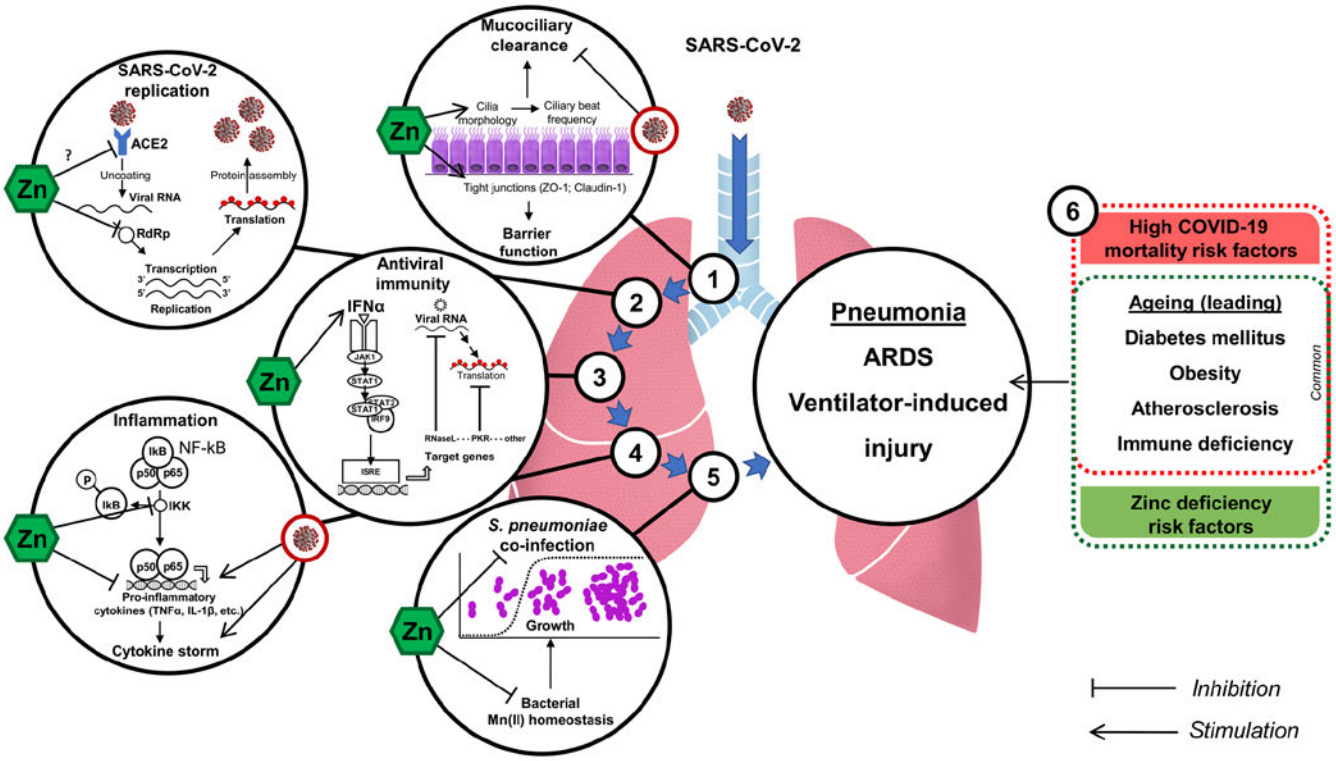

Figure 1. The proposed protective mechanisms of zinc in COVID-19. 1. Zinc significantly improves cilia morphology (54) and increases ciliary beat frequency (55) thus improving mucociliary clearance and removal of bacteria and virus-containing particles. By up-regulating tight junction proteins ZO-1 and claudin-1 (57) and increasing antioxidant activity of respiratory epithelia (56) zinc also increases barrier function of the latter. In turn, coronavirus infection was shown to impair mucociliary clearance (50) predisposing the lung for further viral and bacterial aggression. 2. Zinc may also possess antiviral activity through inhibition of RdRp and blocking further replication of viral RNA as demonstrated for SARS-CoV (38). Indirect evidence also indicates that Zn^{2+} may decrease activity of ACE2 (49), known to be the receptor for SARS-CoV-2 (47). 3. Modulation of antiviral immunity by zinc may also limit SARS-CoV-2 infection at least through up-regulation of IFNα production (63) and increasing its antiviral activity (64). The latter may be mediated through IFNα-induced JAK1/STAT1 signaling and up-regulation of antiviral proteins (RNaseL and PKR) known to degrade viral RNA and inhibit its translation (65). 4. Excessive inflammatory response resulting in overproduction of proiflammatory cytokines and cytokine storm is known to play a significant role in COVID-19 pathogenesis (103). In turn, zinc possesses anti-inflammatory activity through inhibition of IKK activity and subsequent NF-κB signaling resulting in down-regulation of proinflammatory cytokine production (122,124). Modulation of regulatory T-cell functions by Zinc may also limit excessive inflammatory response (125,126) as well as the downregulation of proinflammatory cytokine production (127,123). 5. Given a high risk of bacterial co-infection in viral pneumonia (128), Zn-induced inhibition of *S. pneumoniae* growth through modulation of bacterial Mn(II) homeostasis (137) may also be beneficial. 6. Zinc status is also associated with risk factors for high COVID-19 mortality. Specifically, ageing, immune deficiency, as well as metabolic diseases such as obesity, diabetes, and atherosclerosis, are known to be both risk factors for high disease mortality (31,32) and zinc deficiency (149). In turn, Zn supplementation may have beneficial effect in modulation of at least some of these risk factors. ACE2, angiotensin-converting enzyme 2; IFN, interferon; IKK, IκB kinase; NF-κB, nuclear factor-κB; ARDS, acute respiratory distress syndrome.

Experimental data demonstrate that Zn deficiency increases susceptibility to systemic inflammation and sepsis-induced organ damage including lungs in a murine model of polymicrobial sepsis (113). In a model of polymicrobial sepsis Zn deficiency resulted in increased NF-κB p65 mRNA expression and production in lungs resulting in up-regulation of target genes IL-1β, TNFα, and ICAM-1 (114), whereas Zn supplementation reduced neutrophil infiltration and MPO-mediated oxidative damage (115,116). Modulation of ERK1/2 and NF-κB pathways was shown to be critical for protective effect of zinc in lungs under septic conditions (117).

Correspondingly, patients with sepsis were characterized by low serum Zn levels that may occur due to increased ZIP8 (SLC39A8) mRNA expression. Moreover, serum Zn concentrations inversely correlated with both disease severity and proinflammatory cytokines IL-6, IL-8, and TNFα (118). Reciprocal regulation of ZIP8 and NF-κB expression in response to TNFα or LPS exposure was demonstrated in lung epithelia and alveolar macrophages (119). In addition, ZIP8-deficient mice were characterized by increased airway neutrophil infiltration and elevated CXCL1 and IL-23 production (120).

Zn-mediated respiratory protection was also demonstrated in models of toxic atmospheric pollutant exposure. Particularly, Zn deficiency in agricultural organic dust-exposed animals aggravated neutrophil migration and proinflammatory cytokine (TNFα, IL-6, CXCL1) overproduction, as well as increased IL-23 and CXCL1 expression by macrophages due to NF-κB activation (121). In turn, Zn supplementation in cigarette smoke exposed mice significantly reduced the number of alveolar macrophages in bronchoalveolar lavage (122).

The observed anti-inflammatory effects of Zn in lung tissue seem to be mainly mediated by inhibition of NF-κB signaling through PKA-induced inhibition of Raf-1 and IκB kinase β (IKKβ) (123,124) or A20-dependent inhibition (125). Moreover, Zn-induced modulation of T-cell activity may also play a significant role in limiting inflammatory response (126,127). Lastly, zinc was shown to normalize the overproduction of proinflammatory cytokines induced by zinc deficiency on the epigenetic level (124,128).

7. Zinc and *S. pneumoniae* infection

Although COVID-19 is characterized by viral pneumonia caused by SARS-CoV-2 virus, bacterial co-infection may represent a significant issue due its high incidence in H1N1 influenza-associated pneumonia (129). Specifically, human coronavirus NL63 was associated with increased adherence of *S. pneumoniae* to epithelial cells (130). In turn, *Streptococcus pneumoniae* infection is considered as the most common cause of pneumonia.

Zinc is an essential component of antibacterial immunity (5). Particularly, Zn deficiency was associated with reduced killing activity of phagocytes in pneumococcal infection (131). In turn, Zn supplementation ameliorated the association between nasopharyngeal *S. pneumoniae* carriage and acute lower respiratory infection in children (132). Zn deficiency also predisposed to impaired immune response to Pneumococcal surface protein A, increased nasal *S. pneumoniae* colonization, and severe pneumococcal infection in mice (133) resulting in shorter survival time after infection (134). Correspondingly, patients with better immune response to 23-valent pneumococcal polysaccharide vaccine were characterized by significantly higher serum Zn levels (135). However, no effect (136) or serotype-specific effect (137) of Zn on antibody production in response to polyvalent pneumococcal vaccine was observed. Zn may also exert toxic effect on *S. pneumoniae* reducing its growth through interference with Mn(II) homeostasis and development of cytoplasmic manganese deficiency (138). The latter, in turn, increases bacterial susceptibility to oxygen-dependent killing by neutrophils (139).

A number of studies demonstrated antibacterial effect of zinc oxide nanoparticles (140). Particularly, ZnO was shown to inhibit both growth and biofilm formation by *S. pneumoniae* (141). Similar effect was observed for other bacterial agents involved in etiology of pneumonia, including *K. pneumoniae* (142), methicillin-resistant *S. aureus* (143), and *P. aeruginosa* (144). However, the potential antibacterial application of ZnO-(NPs) may be limited due to their toxicity to human lung cells (145), as well as impairment of phagocytic activity of macrophages in bronchi and lungs (146).

When considering the relationship between *S. pneumoniae* and zinc, one should also note essentiality of Zn ions for bacteria. Specifically, adequate Zn uptake is required for normal bacterial growth and morphology, as well as colonization and virulence (147). Pneumococcal biofilm formation was also shown to be dependent on Zn bioavailability (148).

8. Perspectives and conclusions

The obtained data demonstrate that adequate zinc status of the individual increases immune reactivity. Correspondingly, inadequate zinc supply may predispose to infectious diseases of upper and lower respiratory tract. Although the therapeutic effects of Zn are considered as inconsistent, the existing evidence-based data indicate efficiency of Zn supplementation and improvement of Zn status in prevention of pneumonia and its complications due to anti-inflammatory effect of zinc.

Certain indirect indications of the potential antiviral effect of Zn against nCoV-2019 exist, although their biomedical relevance is yet to be studied. In view of recent data on clinical course of the disease, it appears that adequate Zn status may possess protective effect as adjuvant therapy of COVID-19 through reducing lung inflammation, improvement of mucociliary clearance, prevention of ventilator-induced lung injury, modulation of antibacterial and antiviral immunity especially in elderly (Fig. 1). Further clinical and experimental studies are strongly required to elucidate the potential role of Zn deficiency in COVID-19 susceptibility, as well as effects of Zn supplementation, and the underlying mechanisms.

Abstract

Background: Innovative approaches are needed to complement existing tools for malaria elimination. Ivermectin is a broad spectrum antiparasitic endectocide clinically used for onchocerciasis and lymphatic filariasis control at single doses of 150 to 200 mcg/kg. It also shortens the lifespan of mosquitoes that feed on individuals recently treated with ivermectin. However, the effect after a 150 to 200 mcg/kg oral dose is short-lived (6 to 11 days). Modeling suggests higher doses, which prolong the mosquitocidal effects, are needed to make a significant contribution to malaria elimination. Ivermectin has a wide therapeutic index and previous studies have shown doses up to 2000 mcg/kg (ie, 10 times the US Food and Drug Administration approved dose) are well tolerated and safe; the highest dose used for onchocerciasis is a single dose of 800 mcg/kg.

Objective: The aim of this study is to determine the safety, tolerability, and efficacy of ivermectin doses of 0, 300, and 600 mcg/kg/day for 3 days, when provided with a standard 3-day course of the antimalarial dihydroartemisinin-piperaquine (DP), on mosquito survival.

Methods: This is a double-blind, randomized, placebo-controlled, parallel-group, 3-arm, dose-finding trial in adults with uncomplicated malaria. Monte Carlo simulations based on pharmacokinetic modeling were performed to determine the optimum dosing regimens to be tested. Modeling showed that a 3-day regimen of 600 mcg/kg/day achieved similar median (5 to 95 percentiles) maximum drug concentrations (Cmax) of ivermectin to a single of dose of 800 mcg/kg, while increasing the median time above the lethal concentration 50% (LC50, 16 ng/mL) from 1.9 days (1.0 to 5.7) to 6.8 (3.8 to 13.4) days. The 300 mcg/kg/day dose was chosen at 50% of the higher dose to allow evaluation of the dose response. Mosquito survival will be assessed daily up to 28 days in laboratory-reared *Anopheles gambiae s.s.* populations fed on patients' blood taken at days 0, 2 (Cmax), 7 (primary outcome), 10, 14, 21, and 28 after the start of treatment. Safety outcomes include QT-prolongation and mydriasis. The trial will be conducted in 6 health facilities in western Kenya and requires a sample size of 141 participants (47 per arm). Sub-studies include (1) rich pharmacokinetics and (2) direct skin versus membrane feeding assays.

Results: Recruitment started July 20, 2015. Data collection was completed July 2, 2016. Unblinding and analysis will commence once the database has been completed, cleaned, and locked.

Conclusions: High-dose ivermectin, if found to be safe and well tolerated, might offer a promising new tool for malaria elimination.

Introduction

Ivermectin is a potential new tool that is being considered in malaria transmission reduction strategies [1]. Ivermectin is a broad spectrum antiparasitic endectocide active against a wide range of internal and external parasites. It was originally introduced as a veterinary drug, predominantly for use in domestic livestock, but since 1987 has been widely used in human medicine [2]. Ivermectin at a dose of 150 or 200 mcg/kg is the first-line treatment for *Onchocerca volvulus* (the cause of river blindness) [3], *Wuchereria bancrofti* (the cause of lymphatic filariasis) [4], and *Strongyloides stercoralis* (roundworm, an intestinal helminth) [5]. To date more than 2.7 billion treatments have been distributed as part of mass drug administration (MDA) [6].

Ivermectin has secondary effects on ectoparasites, such as head lice, mites, bedbugs, and scabies, that feed on recently treated individuals [2,7], and it is also active against *Anopheles spp*. at concentrations present in human blood after standard doses. It reduces the re-blood feeding capacity, female fecundity, hatch rate of their eggs, the survival of progeny larvae, and importantly, it reduces the vector's lifespan [1,8-11]. It may also inhibit parasite sporogony [12]. Ivermectin has a different mode of action from other insecticides, and therefore may be effective against mosquito populations that are resistant to insecticides used on long-lasting insecticidal nets (LLINs) or indoor residual spraying (IRS). Furthermore, it is able to kill exophagic and exophillic vectors that can escape the indoor killing effects of LLINs and IRS [8].

However, several studies have shown that the effects after the standard 150 to 200 mcg/kg doses of ivermectin are generally short-lived. Three *in vivo* studies assessed the long-term effect of ivermectin on mosquito survival by conducting feedings at least 7 days after administration of ivermectin [10,13,14]. A single low dose of 200 mcg/kg showed a 1.33 fold increase in mosquito mortality when fed on blood taken from humans who had received ivermectin 1 day earlier, but there was no longer an effect when mosquitoes were fed on blood taken on day 14 post-treatment [10], while a repeated dose of 200 mcg/kg given on days 0 and 2 showed a modest effect on reduced survival 7 days post-treatment [14], and a dose of 250 mcg/kg in a single human volunteer showed a potent effect for at least 2 weeks post-treatment [13]. Population-based studies of the effect of MDA with ivermectin on malaria transmission or mosquito survival showed that MDA with a single dose of 150 mcg/kg for the control of onchocerciasis in Senegal affected survivorship of *An. gambiae s.s.* for up to 6 days, resulting in an estimated reduction of malaria transmission for at least 11 days as a result of a change in the age-structure of *An. gambiae s.s.* [15-17]. Similarly, in 3 different West African transmission settings, this same dose reduced *An. gambiae* survivorship by 33.9% for 1 week, their parity rates for more than two weeks, and sporozoite rates by more than 77% for 2 weeks [18].

Modeling has also shown that adding 3 days of ivermectin (150 mcg/kg/day) to MDA with dihydroartemisinin-piperaquine (DP) would potentially provide an important boost to the effect of MDAs with artemisinin-based combination therapy (ACT) by allowing transmission to be interrupted faster and in areas with a higher malaria prevalence than MDA with ACTs alone [19]. However, the effects are modest, and higher doses, providing a longer effect are required for ivermectin to boost malaria transmission reduction activities [19].

Ivermectin 400 mcg/kg has been suggested as an improved treatment for head lice [20], and has been found to be safe and well tolerated [21]. No studies in humans have compared the effect of ivermectin doses above 400 mcg/kg on the ability of anopheline vectors to transmit malaria (henceforth referred to as infectivity), or evaluated the effect of any dose of ivermectin higher than 400 mcg/kg on mosquito survivorship.

Ivermectin has an excellent safety profile [1], and experience with higher doses show that it is remarkably well tolerated in humans [22-27], even at doses up to 2000 mcg/kg, 10 times the 200 mcg/kg dose currently approved by the US Food and Drug Administration [24] (Table 1). In invertebrates, ivermectin causes the opening of glutamate-gated chloride channels resulting in flaccid paralysis and death [28]. Glutamate-gated chloride channels do not exist in humans. Other weakly sensitive channels are found in the human central nervous system, but the blood-brain barrier limits drug access to these channels [29].

Kamgno 2004 [25-27]	800 mcg/kg	330	657 adult males with onchocerciasis in Cameroon	150[d] (327), 800[d,e] (330)	Transitory mild visual side effects, without structural abnormalities upon ophthalmological exam

[a]Preceded 3 days earlier by 150 mcg/kg or placebo.

[b]Preceded 13 days earlier by 800 mcg/kg.

[c]Repeated 3 times a week (days 1, 4, and 7).

[d]Repeated 3 times monthly or once yearly.

[e]Preceded 3 or 12 months earlier by 400 mcg/kg.

The only known severe adverse events have been in individuals with *Loa loa*, possibly due to rapid lysis of parasite biomass [30]. Assessment of *Loa loa* is recommended before ivermectin administration in areas endemic for *Loa loa* filariasis [31].

DP and ivermectin have, to the best of our knowledge, never been studied under simultaneous administration. Piperaquine, the long-acting component of DP, is metabolized by, and is an inhibitor of, cytochrome-P450 3A4 (CYP3A4) [32]. There is a potential for an increase of piperaquine plasma concentrations when it is co-administered with other CYP3A4 substrates (due to competition) or CYP3A4 inhibitors [32]. Dihydroartemisinin (DHA), the short-acting component of DP, is not metabolized by cytochrome-P450, but is deactivated via glucuronidation catalyzed by UDP-glucuronosyltransferases, in particular UGT1A9 and UGT2B7 [33]. DHA has been shown to induce CYP3A activity and also up-regulate CYP2C19 and CYP2B6 [33]. DHA is a known inhibitor of CYP1A2 [32].

Ivermectin is primarily metabolized by CYP3A4 [34]. *In vitro* studies using human liver microsomes suggest that ivermectin does not significantly inhibit the metabolizing activities of CYP3A4, CYP2D6, CYP2C9, CYP1A2, and CYP2E1 [34]. When DP and ivermectin are administered together, however, there may be some competition for CYP3A4. The CYP3A4-inhibitory properties of piperaquine may lead to an increased availability of ivermectin. As ivermectin is not a CYP3A4-inhibitor, the potential increase in the availability of piperaquine due to competition is expected to be low.

We will conduct a placebo-controlled dose-finding study to determine the safety, tolerability, and mosquitocidal effect of 3-day courses of ivermectin when given in combination with a standard 3-day course of DP to identify safe and practical regimens to boost the arsenal of available tools to reduce or interrupt malaria transmission. Pharmacokinetic data will be collected to facilitate the construction of a pharmacokinetic/pharmacodynamic (PK/PD) model to guide future study design.

Methods

Design Overview

This is a double-blind, randomized, placebo-controlled, parallel-group, 3-arm, superiority trial to determine the safety, tolerability, and mosquitocidal effect of different doses of ivermectin (ClinicalTrials.gov: NCT02511353). The primary endpoint will be mosquito survival 14 days after a blood feed from a patient who started ivermectin 7 days earlier; 5 days after the last dose of ivermectin with a 3-day regimen administering ivermectin at 0, 24, and 48 hours (days 0, 1 and 2). Because mosquito feeding involves approximately 100 mosquitoes per feed, the study will use a clustered design with the patient as the unit of randomization and the mosquito as the unit of analysis. The study will have a nested rich pharmacokinetic component in the first 36 patients that give additional consent for rich/frequent sampling and a sparse sampling population pharmacokinetic component in the remaining patients. A second nested study will compare the effects of ivermectin when assessed by membrane feeding versus direct skin feeding in all patients who give additional consent for direct skin feeding.

Primary Objective

The primary objective of the study is to determine the safety, tolerability, and efficacy of ivermectin doses of 0, 300 and 600 mcg/kg/day for 3 days, when provided with a standard 3-day course of the antimalarial DP, on mosquito survival.

Secondary Objectives

The secondary objectives of the study are (1) to determine the effect of different doses of ivermectin on oocyst development; (2) to determine the pharmacokinetic profile of the different ivermectin regimens; (3) to determine if ivermectin interacts with the pharmacokinetics of piperaquine; (4) to determine whether the addition of ivermectin to DP affects the clinical and parasitological response to DP treatment; (5) to determine the role of genetic variants of CYP3A4 activity in metabolizing

XSL•FO
Ren e

ivermectin; and (6) to determine the effect of direct feeding versus membrane feeding on mosquito survival.

Design Considerations

Rationale for Ivermectin Doses of 300 and 600 mcg/kg/day

The goal was to design and evaluate a high-dose ivermectin regimen that could be given daily as adjunct therapy to a 3-day ACT regimen and that builds on the existing safety data available from previous studies. The highest dose of ivermectin used in studies for onchocerciasis is 800 mcg/kg given as a single dose (ie, about 48 mg in an adult male weighing 60 kg). The pharmacokinetic profile of this 800 mcg/kg dose was used to design a 3-day regimen that would achieve a similar maximum drug concentration (Cmax) after the third dose. Since the highest dose of ivermectin used in humans that was tested and found to be well tolerated and safe is 2000 mcg/kg given as a single dose, this provides a large margin of safety allowing for inter-individual variation of pharmacokinetics. The middle group was chosen at 50% of the highest dose to allow for a dose response in terms of tolerance and efficacy.

Using existing literature data [24,35] we developed a pharmacokinetic model for ivermectin in humans. Using the parameter estimates from the model, Monte Carlo simulations were performed for 1000 theoretical participants assuming a 30% variability in parameter estimates (CL/F 11.8 L/h, Vc/F 195.0 L, Q 18.9 L/h, Vp 882 L, and Ka 0.24/h). The simulations showed that the Cmax associated with a single dose of 800 mcg/kg was estimated at 108 ng/ml and the 95% percentile as 164 ng/ml (Figure 1). A regimen of 600 mcg/kg/day for 3 days would give a similar Cmax (111 ng/mL) and corresponding 95% percentile (161 ng/mL) as the single dose 800 mcg/kg regimen (Figure 2 and Table 2). A regimen of 300 mcg/kg/day for 3 days would give approximately half those values. The 3-day regimens were predicted to increase the time that ivermectin concentrations remain above the lethal concentration 50% (LC50) of 16 ng/ml [12] from 46 hours with the 800 mcg/kg single dose to 86 and 162 hours, respectively, with the 300 and 600 mcg/kg/day regimens. The 16 ng/mL threshold was chosen as this was the median of 3 LC50 concentrations reported previously [12,14,15]. The simulated data were in excellent agreement with actual data observed in a dose-finding study by Guzzo et al 2002 [24], which indicated proportional pharmacokinetics at doses ranging from 30 to 120 mg, thus giving confidence in the parameters used in the simulations.

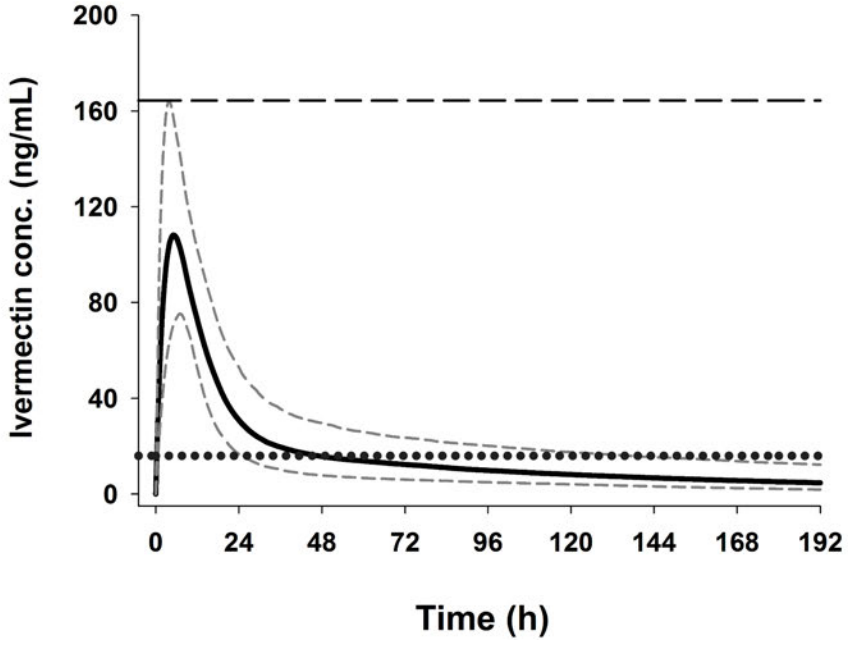

Table 2. Summary of simulated maximum drug concentration and time above lethal concentration 50%.

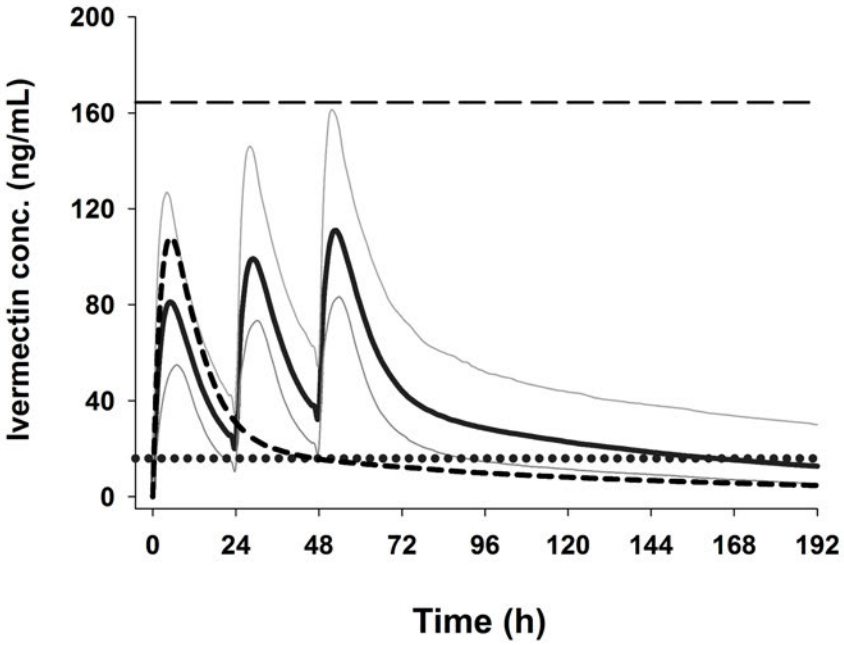
Ivermectin dosing regimen	Cmax[a] (median 5th-95th percentiles)	Days above LC50[b] (median 5th-95th percentiles)
800 mcg/kg single dose	108.1 (75.3-164.4)	1.9 (1.0-5.7)
600 mcg/kg/day for 3 days	111.0 (83.2-161.2)	6.8 (3.8-13.4)
300 mcg/kg/day for 3 days	55.4 (41.6-80.6)	3.6 (2.8-7.5)

[a]Cmax: maximum drug concentration (ng/mL).



[b]LC50: lethal concentration 50% (16ng/mL).

Figure 1. Simulated plasma concentrations of ivermectin 800 mcg/kg single dose. Monte Carlo simulation of 1000 theoretical subjects of ivermectin concentration with 800 mcg/kg single dose (median: solid line, 5th and 95th percentiles: dashed lines). Cmax is 108.1 ng/mL (CI 75.3-164.4). Time above LC50 (16 ng/mL; dotted line) is 1.9 days (CI 1.0-5.7).

XSL•FO
Ren e

Figure 2. Simulated plasma concentrations of ivermectin 600 mcg/kg/day 3-day regimen and 800 mcg/kg/day single dose. Monte Carlo simulation of 1000 theoretical subjects of ivermectin concentrations following 600 mcg/kg/day for 3 days (median: solid line, 5th and 95th percentiles: grey lines), achieving similar Cmax concentrations compared to 800 mcg/kg single dose (median: dash curve, 95th percentile of Cmax: dashed horizontal line). The median time above LC50 (16 ng/mL; dotted horizontal line) increases from 1.9 days with 800 mcg/kg single dose to 6.8 days with 600 mcg/kg/day for 3 days.

Parallel Versus Dose-Escalation Design

The proposed study uses a standard parallel design, comparing the 2 intervention arms with the placebo arm. This parallel design, instead of a dose-escalation design (when the lower dose group would be studied first prior to enrolling patients in the higher dose group), was considered appropriate because the Cmax levels and the 95th percentile concentrations in the proposed highest dose group of 600 mcg/kg/day will be equivalent to the Cmax found with single dose 800 mcg/kg, which has been administered to at least 402 patients before as treatment for onchocerciasis or as part of regulatory studies (see Table 1). Furthermore, with 30% variation assumed, the Cmax is estimated to remain well below the Cmax value obtained with 2000 mcg/kg, the highest dose tested and which was well-tolerated in a dose escalation study.

Why Patients with Malaria?

The study will enroll patients with symptomatic uncomplicated malaria, instead of asymptomatic patients with malaria parasites (carriers) or malaria negative individuals who are the predominant target population in MDA campaigns. However, it is unlikely that the mosquitocidal effect of ivermectin will differ much amongst these groups. Preference is given to symptomatic patients based on the rationale that this study is labor intensive, requiring very frequent patient follow-up and blood sampling, and thus requires a major commitment from study participants. Symptomatic patients, aside from similarly requiring antimalarial treatment, are more likely to favor hospital admission and frequent outpatient visits than asymptomatic patients or other volunteers. The frequent follow-up is potentially also more beneficial to the patients with symptomatic malaria than asymptomatic patients.

Justification for Host Genetic Studies

The cytochrome P450s (CYPs) are the major enzymes involved in drug metabolism. To be able to interpret variations in the pharmacokinetic drug profiles of piperaquine and ivermectin, and any drug interactions, we need to determine the genotypes of the genes encoding CYP enzymes (see above).

Direct Skin Feeding Versus Membrane Feeding

The primary endpoint is based on membrane feeding of mosquitoes using blood obtained by venepuncture from patients recently treated with ivermectin. However, a nested sub-study, in all those that give additional consent, will compare mosquito mortality rates between clusters fed using standard membrane feeding versus clusters fed directly (by allowing them to feed on the arm of the study participant). Ivermectin feeding studies with direct feeding on humans [13], and cattle [36], have shown a longer mosquitocidal effect (greater than 2 weeks) in comparison with studies using membrane feeding (less than 7 days) [14].

We hypothesize that direct feeding could result in higher mosquito mortality due to potential differences between venous blood (used in membrane feeding) and blood in subdermal venuoles and arterioles (the main source of blood for mosquitoes during direct skin feeding) due to drug accumulation in subcutaneous fat, dermal, and facial tissue (2- to 3-fold higher concentrations than in venous blood [37]), or increased exposure of the mosquito to ivermectin through other means like perspiration.

There have been no studies conducted directly comparing direct feeding versus membrane feeding on mosquito mortality following ivermectin administration. However, previous studies looking at infectivity (ie, the ability of the vector to develop oocysts and sporozoites after ingesting gametocytes) showed

XSL•FO
Ren e

FOI 26-3132 - Document 5

significant differences in terms of infectivity in favor of direct feeding (odds ratio 2.39) [38]. Although the mechanisms involved in infectivity studies may differ from studies addressing the killing effect of ivermectin, this recent infectivity study [38] indicates the importance of addressing the potential that the feeding method to expose mosquitoes to ivermectin may be an important effect modifier and that studies using membrane feeding may potentially underestimate the true effect of ivermectin.

Membrane feeding will be used as the primary outcome because direct skin feeding is labor intensive, may be unpleasant to the study participants, and result in higher refusal rates.

Study Setting

The study will be conducted in the Jaramogi Oginga Odinga Teaching and Referral Hospital (JOOTRH) in Kisumu, western Kenya, a major tertiary care hospital. Almost 25,000 outpatients are treated for clinical malaria at JOOTRH annually, of which one-third are laboratory-confirmed. Approximately 20% of these patients are 18 to 50 years old. Malaria positive individuals will also be pre-screened at 5 nearby health facilities; those that pass pre-screening and give consent will be brought to JOOTRH for screening and all further study procedures.

Eligibility Criteria

Inclusion and exclusion criteria for the study are shown in Textbox 1.

Textbox 1. Eligibility Criteria

Inclusion Criteria:

- Symptomatic, uncomplicated *P. falciparum* infection
- Positive malaria microscopy or malaria rapid diagnostic test (RDT, pLDH)
- Age 18 to 50 years
- Provide written informed consent
- Agree to be able to travel to clinic on days 1, 2, 7, 10, 14, 21, and 28

Exclusion Criteria:

- Signs or symptoms of severe malaria
- Unable to provide written informed consent
- Women who are pregnant or breast feeding
- Hypersensitivity to ivermectin or DP
- Rate corrected QT interval (QTc) of greater than 460 ms on electrocardiogram (ECG)
- Body mass index (BMI) below 16 or above 32 kg/m2
- Hemoglobin (Hb) concentration below 9 g/dL
- Taken ivermectin in the last month
- Taken DP in the last 12 weeks
- *Loa loa* as assessed by travel history to Angola, Cameroon, Chad, Central African Republic, Congo, DR Congo, Equatorial Guinea, Ethiopia, Gabon, Nigeria and Sudan
- History and/or symptoms indicating chronic illness
- Current use of tuberculosis or anti-retroviral medication
- Previously enrolled in the same study

Trial Medications and Interventions

Participants will be randomized to one of the following 3 arms: (1) the “0 mcg/kg” (placebo) arm consisting of DP plus ivermectin-placebo 600 mcg/kg/day for 3 days, (2) the “300 mcg/kg” arm consisting of DP plus ivermectin 300 mcg/kg/day and ivermectin-placebo 300 mcg/kg/day for 3 days, or (3) the “600 mcg/kg” arm consisting of DP plus ivermectin 600 mcg/kg/day for 3 days. Patients will receive their weight-based doses of DP and ivermectin/placebo. Each dose will be given as directly observed therapy by study staff, after which participants will be monitored for 30 minutes for any vomiting and adverse reactions. If vomiting occurs within 30 minutes, then the participant will be withdrawn from the study, DP will be re-administered, and no further ivermectin will be given.

Dihydroartemisinin-Piperaquine

DP was selected as the drug of choice as it is the most likely candidate to be used in future MDA campaigns because of the longer prophylactic effect against malaria (4 to 6 weeks) compared with 2 to 3 weeks with artemether-lumefantrine (AL). Each participant will receive a weight-based dose of DP 320/40 mg (Eurartesim, Sigma Tau, Italy) as per the product insert (36 to 75 kg: 3 tablets, greater than 75 kg: 4 tablets) once a day for 3 days.

XSL•FO
Ren e

FOI 26-3132 - Document 5

Ivermectin and Placebo

Ivermectin and/or placebo 6 mg tablets (Iver P, Laboratorio Elea, Argentina) will be administered per bodyweight. The 600 mcg/kg/day arm will receive only ivermectin tablets, the 300 mcg/kg/day arm will receive half the number of ivermectin tablets and an equal number of placebo tablets, and the 0 mcg/kg/day arm will receive only placebo tablets. All participants will receive the same total number of tablets once a day for 3 days based on their bodyweight (45 to 55 kg: 5 tablets, 55 to 65 kg: 6 tablets, 65 to 75 kg: 7 tablets, 75 to 85 kg: 8 tablets, 85 to 95 kg: 9 tablets, 95 to 105 kg: 10 tablets).

Endpoints and Outcome Measures

Primary Efficacy Outcome

The primary efficacy outcome is mosquito survival at 14 days after feeding on blood taken from study participants who started the 3-day ivermectin and DP regimen 7 days earlier (Multimedia Appendix 1).

Secondary Outcomes

Secondary outcomes include (1) mosquito survival at each day, up to day 21 or 28, after each feeding experiments performed at 0, 2 days plus 4h, 7, 10, 14, 21, and 28 days after start of treatment; (2) occurrence of oocysts from day 10 onwards after each feeding as determined by polymerase chain reaction (PCR); (3) malaria clinical and parasitological treatment response by day 28; and (4) plasma concentration profiles of piperaquine and ivermectin as described by standard pharmacokinetic metrics, for example area under the curve measurements from time zero to infinity (AUC0-), time zero to the time of the last measurable concentration (AUC0-tlast), Cmax, and plasma half-life, time to maximum plasma concentration, etc (Multimedia Appendix 1).

Tolerability and Safety Endpoints

Tolerability and safety endpoints are shown in Textbox 2.

Textbox 2. Tolerability and safety endpoints.

- Tolerability
  - Any adverse events assessed in general toxicity questionnaires asked at each study visit
- Safety
  - Primary
  - Mydriasis quantitated by pupillometry [24]
  - Secondary
    - Central nervous system (CNS) effects
    - General toxicity
    - Serious adverse events
    - Hemoglobin concentrations
    - QTc interval (see below “Electrocardiogram Monitoring”)

Participants’ Timeline

Overview Study Phases

The study plan and schedule of assessment is provided in Multimedia Appendix 1. The participant’s timeline will consist of a pre-screening visit (visit 1), consent, screening, and enrolment visit (visit 2), 2 subsequent treatment visits (3 and 4) on days 1 and 2, and 6 follow-up visits for assessment of efficacy parameters (visits 5 to 10). For those enrolled in the pharmacokinetic study additional visits for drug level sample are required as outlined in Multimedia Appendix 2.

Visits 1 and 2: Pre-Screening, Consent, Screening and Enrolment

Patients presenting to the outpatient departments of the study clinics will be pre-screened to determine if they meet readily apparent study eligibility criteria including (1) age 18 to 50 years; (2) uncomplicated malaria; (3) in Kisumu next 4 weeks; (4) hemoglobin (Hb) less than or equal to 9g/dL (if already performed); (5) not pregnant or breast feeding; (6) no known chronic illness; and (7) not previously enrolled in IVERMAL.

Patients passing pre-screening will be approached to obtain consent. For those consenting, study-specific screening procedures will take place, including demographics, full history, past medication use, travel history (*Loa* endemic countries), physical examination, electrocardiogram (ECG), pupillometry, and laboratory tests (to confirm malaria, Hb, and pregnancy). Those fulfilling all enrolment inclusion criteria and not meeting any exclusion criteria will be enrolled into the study, randomized, and treated with the appropriate tablets according to study arm (Textbox 1). Estimated duration is 1.5 to 2.0 hours.

Visits 3 and 4: Treatment Visits

Participants will return to the outpatient clinic on day 1 and 2 for the 2nd and 3rd dose of study drugs. In exceptional cases a participant will be permitted to take the study medication at home or the participant will be visited at home by study staff to administer the medication. A follow-up ECG will be taken just prior to and 4 to 6 hours after the last dose of DP plus ivermectin on day 2.

XSL•FO
Ren e

FOI 26-3132 - Document 5

Visits 5 to 10: Scheduled Follow-Up Visits

Participants will return to the outpatient clinic for follow-up as specified (see Multimedia Appendix 1). A questionnaire will assess the presence of signs and symptoms, including any adverse effects. A brief clinical examination will be performed and a venous blood sample will be taken for malaria diagnosis, Hb, and drug levels. On visits 5 (day 2 plus 4h) and 6 (day 7), drug levels will also be determined in a finger prick sample. A final follow-up ECG will be taken on the day 28 visit. Participants will be asked to provide telephone numbers so that study staff may make every effort to follow-up participants who have missed scheduled visits (Multimedia Appendix 2, section 8.5.5, page 31).

Unscheduled Visits

At any time, participants displaying signs or symptoms of severe malaria will be admitted to the inpatient ward for further evaluation and treatment free of charge. Blood samples for malaria smears, parasite genetics (filter paper dried blood spots) and Hb will be taken if clinically indicated (e.g. documented fever greater than or equal to 37.5°C axillary, or a history of fever in the last 24 hours).

Sample Size

The study requires a total of 141 participants (47 participants in the 0, 300, and 600 mcg/kg/day groups each). This is powered at 80% to detect a relative increase of 30% (RR 1.300) in the 14-day post-feeding mortality rate (primary outcome) from 24% in the control group (0 mcg/kg ivermectin) to 31.2% in the 300 mcg/kg/day group, and a 25% (RR 1.246) increase from 31.2% with 300 mcg/kg/day to 38.9% in 600 mcg/kg/day recipients, measured from blood taken 7 days after the start of intake of ivermectin and using clusters of 100 anopheline mosquitoes allowing for 10% non-feeders (alpha=.05). The same sample size would give 90% power to detect a 35% (RR 1.348) increase from 24% (0 mcg/kg/day) to 32.4% (300 mcg/kg/day), and 27.7% increase (RR 1.285) from 32.4% (300 mcg/kg/day) to 41.3% (600 mcg/kg/day). The calculations assume an intracluster correlation coefficient (ICC) of .0622 and allow for 6.5% loss-to follow-up of participants by day 7 (ie, 44 of the 47 patients per arm contribute to the primary analysis) [14]. The 10% non-feeding rate is based on current data from the same laboratories at Kenya Medical Research Institute (KEMRI), Kisian, Kenya. The 24% mortality rate estimate by day 14 post-feeding in the control arm is average of observation at KEMRI (18.3%) and in a recent study in Burkina Faso, which showed a 21.2% mortality by day 10 [14], which when extrapolated with 4 additional days predicted a mortality of 29.7% by day 14. The ICC value of .0622 was calculated using data from the recent study in Burkina Faso (Bousema, personal communications) [14].

Assignment of Interventions

Allocation

The study will use stratified randomization (4 strata) by body mass index (BMI: high/low) and sex (male/female) as these are important determinants of the pharmacokinetics of ivermectin [14]. The high/low BMI thresholds are 23 kg/m^2 and 21 kg/m^2, for females and males respectively. Participants will be randomly assigned to 1 of the 3 study arms. The study statistician will computer-generate a randomization sequence using permuted block randomization with fixed block sizes.

Blinding

The study will be double-blinded to participants and study staff. Allocation concealment will be achieved by use of sealed opaque envelopes. All study participants in all 3 arms will receive standard dose DP, and also active (600 mcg/kg/day arm), placebo (0 mcg/kg/day arm), or a combination of active and placebo ivermectin tablets (300 mcg/kg/day arm), such that each arm receives the same number of tablets in each weight strata.

Pharmacokinetic Studies

Overview

The first 36 patients to give additional consent for rich pharmacokinetics (approximately 12 per arm), will be enrolled in a rich pharmacokinetic study using frequent sampling per individual (26 samples per patient, see Multimedia Appendix 2 [Table 2, page 15]) to determine the detailed pharmacokinetic profile of the 2 regimens and assess whether any drug interaction occurs with piperaquine that is of clinical relevance. The remaining patients (approximately 35 per arm) will contribute to a population pharmacokinetic study consisting of sparse pharmacokinetic sampling with a maximum of 13 samples per patient including baseline (1 venous sample), 6 scheduled visits as part of the main trial (6 venous and 2 finger prick samples), and 2 extra visits for population pharmacokinetic sampling (2 venous and 2 finger prick samples).

The rich and population pharmacokinetic studies combined will allow us to determine the main sources and correlates of variability in drug concentrations (for both ivermectin and piperaquine), including demographic, pathophysiological, such as BMI and gender, and other factors that might alter dose-concentration relationships. As this is a placebo controlled trial, the sampling methodology for the 47 patients in the ivermectin-placebo arm will be identical to that used for the 300 and 600 mcg/kg arms. The patients in the placebo-ivermectin arm will allow us to determine the piperaquine kinetic profile in the absence of ivermectin.

Finger prick blood draws will be performed at a maximum of 4 time points in addition to the venous blood draws. The aim is to compare the capillary and venous drug concentration levels as it has been hypothesized that these might differ for ivermectin, similar to other drugs including piperaquine. A difference between capillary and venous drug concentrations could help further explain any observed difference in mosquito mortality between membrane and direct skin feeding (see also above “Direct Skin Feeding versus Membrane Feeding”).

Standard Pharmacokinetic Study (Rich Sampling)

All of the rich pharmacokinetic participants (approximately 12 per arm) will have venous blood sampled (4 ml whole blood to obtain 2 ml plasma, or 5.2 mL of whole blood if coinciding with a scheduled follow-up visit for the main trial) at baseline and each of 21 follow-up time points listed in Multimedia Appendix

XSL•FO
Ren e

FOI 26-3132 - Document 5

2 (Table 2, page 15). In addition, 4 finger pricks (0.5 mL whole blood) will be taken at days 2 plus 4 h, 3, 4 and 7. The total blood volume to be drawn from these patients is 98.4 mL whole blood over 28 days, 82.8 mL of which is taken during the first 10 days. If more than 2 patients withdraw from the study without giving more than 12 samples, the withdrawing patients will be replaced. Outpatients who consent to the standard pharmacokinetic study will be admitted in the hospital for the first 3 days.

Population Pharmacokinetics (Sparse Sampling)

Each of remaining patients (approximately 35 per arm), not enrolled in the rich pharmacokinetic sub-study, contribute to the population pharmacokinetic study, which consists of 13 sampling points (see Multimedia Appendix 2, page 15). Seven of the 13 time points coincide with the timing of the sample for membrane feeding (including the baseline sample), and thus do not require an extra venepuncture (ie, days 0, 2 [52 hrs; 4 hrs after last dose of ivermectin], days 7, 10, 14, 21 and 28). Six of the 13 time points are specific for the population pharmacokinetic study and will require an extra venepuncture (50, 54, 60, 72, 96 and 120 hours, ie, 2, 6, 12, 24, 48, and 120 hrs after the third and last dose of ivermectin). To ensure an equal distribution of samples across the different sampling time points for the extra 2 visits, participants will be divided into 4 extra sampling groups; each of which will contribute 2 extra time points, with the exception of group B which will contribute 1 extra time point (Table 3). In addition, a maximum of 4 finger pricks (0.5 mL whole blood) will be taken at days 2 plus 4 h, 7, and at each of the 2 population pharmacokinetic visits. Thus the total number of samples per participant will be 13 and involve a total of 46.4 mL of whole blood (including the 7 samples for the main trial). The sampling times will be noted in the case record form (CRF), and the patient given a reminder card to return to clinic at their allocated time.

Table 3. Schedule of extra sampling points for population pharmacokinetic study by 4 sampling groups.

Subject Group	Sample day[a] (plus hours after 3rd ivermectin dose)	Sample absolute time[a], hours	Number per sampling strata
A	2.08 (+2 hours)	50	9
	2.25 (+6 hours)	54	
B	2.25 (+6 hours)	54	8
C	2.50 (+12 hours)	60	9
	3 (+24 hours)	72	
D	4 (+48 hours)	96	9
	5 (+72 hours)	120	
Total			35

[a]Extra visits that need to be made specifically for the population pharmacokinetic samples. The other 7 visits contributing to the population pharmacokinetic analysis (days 0, 2, 7, 10, 14, 21, 28) coincide with the scheduled visits in the main trial. The first day is day=0; day 1 starts 24 hours after the first dose. The allocation to the sampling strata will be at random. However, if a participant indicates he/she is not able to attend a certain follow-up day, the strata can be replaced by another sampling schedule (within the same allocation strata, eg, for BMI, gender, etc) until all 15 or 16 allocations per sampling group have been used.

In anticipation of a 40% refusal rate or loss to follow-up, we estimate that the combined rich and population pharmacokinetic sub-studies will contribute 361 samples including 47 baseline samples (100%) and 314 (60%) follow-up samples out of a potential 524 follow-up samples across 22 sampling time points after baseline, 20 of which overlap, with a total of 12 to 47 observations per time point (see Multimedia Appendix 2,Table 2, page 15).

Laboratory Procedure

Mosquito Colonies

See the “Procedures for Assessing Efficacy and Safety Parameters” section above for use of mosquito colonies and procedures to assess the primary (mosquito survival) and secondary entomological endpoints (sporogony). The section below describes the maintenance of the mosquito colonies.

The mosquito colony used in this study will be *An. gambiae s.s.* Kisumu strain, originally from Kisumu, Kenya. The strain is maintained at the KEMRI/Centre for Global Health Research (CGHR) insectaries and is susceptible to all insecticides approved by the World Health Organization (WHO). When performing membrane feeds on infected human blood, mosquitoes will be kept and fed in cages or paper cups. The cages or paper cups will be kept in a temperature- and humidity-controlled insectary. The feeding and the storage of live infected mosquitoes will occur in sealed rooms with at least 2 doors and/or barriers separating the inner rooms from the outside. Mosquitoes will not be removed from their enclosures, with exception of the cage for oocyst determination. During transportation, live infected mosquitoes will be transported within paper cups that are covered with a moist towel and enclosed within locked cool-boxes to remove any chances of escape. The cool-boxes will only be opened within the confines of a double door insectary.

Ivermectin Plasma Concentration

The LC50 has been previously estimated using spiked blood (blood to which known concentrations of ivermectin are added) in membrane feeding assays [12,15]. We will test the concentration of ivermectin in human plasma in order to provide data for a pharmacokinetic/dynamic analysis to obtain estimates

XSL•FO
Ren e

of the 10-day LC50 and time post-treatment that the transmission blocking effects (on mosquito survival and oocyst rates) lasts.

Hemoglobin Testing

Hb will be tested using HemoCue (Angelholm, Sweden) photometers.

Thick and Thin Blood Smears for Malaria

Thick and thin blood films for parasite counts will be obtained and examined. Malaria parasites will be counted against 200 high power fields before a slide is declared negative [39].

Processing of Pharmacokinetic Samples

Plasma will be stored locally on site at -20°C or in liquid nitrogen and shipped to a central laboratory for storage at -70°C prior to batch analysis at the Liverpool School of Tropical Medicine. Samples will be shipped in dry ice to the laboratories in Liverpool, United Kingdom where the plasma concentrations of ivermectin and piperaquine will be determined using assays validated to international Food and Drug Administration (FDA) standards. Plasma concentration-time data will be used to evaluate pharmacokinetic parameters including CL/F (oral clearance), V/F (oral volume of distribution), and Ka (absorption rate constant) using population pharmacokinetic methods. Area under the curve (AUC) and half-life will also be calculated.

Statistical Methods

A study statistical analytical plan for the final analysis, that supersedes the study protocol, has been drawn up during the course of the study before the unblinding of data at database lock (see Multimedia Appendix 3).

Procedures for Assessing Efficacy and Safety Parameters

Membrane Feeding Procedure

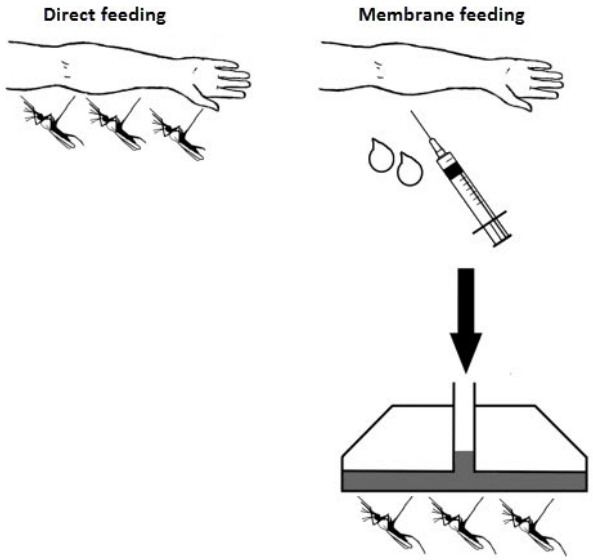
The following procedures will be conducted in accordance with a standard membrane feeding protocol [40]. A 1 mL sample of the participant's blood will be drawn into a sodium heparin (coated) tube pre-heated to 37.5°C. Within 2 minutes the blood will be placed in a glass bell membrane feeding system and cups of mosquitoes will commence feeding. For each feeding 3 new cups (2 cups for mosquito survival, and 1 cup for oocysts) of 50, 3 to 5 day old female, insectary-reared *An. gambiae s.s.* mosquitoes will be presented to the membrane feeder for 20 minutes. The number of mosquitoes with an engorged abdomen will be counted and those with lean abdomens discarded. Each day up to day 28 (mosquito survival cups) or day 10 (oocyst cup), the number of dead mosquitoes will be counted and removed. After the initial feeding on human blood, the mosquitoes will be kept in an incubator and maintained on sugar feeds. Insectary staff assessing mosquito survival and oocyst development will be blinded to all characteristics of the cups (ie, participant identification, study arm, duration between treatment and feeding, and feeding method).

Primary Efficacy Outcome

The primary outcome will be the survival of mosquitoes (from the 2 mosquito survival cups) at 14 days after feeding on blood taken from study participants who started the 3-day ivermectin and DP regimen 7 days earlier.

Secondary Efficacy Outcomes

Although the primary endpoint is assessed at day 14, the study will collect survival data of mosquitoes at each day up to day 21 or 28 for the mosquito survival cups and day 10 in the case of oocyst cups, after each feeding experiments performed at 0, 2 days plus 4h, 7, 10, 14, 21, 28 days after start of treatment. The methods will be identical to that described for the primary outcome where each day beyond day 14 the number of dead mosquitoes will be counted and removed until day 28 inclusive. The exact number of follow-up days (21 or 28 days) will be subject to logistical constraints of the laboratory, and mortality rates in the mosquito populations which will be further determined prior to the start of the study. The aim is to determine the median time to mortality, which requires that at least half of the mosquito population has died in each arm. It is anticipated that 21 days will be sufficient.



Direct Skin Feeding and Mosquito Survival

A sub-study will determine the effect of direct feeding versus membrane feeding on mosquito survival, after feeding experiments performed at 7 days after the start of treatment. In direct skin feeding assays, 1 cup of 50 mosquitoes is placed directly on the skin of the human host and allowed to feed for 15 minutes (Figure 3). Further procedures after direct feeding are identical to those after membrane feeding.

XSL•FO
Ren e

FOI 26-3132 - Document 5

Figure 3. Difference between membrane feeding and direct feeding (adapted from Bousema et al 2012 [38]).

Infectivity to Mosquitoes (Oocyst Polymerase Chain Reaction)

On day 10 post membrane feeding, when residual DNA from the blood meal is highly unlikely [14,41,42], all surviving mosquitoes in the oocyst cup will be preserved to determine oocyst prevalence by PCR. Mosquitoes will be homogenized and processed, in 2 pooled batches per cup.

Asexual Treatment Response and Parasite Clearance

Standard methods will be used to assess the in vivo treatment response to DP using the microscopy and rapid diagnostic test (RDT) data collected at each scheduled follow-up visit and criteria described by World Wide Antimalarial Resistance Network (WWARN) [43].

Pupillometry

In animal studies, mydriasis has been shown to be a first sign of ivermectin toxicity. To monitor for possible toxicity, pupil diameter size will be measured at baseline and each scheduled visit using a portable, single-button activation, battery operated hand-held pupillometry device that very accurately measures pupil size requiring no calibration (NeurOptics VIP-200 Variable Pupillometer). This device measures the pupil 30 times per second over a 5-second period and provides the average pupil diameter and standard deviation (+/- 0.1 mm). The measurements will be taken in a dark room with standardized lighting conditions.

Electrocardiogram Monitoring

Piperaquine can potentially lead to prolongation of the rate corrected QT interval (QTc) on an electrocardiogram (ECG). To exclude a possible interaction between ivermectin and piperaquine leading to an increased QTc interval, 12-lead ECGs will be performed to measure the QTc interval at baseline, day 2 pre last dose, day 2 at 4 to 6h post last dose and again at day 28. The day 28 sample is included as it can be difficult to assess a true baseline in patients with acute malaria, as malaria and fever are known to increase the heart rate and decrease the QTc interval. On day 28 most, if not all, patients will be malaria free and residual piperaquine levels low enough not to affect QTc intervals. A portable ECG machine (MAC 600, General Electric, US) will be used with automated ECG interpretation. Patients with a QTc value of 480 ms or greater prior to the last dose of DP will not receive the last dose of DP, but receive a full course of artemether lumefantrine instead. Fridericia's correction will be used to calculate the QTc values for final data analysis using the following equation: $QTc = QT/RR^{0.33}$.

Adverse Events

Adverse events and serious adverse events will be monitored, managed, and recorded during the course of the study. They will be recorded and tabulated for each treatment arm, overall, and per body system (see Multimedia Appendix 2, Section 9.6, Safety Monitoring and Reporting).

Ethics Approval and Consent to Participate

This protocol, the informed consent documents, and patient information sheets have been reviewed and approved by the Research Ethics Committees at KEMRI (protocol #2775), LSTM (protocol #14.002), and JOOTRH. The Centers for Disease Control and Prevention (CDC, protocol #6720) gave approval for reliance on the KEMRI institutional review board (see Multimedia Appendix 4 Ethics Approvals KEMRI, CDC, LSTM, and JOOTRH).

Results

Recruitment started July 20, 2015. Enrolment was completed May 2016, and clinical follow-up was completed 4 weeks later in June 2016. Mosquito follow-up was completed in July 2016, 4 weeks after completion of the clinical follow-up. Unblinding and analysis will commence once the database has been completed, cleaned, and locked.

Discussion

Principal Findings

New strategies for malaria control, and eventually for elimination are critically needed. This study will seek to answer the question as to whether higher doses of ivermectin (300 and 600 mcg/kg/day for 3 days) are well tolerated, safe, and result in longer durations of mosquitocidal effects than standard 150 to 200 mcg/kg single dose treatments. This study requires major infrastructure and collaboration, as it brings together the disciplines of clinical medicine, entomology, parasitology, pharmacokinetics, and pharmacogenetics in a clinical trial. For this study, 141 patients and 150,000 mosquitoes will each be followed for 28 days. For this reason, this trial has been placed at the KEMRI, CDC, and LSTM collaboration in western Kenya, a research site, which in collaboration with its partners, has been conducting research for over 35 years and has the capacity to undertake such a trial. An important possible limitation of this study is that it will enroll participants with symptomatic malaria, whereas possible future applications of high-dose ivermectin may involve MDA with ACT's targeting asymptomatic carriers and uninfected individuals in addition to symptomatic patients. Should this study show promising results, then the next step will be to evaluate safety, tolerability, and efficacy in younger age groups with the ultimate goal of testing its effect on malaria transmission when applied at the population level through MDA.

Conclusion

High-dose ivermectin, if found to be safe and well tolerated, could potentially complement existing tools for malaria elimination.

Acknowledgments

Many thanks to the members of the Trial Steering Committee (Teun Bousema, Kevin Kobylinski, and Brian Foy) and the Data Monitoring and Ethics Committee (Alejandro Krolewiecki, James Oloo, Timothy Collier, and Carlos Chaccour). Further thanks to the Mundo Sano Foundation and Elea Laboratories for donating the ivermectin, and NeurOptics for donating pupillometers. Finally, we would also like to thank Dr Juliana Otieno, Medical Superintendent, for accommodating the study at JOOTRH; Donald Tjia, Ophthalmologist, for supporting the study; and Jacco Veldhuyzen, Emergency Medicine Physician, for assisting in interpreting ECGs. This paper is published with the permission of KEMRI Director.

This study is funded by the Malaria Eradication Scientific Alliance (MESA), through a sub-grant from the Bill and Melinda Gates Foundation (BMGF). Neither MESA nor the BMGF has or will have any role in the design of the study, the collection, analysis, and interpretation of data, or in the writing the manuscript.

Authors' Contributions

FtK and MS conceived the study. MS, PPH, and FtK wrote the grant. MS, EO, and FtK drafted the protocol. DW provided statistical expertise and verified the sample size calculation. GA and SW conducted the Monte Carlo simulations to define the dosing regimen and further developed the pharmacokinetic sub studies. All investigators contributed to the refinement of the study protocol and approved the final version. MS and FtK drafted the manuscript. All authors read and approved the final manuscript prior to submission. The findings and conclusions in this paper are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Abstract

Background: On March 11, 2020, the World Health Organization (WHO) officially declared coronavirus disease 2019 a global pandemic. Ivermectin and Doxycycline against SARSCoV-2 under in-vitro conditions showed beneficial results. However, large population studies with this combination are not elaborately studied, which was the aim of our study.
Materials and Methods: A total of 122 patients admitted in a tertiary care centre, who tested positive for Reverse-transcriptase-polymerase-chain-reaction (RT-PCR) for SARS-CoV2 were included in the study and a total sample size of 100 patients was obtained after exclusion. 50 patients of the treatment group were treated with Ivermectin-Doxycycline combination.
Results: The results had shown a significant reduction not only in mean duration of hospital (3.70 ± 2.27 days vs 4.69 ± 2.3 days), but also in complete resolution of symptoms stay (6.67 ± 2.01 days vs 4.69 ± 2.3 days). In a small subset of 10 patients RT-PCR for COVID was tested on 10th day after the symptom onset in both the groups and there was no difference to be found. There was no significant difference in the side effect profile of either groups.
Conclusion: Our study supports the benefits of utilization of combination of Doxycycline and Ivermectin in mild to moderate COVID-19 infection in terms of early recovery based on the time for symptom resolution and the mean duration of hospital stay.

Key words

COVID19, SARS-CoV2, Ivermectin-Doxycycline, RT-PCR.

Veerapaneni Spoorthi, Surapaneni Sasank. Utility of Ivermectin and Doxycycline combination for the treatment of SARS-CoV-2. IAIM, 2020; 7(10): 177-182.

Introduction

After the origin of novel coronavirus (2019-nCoV) in December 2019 at Wuhan, On March 11, 2020, the World Health Organization (WHO) officially declared coronavirus disease 2019 a global pandemic, the prevalence of this virus had shown an exponential growth throughout the world [1].

Though Hydroxychloroquine was initially tried and multiple small trials showed marginal benefit, a recent meta-analysis showed that Hydroxychloroquine does not appear to offer significant benefits in terms of reducing the viral load, resolution of radiological findings, or progression of the COVID-19 and Hydroxychloroquine might be associated with increased all-cause mortality [2].

Recent study on Ivermectin against SARSCoV-2 under in-vitro conditions revealed that it can inhibit viral replication. The single treatment of this drug was able to reduce the SARS-CoV-2 virus up to 5000-fold in Vero-hSLAM cells bathed with Ivermectin within 48 hours. However, no further reduction was reported with further increase in time period i.e. up to 72 hours. Moreover, no toxicity was seen with the drug at any point of time [3]. Doxycycline acts on Zinc as part of their MMP complex, chelates it and also acts via reduction in pro-inflammatory IL-6 levels, hence may reduce the viral load [4].

Ivermectin-Doxycycline combination showed a trend toward superiority to the Hydroxychloroquine-Azithromycin combination therapy in the case of patients with mild to moderate COVID19 disease [5].

Materials and methods

A total of 100 patients admitted in a tertiary care centre, which tested positive for RT-PCR for SARS-CoV2 were included in the study.

Patients were seen at baseline for enrollment, initial data collection and treatment at day-0, and again for daily follow-up. Each day, patients received a standardized clinical examination and all clinical data were collected using standardized questionnaire.

Study variables collected on each patient included the following; patient demographics: age, gender; clinical characteristics: admission date, discharge date, length of stay (LOS), day of symptom resolution; comorbidities including: chronic lung disease, hypertension, asthma, chronic obstructive pulmonary disease (COPD), diabetes mellitus, immunodeficiency, and cancer (defined as active or past/ resolved). Additionally, intensive care unit (ICU) status and ventilator use at any point during admission, minimum O2 saturation level collected on day of admission in the emergency department. The duration and dosages of all therapies for COVID-19 were collected.

This prospective study was aimed to establish the efficacy of combination of Ivermectin and Doxycycline in the treatment of mild to moderate Covid-19 in India.

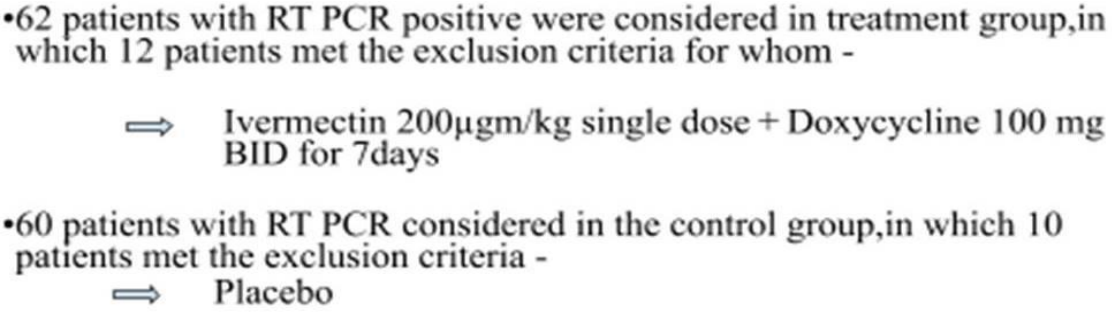
To study the outcome of the above mentioned drugs in at least 50 patients of covid-19 in comparison with the patients of covid-19 administered with placebos (Vitamin B6).

.

Inclusion criteria

- All patients diagnosed with Covid-19 by RT-PCR, with mild to moderate symptoms.
- Respiratory Rate < 24/min and SpO2 > 93% on room air.
- Absence of Oxygen support on admission.
- Duration of symptoms prior to admission ≤ 7 days.

Exclusion criteria



- Patients with a history of allergy to Ivermectin or Doxycycline
- Pregnant or lactating women.

Veerapaneni Spoorthi, Surapaneni Sasank. Utility of Ivermectin and Doxycycline combination for the treatment of SARS-CoV-2. IAIM, 2020; 7(10): 177-182.

- Patients with a history of chronic liver disease (SGPT > 3 times of normal value).
- Patients with a history of chronic kidney disease (eGFR <60 ml/min/1.73 m^2).
- Patients with a history of chronic heart disease.

This study was done on 122 patients taken as a study population (**Figure – 1**) and Ethical committee clearance was obtained.

Figure – 1: Group distribution.

Statistical analysis

The quantitative data were described as the mean ± standard deviation, or as the median (min − max). The qualitative data were described by number of cases (proportion, %). Patient characteristics were compared using the χ^2 test or Fisher's exact test for categorical data, and the Wilcoxon rank-sum test or Student's *t* test for continuous data. Potential influencing factors of viral clearance were analyzed by univariate and multivariate Cox regression models. A p value lower than 0.05 was required for statistical significance. All of the analysis was performed using SPSS Version 22.0.

Results

Out of 62 patients in the treatment group, 6 patients had a history of chronic kidney disease, out of which 3 were on Hemodialysis and all the patients had e GFR < 30 ml/kg/min/m^2, 2 antenatal patients along with 1 lactating patient, 2 had congestive heart failure and 1 had decompensated chronic liver disease with severe transaminitis.

Out of 100 patients, male population was slightly higher than the female population in both the groups, diabetics were slightly more in the placebo than in the treatment group. Very small number of patients had pulmonary issues, which were almost equal in both the groups (**Table – 1**).

The mean duration of hospital stay was 6.67 ± 2.01 days in treatment Group and 7.89 ±2.35 days and the entities were compared using unpaired t-test, which attained statistically significant (P = 0.01) as per **Figure – 2** and **Table - 2**.

Table – 1: Baseline characteristics of patients.

Patient baseline characteristics	Treatment group	Placebo group
Age (Median ± SD)	50.95 +_13.64	48.72+_13.42
Males	26 (52%)	28(56%)
Females	24(48%)	22(44%)

Veerapaneni Spoorthi, Surapaneni Sasank. Utility of Ivermectin and Doxycycline combination for the treatment of SARS-CoV-2. IAIM, 2020; 7(10): 177-182.

Figure – 2: Hospital stay and symptoms duration.

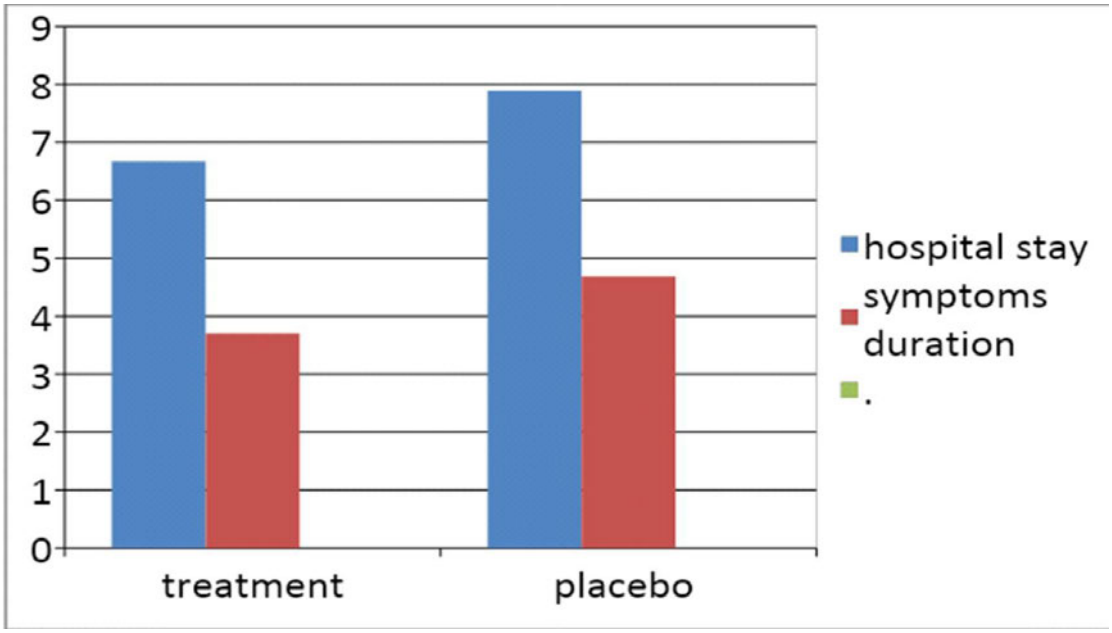

Table – 2: Hospital stay and symptoms duration.

	Mean +_SD	Mean +_SD	P value
Mean duration of hospital stay (days)	6.67 ± 2.01	7.89 ±2.35	0.01
Time for symptom resolution (days)	3.70 ±2.27	4.69 ±2.3	0.03

Table – 3: Side effects.

Side effects	Treatment group	Placebo group
Diarrhea	4	2
Vomiting	3	2
Pruritus	1	0

The duration for complete resolution of symptoms was 3.7 ± 2.27 days in the treatment Group and 4.69±2.3 days and a similar comparison between the either groups obtained statistically significant (P = 0.03). Comparison of side effects in both groups was as per **Table – 3**.

Discussion

Our findings are consistent with the benefits of utilization of combination of Doxycycline and Ivermectin in mild to moderate COVID-19 infection. The results have shown a significant reduction not only in mean duration of hospital (3.70 ± 2.27 days vs 4.69 ±2.3 days), but also in complete resolution of symptoms stay (6.67 ± 2.01 days vs 4.69 ± 2.3 days). These results were consistent with another study done at Bangladesh, where mean resolution of symptoms were around 5.93 days [6].

Compared to the prior studies, the cohort of our patients was elderly, with slight male predominance. The previous studies done similarly had a slightly younger age group of population.

In a small subset of 10 patients RT-PCR for COVID was tested on 10th day after the symptom onset in both the groups, there was no difference, with RT PCR being positive in 2 members of either groups on day 7 or positive in a single individual of each group on day 10. A recent multi-centric study compared to 1,918 conventionally treated patients, a survival benefit for Ivermectin mortality rate was observed. In the same study, the mean duration of symptom

resolution was reduced by 7.1 ± 2.1 days compared to those without Ivermectin. However, this study also included patients with respiratory failure [7].

Tetracyclines may be effective agents in the treatment of Covid-19 due to their ability to chelate Zinc compounds on matrix metalloproteinases (MMP) on which coronaviruses rely heavily for survival, cell infiltration, cell to cell adhesion and replication, many of which has Zinc as part of their MMP complex [3]. Ivermectin destabilizes the Impα/β1 heterodimer, via which the host cell antiviral response is reduced [8, 9].

In our study, the side effects of these drugs were reviewed and the common side effects included GI disturbances seen in 4 patients, however with the administration of proton pump inhibitors and regularizing the timing of the antibiotic after food intake, these side effects reduced after 2 days .1 patient had pruritus relieved with antihistamines .One patient in the treatment group expired after deteriorating on 5th day after he developed coagulopathy.

Our study had a few limitations, first the size of our sample was smaller, consisting of 100 patients only. Second all the patients could not be tested for RT PCR on the 10th day of symptoms, as most of them were discharged after symptomatic relief i.e., after around 7 days of admission.

Third, we could not consider patients with atypical covid symptoms such as diarrhea, acute gastritis [10] as we could not categorize them based on severity.

Conclusion

Our study supports the benefits of utilization of combination of Doxycycline and Ivermectin in mild to moderate COVID-19 infection in terms of early recovery based on the time for symptom resolution and the mean duration of hospital stay.

ABSTRACT

Objectives: This study aims to assess the efficacy of a combination treatment of doxycycline and zinc in the primary prevention of COVID-19 infection in Tunisian health care workers compared with two control groups.

Methods: We conducted a prospective, randomized, double-blind clinical trial over 5 months to determine the efficacy of a preventive combination treatment dose of doxycycline (100 mg/day) and zinc (15 mg/day), compared with a single-dose treatment with doxycycline versus placebo. The effectiveness of preventive treatment was measured by the significant decline in the number of cases of COVID-19 infection and/or a decrease in the viral load as determined by SARS-CoV-2 cycle threshold value using reverse transcription polymerase chain reaction tests.

Results: We detected a significant decrease of SARS-CoV-2 infection in the group that received both doxycycline and zinc compared with other participants. We also demonstrated that COVID-19 infection was neither associated with diabetes ($P = 0.51$) nor associated with hypertension ($P = 0.99$), asthma ($P = 0.52$), and chronic obstructive pulmonary disease ($P = 0.27$).

Conclusion: Our findings indicated that preventive therapy reduced the risk of SARS-CoV-2. These results suggest that the combination of doxycycline and zinc has a protective effect in patients with SARS-CoV-2 infection.

Introduction

Prevention of COVID-19 transmission and infection includes nonpharmacologic intervention and specific protection through chemoprophylaxis or immune prophylaxis (Agrawal et al., 2020). Since the 1970s, the protective efficacy of doxycycline has been demonstrated in the prophylaxis of malaria for travelers to endemic areas (Tan et al., 2011). In Tunisia, doxycycline has been widely used in the prevention of malaria for military personnel going on missions to endemic areas (Ajili et al., 2013). It has a low cost and a favorable safety profile and has been proposed as a treatment for COVID-19 (Malek et al., 2020). Doxycycline has been used as a curative treatment for COVID-19 in Brazil and India (Butler et al., 2021), whereas in the UK, it is recommended for suspected COVID-19 pneumonia in patients who are at high risk for adverse outcomes or where bacterial infection is suspected (Butler et al., 2021).

Zinc also has antiviral effects against certain viruses (Guo et al., 2004). In fact, zinc supplementation improves the mucociliary clearance, strengthens the integrity of the epithelium, decreases viral replication, preserves antiviral immunity, attenuates the risk of hyperinflammation, supports antioxidative effects, reduces lung damage, and minimizes secondary infections (Wessels et al., 2020).

The purpose of this study was to evaluate the efficacy and safety of doxycycline with or without zinc in preventing COVID-19 infection. The study focused on Tunisian health care workers (HCWs), and the outcome measures were the decreased number of infected cases with COVID-19 and/or the decrease in the viral load, as determined by the cycle threshold (Ct) values of the reverse transcription polymerase chain reaction (RT-PCR) tests for SARS-CoV-2.

Materials and methods

Patients and methods

We conducted a prospective, randomized, double-blind clinical trial for 5 months (from November 12, 2020, through February 10, 2021). The study was conducted at different military sites of investigation (Military Hospital of Tunis, Military Hospital of Bizerte, Military Hospital of Gabes), was registered in the clinical trial database (NCT04584567), and approved by the local ethical committee of the General Directorate of Military Health.

The study included consenting HCWs, aged between 20 and 65 years, who did not have signs or symptoms of respiratory infection (cough, fever >38.0°C, difficulty breathing, shortness of breath, chest pains), or other symptoms associated with COVID-19, such as faintness, myalgia, headaches, and nausea or vomiting.

The study excluded HCWs with positive SARS-CoV-2 RT-PCR results or positive SARS-CoV-2 serum tests (IgM or IgG). Positive SARS-CoV-2 RT-PCR was determined by a cycle threshold (Ct) value below 33, using the Xpress SARS-CoV-2 kit (Xpert, Cepheid, Sunnyvale, CA). The GeneXpert is a system that automates and integrates sample preparation, nucleic acid extraction, amplification, and detection of the target sequences using real-time RT-PCR assays. The real-time RT-PCR reagents, including primer N2, target the virus nucleocapsid phosphoprotein (N) gene for specific detection of SARS-CoV-2 and human nucleic acid. The Cepheid Xpert Xpress SARS-CoV-2 kit detects N2 and E gene, and solely N2 indicates positive results. The presence of only E indicates presumptive positive results, whereas the presence of only A Sample Processing Control (SPC) indicates negative results. The absence of all markers indicates an invalid result (Moran et al., 2020).

Ct is a value that can broadly classify the concentration of viral genetic material as low, medium, or high in a patient sample, using RT-PCR test. It tells us approximately how much viral genetic material is in the sample. A low Ct indicates a high concentration of viral genetic material, which is associated with high risk of infection. A high Ct indicates a low concentration of viral genetic material, which is associated with a lower risk of infection.

For the qualitative detection of antibodies against SARS-CoV-2, we used the Biosynex COVID-19 Ag+ BSS test (Illkirch-Graffenstaden, France).

Additionally, we excluded HCWs who had a known hypersensitivity to doxycycline or zinc. HCWs with comorbidities (gastric bypass, epilepsy, cardiovascular disease, renal failure) or being treated with vitamin A during the study were excluded. Women who were pregnant or nursing were also excluded.

Eligible participants were randomized in three parallel groups as follows:

Group A: doxycycline (100 mg/ day) and zinc (15 mg/ day) combined orally for 6 weeks.

Group B: doxycycline (100 mg /day) orally for 6 weeks.

Group C: placebo orally for 6 weeks.

Allocated study groups were randomly assigned by an interactive web response system (Dacima), using simple 1:1 nonstratified sequence and a block size of six. Allocation sequences are set automatically by the interactive web response systems software.

Doxycycline was manufactured by Philadelphia Pharmaceutical (batch number 12927222). Placebo was also produced by the same manufacturer (Philadelphia Pharmaceutical). Placebo contains the same excipients and no active substances. Zinc (zinc bisglycinate) was manufactured by Albion human nutrition (batch number F001).

The participants were screened 72 hours before enrollment. They were examined physically, tested for SARS-CoV-2 RT-PCR and serum test (IgM/IgG). All personal data were anonymized, and signed written informed consent forms were obtained before the beginning of the study. The participants were monitored at days 21, 42, and 49 after enrollment. At each follow-up visit, participants were asked about their medical compliance and drug safety, underwent a clinical examination, and had an RT-PCR with calculated Ct values. After screening for patient's eligibility, a balanced randomization was done on the same day by the investigator. Allocated study drug was provided to the patient by the Military Hospital Pharmacist, according to the allocation details provided by the interactive web response systems. The patient received the drug on the same day of the randomization. Study blindness was maintained by a blind allocation, and drugs bottles were labeled anonymously by the pharmacist. Statistical analysis of the database was performed with blinded groups. Unblinding was performed at the final statistical report review. The Dacima Clinical Suite software (Montréal, Québec, Canada) was used to collect the data and to randomize participants on the basis of the Food and Drug Administration 21 Code of US Federal Regulations part 11, Health Insurance Portability and Accountability Act, and International Conference on Harmonization requirements.

Study end points

The first end point of this study was to assess how doxycycline with low dose can be used as a preventive treatment to decrease the number of cases of COVID-19 in the active arms compared with the placebo. Participants for each randomized treatment arm (doxycycline-only or combined with zinc) were compared with placebo. The second end point was intended to quantify by RT-PCR the number of infected cases with COVID-19 and the viral ribonucleic acid load after each treatment.

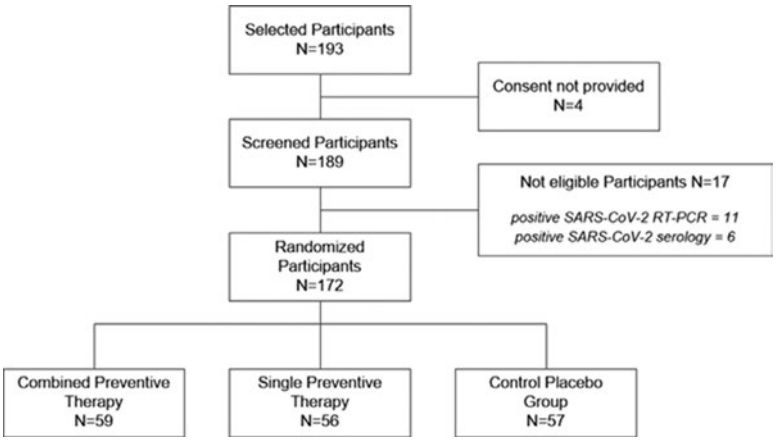

Figure 1. Design and analysis of the study. A total of 172 eligible participants were randomized into the three study arms: 59 in the combined doxycycline and zinc arm, 56 in the doxycycline-only arm, and 57 in the placebo arm. RT-PCR, reverse transcription polymerase chain reaction.

Sample size

Sample size was estimated by the Cochran-Armitage test for linear trend in proportions. Considering "a sample power of 80%", an expected proportion of the primary end point of 8% in group A, 10% in group B, and 14% in group C, with a confidence level of 95%. The expected sample size was estimated up to 1100 overall eligible subjects. However, due to the pandemic situation and the rush for nationwide vaccination against the SARS-CoV-2, the study was ended after including 172 randomized patients.

Evaluation

During the follow-up period (6 weeks), we monitored the SARS-CoV-2 infection by RT-PCR tests at days 21, 42, and 49. The last evaluation was done by day 49 to determine if a potential infection occurred after the treatment stopped at day 42.

Statistical analysis

For statistical analysis, qualitative data were described by frequency and percentage of valid values. Continuous variables were used to describe mean and standard deviation (SD). Chi-square, Mann-Whitney *U* test, and Kruskal-Wallis tests (one-way analysis of variance) were used to make inferential comparisons, with a 5% significance level as a threshold. Differences were considered significant if $P \leq 0.05$. No further statistical analysis was performed due to the study's premature interruption.

Results

From the 193 selected HCWs, 189 were screened. Four subjects declined to participate in the study. The screening phase excluded 17 subjects who were infected with COVID-19: positive SARS-CoV-2 RT-PCR (n = 11) and positive SARS-CoV-2 serology (n = 6). Participants were not symptomatic at the time of RT-PCR/serology testing at inclusion (Figure 1).

The remaining 172 eligible participants were randomized to one of the three study arms: 59 in the combined doxycycline and zinc arm (group A), 56 in the doxycycline-only arm (group B), and 57 in the placebo arm (group C).

The mean age was 38.4 ± 10.7 years (20 to 60 years). In groups A, B, and C, the average age was 38.0 ± 10.6, 38.5 ± 10.0, and 38.7 ± 11.4 years, respectively ($P = 0.934$) (Table 1).

The sex ratio was 1.6 (males = 5, females = 67), with no significant differences between the three study groups ($P = 0.143$). The study arms did not differ significantly for history of influenza (n = 43; 25.0%; $P = 0.927$), hypertension (n = 7; 4.1%; $P = 0.056$), diabetes (n = 4; 2.3%; $P = 0.162$), asthma (n = 2; 1.2%; $P = 0.590$), and chronic obstructive pulmonary disease (COPD) (n = 1; 0.6%; $P = 0.363$) (Table 1).

All participants worked at the Military Hospital of Tunis, which has been active since the beginning of the COVID-19 pandemic. Among the participants, there were different levels of exposure to COVID-19 infection in the workplace, including invasive bedside procedures with patients with COVID-19 (n = 40; 23.3%), intra-operative procedure (n = 19; 11.0%), and routine care (n = 113; 65.7%), with no significant differences between the studied arms ($P = 0.2$).

At the end of the study, a total of 24 subjects tested positive for SARS-CoV-2 (14.0%): 5 (8.5%) in group A, 5 (8.9%) in group B, and 14 (24.6%) in group C, with a significant difference between the three arms ($P = 0.018$) (Figure 2).

In the first group (group A), most participants (4 of 5) were asymptomatic, 1 participant developed symptoms with a persistent fever for 3 days. In the second (doxycycline-only) group (group B), 2 participants were asymptomatic and 3 developed moderate symptoms with fever, headache, and mild nonpersistent cough. In the third (placebo) group (group C), 6 of 14 participants developed symptoms such as fever, cough, and headache. For 2 of them, the cough was persistent, and corticosteroid treatment was prescribed. None of the participants in the three groups required oxygen (Table 2).

This difference was also found from day 21 of the follow-up, when 9 subjects tested positive for SARS-CoV-2 RT-PCR (5.2%), as opposed to 2, 0, and 7 in the A, B, and C groups, respectively ($P = 0.01$). Figure 2 shows the cumulative positive RT-PCR frequency trend among the three groups during the follow-up visits.

The average Ct for participants with a positive SARS-CoV-2 RT-PCR was 22.6 ± 4.7. Comparison between the study arms revealed a significant difference in Ct levels ($P < 0.001$), with the highest mean level of Ct in group A (29.0 ± 1.3), then group B (22.8 ± 4.0), then group C (19.4 ± 2.5). Table 3 shows Ct profiles of the three groups during the study.

We observed that a higher risk of COVID-19 infection was not associated with diabetes ($P = 0.51$), hypertension ($P = 0.99$), asthma ($P = 0.52$), or COPD ($P = 0.27$). Table 4 shows the patient's baseline profile according to SARS-CoV-2 infection. Four of the 24 infected participants had comorbidities. In the combined treatment arm, there were no participants with comorbidities. In the single treatment arm, there was 1 patient with diabetes and 1 with hypertension. In the placebo group, there was 1 participant with

Comparison between three groups using Kruskal-Wallis analysis. Results were considered significant if *P*-value <0.05

asthma and 1 participant with COPD. However, in the combined treatment arm, there were no participants with comorbidities.

The safety of the doxycycline/zinc intervention was also assessed during the study follow-up. The most common adverse events reported epigastralgia (n = 14) and nausea (n = 8). In term of side effects, the difference between studied groups were significant only for nausea ($P = 0.032$) but not for epigastralgia ($P = 0.249$) (Table 5).

Discussion

As of January 2022, there are 106 clinical trials underway for prophylactic alternatives to COVID-19, some of which involve antivirals, such as favipiravir or interferons (Ben-Zuk et al., 2021). To the best of our knowledge, this is the only study to evaluate the effect of doxycycline in patients infected with SARS-CoV-2.

In addition to its anti-inflammatory effects, doxycycline has also antiviral activity against several ribonucleic acid viruses *in vitro* (Gendrot et al., 2020). It also chelates zinc from metalloproteases (MMPs) (Sodhi and Etminan, 2020). As a result, their chelating activity may help to inhibit SARS-CoV-2 infection by limiting the virus' ability to replicate in the host, thereby acting as a prophylactic agent (Sodhi and Etminan, 2020).

There have already been some recommendations of doxycycline for COVID-19, particularly in patients with pneumonia and those who are at high risk for complications. There is now evidence of increased use of respiratory antibiotics, including doxycycline, during the COVID-19 pandemic in both the United Kingdom and United States (de Lusignan et al., 2021).

In this randomized, double-blind, placebo-controlled study, we compared doxycycline and zinc with only doxycycline or placebo as prophylaxis for COVID-19 in Tunisian HCWs.

In this trial, however, the results are underpowered (69.2%) because we were unable to meet the scheduled sample size, which was estimated at a total of 1100 samples. Moreover, the recruitment of HCWs remains difficult because the enrollment of patients overlapped with the vaccination campaign. The study recruited only 15.6% of the estimated sample size.

The prophylactic effect observed with doxycycline may be attributed to the fact that it inhibits MMPs. In fact, it has been

Values are presented as number (percentage).

demonstrated that coronaviruses exploit MMPs for a range of activities (replication, cell infection, and survival). Therefore, doxycycline may have an antiviral effect on SARS-CoV-2 (Dutta and Basu, 2011).

Researchers have suggested that doxycycline may delay COVID-19 progression through anti-inflammatory activities, including viruses that regulate the NF- κB pathway (nuclear factor kappa-light-chain-enhancer of activated B cells) and inhibit proinflammatory cytokine levels (interleukin 6 (IL-6), interleukin 1β (IL-1β), TNFα tumor necrosis factors (TNFα)) during acute respiratory distress syndrome (ARDS) in severely ill patients with COVID-19 (Anwar et al., 2020). Earlier studies demonstrated the effectiveness of chemically modified tetracyclines against SARS, preventing septic shock and ARDS development (Griffin et al., 2010). Additionally, several case reports suggest beneficial effects of doxycycline preventive treatment. In this context, a study demonstrated an improvement of clinical symptoms after treatment with standard doses of doxycycline in 4 patients with COVID-19 with a high-risk pulmonary disease (Yates et al., 2020).

Additionally, the combination of doxycycline and zinc also seems interesting because doxycycline has been shown to protect against lung infection by inhibiting MMPs, in which it is dependent on zinc (Doroszko et al., 2010). An interesting result of this clinical trial is the reduction in viral load in the combined group therapy (doxycycline and zinc) compared with other groups. This finding is supported by cumulative Ct values at day 49, which shows an inverse relationship with viral messenger ribonucleic acid (Supplementary Figure 1). These results are in agreement with other studies, which have suggested that Ct values are inversely associated with the viral load, and every threefold increase in Ct values indicates a 10-fold decrease in starting material (Tom and Mina, 2020). Low Ct values were also reported to be associated with virus growth in cell culture and infection (Platten et al., 2021). It is possible that the antiviral effect of zinc and inhibiting MMPs with doxycycline may help repair the damaged lung tissue, thus decreasing the virus' availability in the nasal tract and enhancing recovery.

The potential effect of combined therapy may be explained by the ability of doxycycline to catalyze Zn^{2+} ions, which are required for the activity of MMPs, independently of its antimicrobial properties (Castro et al., 2011). Doxycycline is the most potent tetracycline derivative inhibitor of MMPs, even at low doses (25 mg) (Castro et al., 2011). It may act as an ionophore by increasing intracellular zinc concentrations, suppressing viral replication, and strengthening the immune system (Griffin et al., 2010; te Velthuis et al., 2010). In addition to doxycycline's effects, zinc also has a beneficial role in protecting against COVID-19 infection. In fact, many reports have shown that zinc can inhibit the enzymatic activity and replication of SARS-CoV-2's ribonucleic acid polymerase and can inhibit angiotensin-converting enzyme activity (Ratia et al., 2006; Skalny et al., 2020). It was suggested that zinc can prevent fusion with the host membrane, decrease the viral polymerase function, impair protein translation and processing, block viral particle release, and destabilize the viral envelope (Wessels et al., 2020). Therefore, zinc has anti-inflammatory and antioxidative properties and underlying mechanisms, which have been the focus of numerous studies (Wessels et al., 2017).

In this study, we recruited 193 HCWs for 4 months (from November 2020 to February 2021). The percentage of HCWs who tested positive for COVID-19 was 21 (24%). A meta-analysis conducted during the first 6 months of the pandemic from January 1 to July 9, 2020 found a percentage of infected HCWs of 51.7% (Gholami et al., 2021). These results show that HCWs are at high risk for COVID-19 infection; thus, prevention strategies should be developed in this category. This will have a positive impact on patient's safety and could decrease the absenteeism level.

Our study was stopped after 4 months due to the start of the vaccination campaign, which prioritized HCWs (Kefi et al., 2021). We achieved 15.6% of the estimated sample size. Therefore, we recommend additional research on chemoprophylaxis that could enhance COVID-19 vaccine and litigation strategies to protect against COVID-19.

Although diabetes, hypertension, and asthma were considered COVID-19 risk factors (Gómez-Ochoa et al., 2021), they were not significantly associated with an increased risk of infection in the sample studied. Moreover, we did not consider the adherence of the HCWs to protective measures. The risk of COVID-19 infection directly depends on our physical preventive measures.

Despite the low number of participants in this study, the data suggest that a combined treatment of doxycycline and zinc may have a potential preventive effect. Public health suggestions can be made on the basis of this information for a wider adaptation of prophylaxis treatment in HCWs and the general population. Additional studies should be conducted considering vaccination laws.

FOI 26-3132 - Document 5

Conclusion

The only indication approved by the US Food and Drug Administration for the use of doxycycline in patients is as a malaria prophylaxis (<4 months). According to the portal *clinicaltrials.gov*, to date, there are not less than 405 clinical trials registered involving doxycycline, targeting different diseases, such as bacterial infections, cystic fibrosis, acne, vascular diseases, and HIV-AIDS. However, the prescription of long-term antibiotics must be cautious and supervised. Overuse is linked to bacterial resistance and alterations in gut microbiota, which have been related to risks of various chronic diseases. In this study, doxycycline combined or not with zinc has been used before the beginning of vaccination campaign. Nevertheless, this alternative therapy might be useful for certain HCWs and/or others who have comorbidities and are not responding to vaccines or have refused them.

Taking preventive measures decreased the risk of contamination by SARS-CoV-2. In this study, doxycycline and zinc were found to have a protective effect when taken together. Chemoprophylaxis can be used in conjunction with COVID-19 vaccination and personal protective measures, but more research is needed.

Abstract

Background. The emergence of COVID-19 in March 2020 challenged Zimbabwe to mount a response with limited medical facilities and therapeutic options. Ivermectin (IVM) had by then been safely used to treat a variety of human diseases affecting millions, as noted by the Nobel Committee in awarding its 2015 prize for medicine. Based upon early clinical indications of efficacy against COVID-19, IVM-based combination treatments were deployed to treat this infection in Zimbabwe.

Methods. Data were retrospectively analyzed for 34 severe COVID-19 patients treated with IVM-based combination therapy between August 2020 and May 2021, for whom pre- and post-treatment SpO2 values were all recorded on room air. Mortality and deterioration outcomes were also analyzed for a larger set of 92 severe COVID-19 patients receiving IVM-based treatment.

Results: For the 34-patient SpO2 tracking series, all but two patients had significantly increased SpO2 values after the first IVM dose, and all patients recovered. Mean increases in SpO2 as percentages of full normalization to SpO2=97 were 55.1% at +12 hours and 62.3% at +24 hours post-treatment. These results paralleled similar sharp increases in SpO2, all on room air, for a series of 24 RT-qPCR confirmed, mostly severe COVID-19 patients in the USA (California) who were given IVM combination treatment, all of whom recovered. For 19 of those patients having SpO2 $\leq$ 90 prior to IVM, the mean SpO2 normalization at +24 hours post-treatment was 65.2% as calculated from the SpO2 values reported. For our larger series of 92 severe COVID-19 patients in Zimbabwe, median age 53, only two died and two more deteriorated prior to recovery, far less than a predicted 7 deaths and 17 deteriorations for the demographics and risk factors of these patients.

Conclusions. The rapid, marked increases in SpO2 for both the Zimbabwe and California patients stand in sharp contrast to the decline in SpO2 and associated pulmonary function following onset of moderate or severe COVID-19 symptoms under standard care. These rapid SpO2 increases and low mortality rates support extended deployment of IVM treatment for COVID-19, complementary to immunizations for prevention.

Background

Evaluations of efficacy for COVID-19 therapeutics are challenging since most patients with this disease typically recover; the worldwide cumulative case fatality rate is 2% as of September 2021.[1]. Thus, randomized clinical trial (RCT) results are important, yet interpretations, for example, of the more than 20 mostly positive RCT results for COVID-19 treatment with the drug ivermectin (IVM), a macrocyclic lactone used widely worldwide since 1987, as summarized below, are controversial. Even for a drug such as remdesivir that was tested with several RCTs having large patient cohorts, opposite conclusions were drawn by the US FDA[2] and the World Health Organization[3] as to efficacy against COVID-19.

As a complement to positive RCT results for a COVID-19 therapeutic, a quantifiable determination of rapid, major improvement in pulmonary function, especially for severe COVID-19 patients, would further indicate efficacy and provide insights into that drug's underlying biological mechanism. The simplest indicator of lung function is blood oxygen saturation level, SpO2, as detectable using a pulse oximeter. However, the immediate administration of supplemental oxygen to any severe COVID-19 patient would typically preclude meaningful

pre-and post-treatment comparisons of SpO2 values. For this retrospective study conducted in Zimbabwe, ironically, challenges that constrained treatment capabilities also provided the opportunity to track changes in SpO2, all on room air, for 34 severe COVID-19 patients within 12 to 48 hours after beginning IVM treatment (see Figure 1). At the same time, these challenges tested whether severe COVID-19 patients with limited opportunities for hospitalization could be successfully treated at home or in clinics with rudimentary facilities.

Zimbabwe, a landlocked country in Southern Africa that shares a border with South Africa, had its first reported case of COVID-19 in March 2020.[4] Eight cases and one death from COVID-19 followed in the same month.[5] The first death occurred in the Wilkins hospital, Zimbabwe's main COVID-19 treatment center in the capital city of Harare. Facilities were limited at this hospital at the time; no capacity for ventilation was available. Given the rapid increase in COVID-19 patients in Harare after March 2020,[6] additional medical facilities began treating them.

COVID-19 wards were created at a general practice clinic by converting two staff rooms into a 4-bed ward and a storeroom into a 2-bed ward. Available equipment included several oxygen cylinders, an oxygen concentrator, six beds, and three monitors for SpO2 and blood flow parameters. The staff consisted of the lead author and another primary care physician who was off duty for several weeks after being injured in a vehicle accident on July 27, 2020, and either one or two nurses at different times, each on 12-hours shifts. During the initial months of the pandemic, in the absence of proven therapies and protocols, the standard of care evolved through early August 2020 to include corticosteroids, clopidogrel, aspirin, enoxaparin, rivaroxaban, a nebulized nano-silver preparation, zinc sulfate, hydroxychloroquine, azithromycin, doxycycline and in some cases an IV antibiotic.

However, the efficacy of these treatments was found to be limited, and by the end of July 2020, several COVID-19 deaths were recorded in the country. Based upon reports of initial success using IVM for COVID-19 treatment from colleagues in Johannesburg, South Africa, the College of Primary Care Physicians of Zimbabwe (CPCPZ) adopted and included IVM in their COVID-19 treatment protocol from August 8, 2020, starting initially with a 10-12 mg stat dose. Treatment of COVID-19 with IVM continued after the first patients showed improved outcomes, with more rapid recoveries achieved at doses higher than the standard of 200 ug/kg as initially used.

In August 2020, after it became apparent that IVM added to standard of care was significantly reducing the death rate, together with the hospital system being overwhelmed, CPCPZ physicians decided to treat COVID-19 patients where an IVM-based protocol could be administered, including at local general practice clinics which had nursing care and oxygen, and at some patients' homes with nursing support and oxygen supplementation as available. As knowledge of this successful treatment regimen spread in Zimbabwe, other physicians began offering the same treatment, with improved outcomes, which led to the formation of the Zimbabwe COVID Front Line Clinicians Society.

IVM for COVID-19 treatment

The decision to include IVM in COVID-19 treatment protocols in Zimbabwe was made as the pandemic swept through that nation, overwhelming limited clinical care facilities, with no drug developed to treat COVID-19

being generally accepted as effective. A published case-controlled study of IVM treatment for COVID-19 conducted at four US hospitals[7] that had been initially released in a preprint in June 2020 found a 40% reduction in mortality among 173 patients treated with low dose IVM vs 107 case-matched controls (15% vs 25.2% deaths). Interest in IVM was supported by its Nobel prize-honored pedigree and its extensive use to treat a variety of human diseases in over 3.7 billion doses worldwide since 1987.[8–10] Another favorable characteristic of this drug is its extraordinary record of safety, well tolerated at high doses,[11,12] including in studies for COVID-19 treatment.[13,14] It is generally non-toxic even at doses far exceeding the therapeutic range.[15,16] Since August 2020, inpatient and outpatient treatments of COVID-19 with IVM have been applied across 25 countries,[10] with more than 20 RCTs conducted for IVM treatment regimens.[10,17,18]

Seven of nine meta-analyses of these RCTs for IVM treatment reporting in 2021, all conducted using Cochrane analysis methodology, found significant[18–22] or possible[23,24] indications of IVM efficacy, with a mean 0.33 relative risk (RR) of mortality vs controls. Most of these 20 RCTs for IVM treatment of COVID-19 showed statistically significant mortality reductions or other clinical benefits. Among the most recent and detailed of the nine meta-analyses noted above reported a pooled total 67% reduction in mortality for IVM vs controls, with a statistical significance for an overall effect of p=0.005.[20] A comprehensive review of the entire body of clinical studies for IVM treatment of COVID-19 by the Nobel co-laureate for IVM, Dr Satoshi Omura and colleagues, concluded that IVM yielded major reductions in mortality.[10] Two animal studies of IVM treatment at low human-equivalent doses, one for the SARS-CoV-2 virus in golden hamsters[25] and another for a related betacoronavirus (MHV-A59) in mice,[26] found statistically significant treatment benefits, consistent with those found in the RCTs noted above. The indicated biological mechanism of IVM, competitive binding with SARS-CoV-2 spike protein,[27] is likely non-epitope specific, possibly yielding full efficacy against emerging viral mutant strains.

The demonstrated safety of IVM at much higher than standard doses[11–14] allowed the latitude for dose escalation for IVM treatment of COVID-19 over time. On September 19, 2020, the CPCPZ held a seminar at which the use of a combination of IVM, doxycycline and zinc was presented, along with aggressive diabetes control, steroid use and anticoagulation, and this was suggested as the most effective and affordable care available at the time. Afterwards, combination therapy centered around IVM plus doxycycline and zinc became the standard COVID-19 treatment protocol used by the CPCPZ. The potential efficacy of these adjuncts was later supported by successful clinical trials results with treatments using IVM in combination with doxycycline[28] or with doxycycline and zinc.[29] This combination therapy for COVID-19 has been researched and advanced by Thomas Borody,[30] who in 1990 published the first clinical trial of using a triple therapy of three inexpensive repurposed drugs for *H. pylori*,[31] the underlying bacterial cause of peptic ulcers. This triple therapy of repurposed drugs became the worldwide standard of care for peptic ulcers a decade later, after the patents for the palliative drugs Tagamet and Zantac expired, and the discovery of *H. pylori* as the cause of peptic ulcers was honored with the Nobel Prize for Medicine in 2005.[30]

Methods

This study is a retrospective review of clinical data collected during the course of treatment of COVID-19 patients with therapeutic agents selected by their physicians to offer the greatest chances for clinical benefits and recovery.

Outcomes

Outcomes tracked were 1) changes in SpO2 values from within one hour before treatment to 12, 24 and 48 hours after treatment, for a set of 34 COVID-19 patients for whom a pre-treatment SpO2 value and at least one SpO2 value up to +48 hours after start of treatment (first IVM dose) were available, all obtained on room air; and 2) mortality/deterioration: recovery, deterioration to critical status, or death for a larger set of 92 COVID-19 patients. For most of these patients, blood values for lymphocyte count, LDH, D-Dimer and CRP were also recorded, but complete blood test results were not obtained for every patient and therefore were not analyzed.

Participants

Sixty of the patients analyzed in this study, including all 34 in the SpO2 tracking series, were from Harare, treated by CPCPZ physicians either at local clinics or at patients' homes. Additional data for the mortality/deterioration series were obtained through inquiries sent on March 10, 2021, to all in a WhatsApp group of CPCPZ physicians treating COVID-19 with IVM asking for records of any of their patients so treated. Six physicians responded by furnishing records of 32 such patients, grouped with the 60 patients treated by CPCPZ physicians to comprise the mortality/deterioration series. For most of these six physicians, not every patient treated to recovery without incident was included, but it was confirmed that no other patient treated by them with IVM had died. Under pressures of patient care during the pandemic, record-keeping tended to be most comprehensive for the sickest patients, who thus are represented disproportionately in this study.

Table 1
Age group, sex, and pre-treatment SpO2 (%) value range of the 92-patient mortality/ deterioration series (mean age=54; median age=53).

Age		Initial SpO2 (%)			
Group	**Sex**	**66-84**	**85-89**	**90**	**Total**
25-49

	Male	1	2	0	3
	Total	**1**	**4**	**0**	**5**
TOTAL		**34**	**52**	**6**	**92**

Inclusion and Exclusion criteria

In both the SpO2 tracking and mortality/deterioration series, patients selected for analysis were of age 18 or older and had treatment start dates between August 8, 2020, and May 31, 2021. Patients selected had an SpO2 value on intake of 51% or above and were administered a treatment protocol including IVM. Furthermore, patients selected were required to have been found COVID-19 positive either by a PCR test or a clinical diagnosis made by criteria including exposure to a COVID-19 patient, hypoxia, lymphopenia,

monocytosis, elevated LDH, elevated dimer, and/or radiology consistent with pulmonary abnormalities caused by the virus.

For the mortality/deterioration analysis, the set of patients was further restricted to those with pre-treatment SpO2 of 90% or below (and a minimum SpO2 for all patients of 51%, as noted above). Table 1 shows the distribution of age, sex and pre-treatment SpO2 value of the 92 patients in this series. For the SpO2 tracking series, the subset of patients was restricted to those patients with pre-treatment SpO2 values of 51% through 93%. That series was further restricted to those for whom these SpO2 values were recorded and positively documented to have all been obtained on room air (in almost every case because oxygen was not available), and at least one SpO2 value obtained within 48 hours after IVM administration, with 34 patients fitting those criteria. Six of those patients had pre-treatment SpO2 values of 91-93% and were thus not included in the 92-patient mortality/deterioration series. All patients in both the mortality/deterioration and SpO2 tracking series thus fit the US National Institutes of Health's definition of severe COVID-19, a sufficient condition of which is SpO2 of 93% or below.[32]

Treatment

In the 92-patient mortality/deterioration series and in the overlapping 34-patient SpO2 tracking series, every patient received IVM at dosages described below in addition to selected other agents from the standard of care before August 2020. These other agents included corticosteroids, clopidogrel, aspirin, enoxaparin, a nebulized nano-silver preparation, rivaroxaban, zinc sulfate, azithromycin, doxycycline, and in some cases, an IV antibiotic. Patients treated in a clinic were assessed by a nurse upon admittance, with blood drawn and PCR tests conducted as feasible given the patient's condition and with severe symptoms necessitating immediate treatment. For those patients who contacted a CPCPZ physician from home requesting treatment, an online questionnaire was first completed by the patient, after which, if COVID-19 was still a suspected diagnosis, a nurse visit to the home was conducted, with associated follow up per the procedures described for in-clinic patients.

As evidence of IVM safety and tolerability accrued following its use beginning in August 2020, its stat dose of 10 mg as used for the earliest patients was increased on September 11, 2020, to 10-12 mg every four days for three doses. Subsequently, the dosage was further increased to 12 mg IVM on the day of admission and then on days 4 and 8 plus doxycycline (100mg b.i.d.) and zinc sulfate (60mg/day). The latter regimen was used up through December 2020, when the second pandemic wave emerged in Zimbabwe. At that time, additional evidence of safety and tolerability of this regimen supported further dose escalation to a standard IVM dose regimen of 12 mg daily for five consecutive days, with adjunct use of doxycycline and zinc sulfate continued at the doses noted. In some cases, for which this standard treatment regimen did not yield significant clinical gains within a few days, even higher doses of IVM were used, in some cases as high as 100 mg for a single dose. Transient adverse effects (AEs) such as blurred vision characteristic of high dose IVM often occurred at those dose levels, but no serious AEs associated with IVM were manifested in any patient. Each of the 34 patients in the SpO2 tracking series was treated with IVM, doxycycline and zinc.

Data collection

For patients in the SpO2 tracking series that were treated in clinics, values were tracked using monitors that continually displayed SpO2 values and readings for pulse rate and blood pressure and waveform images of blood pulses. For those treated at home, the intake nurse provided a pulse oximeter to the patient, unless the patient had one which the nurse deemed of reliable quality. The patient or a family member took SpO2 readings regularly, using the same oximeter as used for the pre-treatment reading. In most cases, these readings were taken daily, with much lower frequency after SpO2 values had risen significantly and the patient's clinical condition had correspondingly improved. Patients were instructed to message the nurse immediately if SpO2 ever decreased from a higher value to 93% or below or if any new clinical symptoms of concern developed.

Patient outcomes were categorized as recovered, died, or deteriorated before recovery, as follows. Recovered: patients who recovered following IVM treatment and were still alive on September 1, 2021, three months or more after intake. Died: those who died following IVM treatment, whether or not the cause could have been unrelated to COVID-19. Deteriorated (before recovery): if at any time following the first dose of IVM, any incident or condition, whether of indicated connection to COVID-19 or not, either caused them to be hospitalized or made that a reasonable course of action had that been an available and viable option.

Analytical methods

For the 34-patient SpO2 tracking series, a measure of percent normalization toward a fully optimal SpO2 value of 97 was applied, which for pre-and post-treatment SpO2 values S_0 and S_1, is: $100*(S_1-S_0)/(97-S_0)$, capped at 100%. Pre- and post-treatment SpO2 values were plotted for all 34 patients using this percent normalization measure in Figure 1 and were also presented directly in Figure 2, Figure 3, and Table S2. Regarding the 92-patient mortality/deterioration series, precise statistical comparisons of results from treatment vs control groups cannot be made other than in the context of an RCT. It is nevertheless of interest to compare the mortality results for this Zimbabwe mortality/deterioration patient series to the expected mortality of COVID-19 patients with similar characteristics. A review conducted in 2021 considered 46 prediction models for COVID-19 mortality,[33] two of which[34,35] were rated as having a low risk of bias; the same two were identified as being of the highest quality in another overview of COVID-19 mortality risk assessment models.[36]

The risk assessment model used here is the one of these two that used pre-treatment SpO2 as one of its prediction variables.[35] This model, designated as the 4C mortality risk predictor, was developed by 35 investigators on behalf of a consortium of 260 hospitals in the UK. It was derived from 57,824 hospitalized patients, a comparable group to this study's mortality/deterioration series of patients, who, as noted, all had pre-treatment SpO2 values ≤ 90% and would have been hospitalized had that been an available, viable option. The overall mortality rate of 4C model patients, using data collected February through June 2020, was 31%. In Harare's main hospital system, the Parirenyatwa Group, in its red zone, where COVID-19 patients are admitted and treated, per statistics available for June through December 2020, the COVID-19 case fatality rate (CFR) was 35.4% (119 deaths of 336 total patients).[37] This exceeds the overall CFR for the patient set of the 4C mortality risk predictor and indicates that using the 4C mortality risk predictor for the patient set in this study would not overestimate the risk factor.

The same UK consortium that developed the 4C mortality predictor also developed a model to assess the risk of clinical deterioration among inpatients with confirmed or highly suspected cases of COVID-19.[38] This deterioration model was developed using 73,948 patients recruited between February and August 2020, with clinical deterioration defined as any requirement of ventilatory support or critical care, or death. This model was also applied to the Zimbabwe mortality/deterioration series, and predicted deterioration outcomes were compared with the number of patients who could be considered to have deteriorated, per the criteria specified above.

To calculate both mortality and deterioration probability estimates for the Zimbabwe mortality/deterioration series, three base variables were used: age, sex and pre-treatment SpO2 value on room air, while for mortality, the 4C model used the count of comorbidities as another variable, as was also recorded for the study patients. Abnormal values for respiratory rate, urea, CRP, lymphocyte count, and presence of radiographic chest infiltrates would have added extra points and would have increased associated probabilities to these risks calculated for mortality and/or deterioration. However, since only these four base variables were available for every patient, only these were used to calculate the 4C-predicted risks.

The comorbidities used in the 4C mortality predictor were the following: chronic cardiac disease, chronic respiratory disease (excluding asthma), chronic cardiac disease, chronic respiratory disease (excluding asthma), chronic renal disease, mild to severe liver disease, dementia, chronic neurological disease, connective tissue disease, diabetes, HIV or AIDS, malignancy, and clinician-defined obesity.[38] For applying this risk predictor to the Zimbabwe mortality/deterioration patient series, these were the comorbidities used for the counts shown in Table S1. For some of these patients, certain variables used for the deterioration but not the mortality risk calculation would likely have significantly increased the deterioration probability values, and the calculated deterioration risk estimate is lower than that for mortality.

The 4C mortality and deterioration risk predictors were used to calculate probabilities for each of the 92 patients for mortality and deterioration, respectively. Although the Poisson distribution function can roughly approximate the probability of having a given number n or less total events from such a series having different probabilities, Monte Carlo simulation gives a much more precise probability estimate.[39] Monte Carlo simulations were executed, with 10,000,000 simulations performed ten times each for the mortality and deterioration estimations. These were performed using visual basic source code as listed in Supplementary File S3.

Ethics Approval

The Medical Research Council of Zimbabwe granted IRB approval (#E293) for this retrospective study. Patients consented for their medical treatment and to having their de-identified data used in this study.

Results

For COVID-19 patients treated with IVM in Zimbabwe between August 8, 2020, and May 31, 2021, results are presented for the following: A) Pre- and post-treatment SpO2 values for 34 patients for whom these values were recorded all on room air, each patient having a pre-treatment SpO2 value of 51-93% and at least one

post-treatment value obtained within 48 hours after first dose of IVM; and B) analysis of mortality and deterioration outcomes for 92 patients having pre-treatment SpO2 values of 51-90%.

Results for pre-and post-treatment SpO2 values

Figures 1 and 2 and Table S2 show the progression of pre-treatment and post-treatment SpO2 values within 48 hours after first dose of IVM for the 34 patients described above, all of whom were treated with IVM, doxycycline and zinc. All of these patients recovered. SpO2 values are shown at pre-treatment, all recorded within one hour before the start of treatment and at 12, 24 and 48 hours after treatment. The SpO2 value shown for a given patient at time x is that for the latest post-treatment time $\leq$ x. (Thus, for some patients, for example, having a post-treatment value within 12 hours before +24 hours but none in the next 24-hour period, the latest value at +48 hours is the same as that at +24 hours.)

Figure 1 shows, for all 34 patients, SpO2 value changes from before IVM administration to post-treatment as percentages of full normalization to an optimal SpO2 value of 97 (95 is considered the minimum normal SpO2 value for a healthy child or adult by the US CDC[41]). Red, orange and blue lines show, respectively, SpO2 values at +12, +24 and +48 hours post-treatment. The mean (±SD) SpO2 changes as this specified percent of optimal normalization were 55.1% ± 28.0% at +12 hours, 62.3% ± 26.3% at +24 hours and 64.3% ± 24.5% at +48 hours. As shown in Figure 1, these percentages of full normalization to SpO2=97 have a roughly uniform distribution across the full range of pre-treatment SpO2 values, from 66 to 93.

Figure 2 shows all pre-and post-treatment SpO2 values grouped into nine graphs (A-I) by the range of pre-treatment SpO2 values and post-treatment times (after first IVM dose) of +12, +24 and +48 hours. As shown in Figure 2 and identically in Table 2, those patients with lowest, mid-range and highest pre-treatment SpO2 values had mean SpO2 increases at +12 hours of 12.8, 5.4 and 2.8, respectively (all SpO2 values in percentage units). Figure 3 shows pre-and post-treatment SpO2 values throughout the entire observation period for each of the 34 patients. Note that these values were recorded less frequently after SpO2 had normalized.

Table 2
Mean ± SD of changes in SpO2 from pre- to post-treatment (after first IVM dose) for 34 severe COVID-19 patients treated with IVM, doxycycline and zinc.

SpO2 (%)			
Pre-treatment	at +12 hours	at +24 hours	at +48 hours
66 - 84%	+12.8 ± 6.7	+11.4 ± 6.1	+11.7 ± 5.8
85 - 89%	+5.4 ± 2.6	+6.2 ± 2.8	+6.3 ± 3.0
90 - 93%	+2.8 ± 2.7	+3.7 ± 2.3	+3.9 ± 1.8

Figure 4 shows successive SpO2 values for one patient who had a particularly rapid increase in these values after his first dose of IVM. This patient was a 25-year-old male, treated by a CPCPZ physician at a GP clinic without a supplemental oxygen capability. He received his first 12 mg IVM dose (repeated over the next four

days) immediately after entering the clinic with respiratory distress and bilateral pneumonia indicated by stethoscopic examination. His COVID-19 diagnosis was confirmed by a positive result from a rapid antigen test. As shown, his SpO2 values increased from that recorded immediately before treatment (79%) to values at 45 minutes (87%), 90 minutes (92%) and 3 hours (95%) post-treatment. He was discharged later that same day, and his home SpO2 readings then fluctuated between 92% and 95% over the next three days. By the fourth day after discharge, his SpO2 stabilized at 97%, his pulse dropped to 77 from prior values over 100, and he resumed working from home.

For the 34 patients in the SpO2 tracking series, as shown in Figure 2, all but two had increases in SpO2 within the first 48 hours after first dose of IVM. As shown in Figure 3, this overall increase in SpO2 continued throughout the entire observation period. However, several studies of moderate and severe COVID-19 patients under standard care that track SpO2, pulmonary abnormalities, or both establish that for most patients, SpO2 decreases in tandem with an increase in the extent of pulmonary CT abnormalities from the day of onset of disease symptoms through the second week following.[42–48] Thus, the expected change in SpO2 within 48 hours after first IVM dose would be < 0, and one-tailed paired t-test calculations can assess whether SpO2 values increased significantly > 0 at each time period tracked.

Taking into account some missing post-treatment values (see Table S2), there are 25, 33 and 34 pairs of pre- and post-treatment SpO2 values at +12 hours, +24 and +48 hours, respectively. Applying these paired t-test calculations, the SpO2 increases were highly significant for each time period: t=6.28, p=8.5E-07 at +12 hours; t=8.42, p=6.36E-10 at +24 hours, and t=8.81, p=3.47E-10 at +48 hours.

Results for mortality and deterioration

The mortality/deterioration series, as noted above, consisted of 92 COVID-19 patients with pre-treatment SpO2 values between 51% and 90%. Table S1 shows individual values for these patients for age, sex, pre-treatment SpO2 value, number of comorbidities, treatment outcome (recovered, deteriorated or died), and the respective probabilities from the 4C mortality and deterioration risk predictors.

Of these 92 patients, 90 recovered, and two died. (The latter two patients did not have recorded SpO2 values on room air and were not included in the 34-patient SpO2 tracking series.) To compare this result with the mortality outcome expected for a series of 92 COVID-19 patients with matching values of age, sex, pre-treatment SpO2 and the number of comorbidities, 4C mortality probabilities were calculated for each patient. Monte Carlo simulations were then executed, with 10,000,000 simulations run ten times. The number of simulated deaths in each run ranged from 7.079 to 7.081, with a mean of 7.080, and the mean of the associated individual standard deviations = 2.494. The probability of having zero to two simulated deaths in this series ranged in these ten runs was 0.0214 (identically for mean, minimum and maximum values).

Two patients other than the two who died fit the deterioration criteria noted above. One was transferred to a hospital for three days because he became weak from not eating, and another was hospitalized for six days due to a drop in oxygen saturation. Both resumed IVM treatment after returning home and subsequently recovered. These two plus the two patient deaths yield a total of four deteriorations according to the 4C risk model for deterioration. 4C deterioration probabilities were calculated for each of the 92 patients, and Monte Carlo simulations were then executed for deterioration risk estimation, with 10,000,000 simulations run ten

times. The number of simulated deteriorations in each run was 17.23 (identically for the mean, minimum and maximum of these values), with the mean of the associated individual standard deviations = 3.54. The probability of having zero to four simulated deteriorations in this series ranged in these ten runs from 0.0000196 to 0.0000216, with a mean of 0.0000207.

With the caveat above as to the limits of statistical analyses outside the context of an RCT, this calculation nevertheless suggests that the occurrence of four or fewer deteriorations among these 92 severe COVID-19 patients would be highly improbable under standard care. For comparison, note that in this series of 92 patients, 21 had pre-treatment SpO2 values ≤ 78%, and among these 21 patients, only two deteriorated (the patients who died). In sharp contrast were deterioration outcomes reported by Mukhtar et al. in a study of 72 critically ill COVID-19 patients.[49] Thirty-four of those 72 patients had hospital admission SpO2 values ≤ 78% on room air, and all of those subsequently required mechanical ventilation, whereas only 16 of 38 (42%) of patients having intake SpO2 value > 78% required ventilation (Mohamed Hasanin, corresponding author of this study, personal communication, August 15, 2021).

Discussion

This study is a retrospective review of clinical data collected amid the challenges of providing treatment with limited facilities and resources to COVID-19 patients with severe disease. Under such conditions, it was not possible to obtain blood test values for all patients, including values for lymphocyte count, LDH, D-Dimer and CRP, which were thus not analyzed. On the other hand, the lack of availability of oxygen supplementation for many of the patients treated resulted in the rare opportunity to track changes in SpO2 values all recorded on room air before and after administration of IVM to 34 patients, with several of these patients having presented with SpO2 values well below 90%.

The increase in SpO2 for these 34 patients as the percentage of fully optimal normalization to SpO2=97, as reported above, was (mean ±SD) 55.1% ± 28.0% at +12 hours, which rose to 62.3% ± 26.3% at +24 hours and then to 64.3% ± 24.5% at +48 hours after first IVM dose. All but two of these 34 patients had SpO2 values that increased at all post-treatment times for which values were obtained. Paired t-test calculations yield $p<0.0000001$ for the SpO2 increases at +12, +24 or +48 hours having occurred by chance had the IVM-based combination therapy applied had no clinical activity against COVID-19. Because the dearth of significant spontaneous improvements in SpO2 levels and respiratory function one day after a severe COVID-19 patient's presentation for medical care is a well-established norm for this disease per the studies cited above, these probability values are significant and noteworthy.

The results for this SpO2 tracking series, with recoveries for all 34 patients, parallel those recently reported by Hazan et al., for which SpO2 values all on room air for 24 RT-qPCR confirmed COVID-19 patients were tracked before and +24 hours after combination treatment with IVM, doxycycline and zinc.[40] For the 19 severe COVID-19 patients in that series who had pre-treatment SpO2 values of 90% and below (minimum=77%) and had +24 hour post-treatment SpO2 values (see Table S3), the mean (±SD) SpO2 values were 86.7 ± 4.5 pre-treatment and 93.3 ± 2.6 at +24 hours after first IVM dose. As the percentage of normalization to SpO2=97, the mean (±SD) relative SpO2 increase for these 19 patients was 65.2% ± 17.5%, which is close to the +24 hour relative increase of 62.3% for the 34-patient Zimbabwe SpO2 tracking series. The one-tailed paired t-test for these

increased SpO2 values in these 19 patients yields t=9.34, p=1.27E-08, which as for the Zimbabwe SpO2 series is highly significant.

The similar results for the SpO2 patients in the Zimbabwe SpO2 series and the 24 patients of Hazan et al. suggest that the triple therapy of IVM, doxycycline and zinc provides efficacy regardless of which other adjunct agents were used, or may indicate that each study used different sets of adjuncts that further boosted the activity of this regimen to the degree of efficacy manifested in the clinical outcomes for each. One limitation of this study is that except for nebulized nano-silver, used for all patients at the start of the treatment regimen, other adjuncts were deployed on a case-by-case basis, per the patient's condition. Also, IVM dosages were increased during the study period based on the observations that no serious AEs were observed at higher doses, and higher doses appeared to be most effective for the patients with the most severe symptoms. A follow-up clinical study of IVM-based combination treatment of COVID-19 would benefit from a more structured specification and tracking of dosages and adjuncts used.

The distinct improvements in respiratory function for this study's 34-patient SpO2 tracking series, paralleling similar results reported by Hazan et al., provide a quantifiable demonstration of rapid clinical improvement in severe COVID-19 patients after IVM treatment. Such rapid improvements had been observed since the first major clinical trial of IVM treatment of COVID-19.[7] The lead investigator of that clinical trial had observed that stabilization and then improvement in breathing function frequently occurred in 12-48 hours after IVM treatment, even for patients who had been deteriorating rapidly and had required supplemental oxygen at up to a 50% mixture.[50]

The SpO2 increases within a day after IVM treatment observed in this study and by Hazan et al. provide a distinct indication that IVM not only yields statistically significant clinical benefits in groups of patients as reported in most of the 20 RCTs for IVM treatment but provides rapid, directly observable resolution of pulmonary dysfunction as tracked by SpO2 values for COVID-19 patients. This finding offers clues as to the potential biological mechanism of IVM activity against SARS-CoV-2 since, for example, even an effective freeze on viral replication or rapid repair of damaged pulmonary alveoli would be unlikely to cause such rapid clinical improvements. One indicated biological mechanism of IVM activity, competitive binding with SARS-CoV-2 spike protein, as reviewed,[27] may, through a reversal of viral hemagglutination, act quickly to increase pulmonary capillary flow and in turn account for normalization of blood oxygenation. An additional plausible mechanism of IVM activity is the activation of the cholinergic anti-inflammatory pathway under the control of the vagus nerve,[51] which is regulated by acetylcholine and potentiated by the high-affinity binding of IVM (a positive allosteric modulator) to the alpha 7 cholinergic receptor a7nAChr[52] expressed on bronchial, vascular as well as to cytokine-producing cells (i.e., TNF, IL1 and IL6 secreting macrophages, lymphocytes and mast cells).[53]

For the SpO2 tracking series, the pattern of rapid increases in SpO2 after start of IVM treatment as occurred for all but two of these 34 patients resulted in recoveries for all of them. This same pattern of highly successful outcomes extended to the 92-patient mortality/deterioration series, with recoveries of all but two patients. As noted above, although statistical significance cannot be determined through the 4C mortality and deterioration calculations, these odds calculations suggest that the probabilities for achieving the mortality and deterioration results obtained in this study were, respectively, low and extremely low under standard care.

No serious adverse effects (AEs) from IVM treatment were observed in any patient, although transient AEs such as blurred vision characteristic of higher-dose IVM administration were observed in some patients given doses as high as 100 mg. While comparative results using higher vs lower doses were not systematically tracked, the practice of increasing IVM doses for patients not initially responding to treatment worked out well and supports the indication that higher doses provide greater efficacy.

Conclusions

Pre-and post-treatment SpO2 values were recorded all on room air for 34 severe COVID-19 patients who were treated with the combination therapy of IVM, doxycycline and zinc plus other adjuncts. This application of multiple drugs against COVID-19 was based on Zimbabwe's experience with prior infectious diseases, for which early, aggressive use of multiple drugs has been a core treatment principle. For these 34 patients, all but two had increases in SpO2 from pre- to post-treatment, at every time interval of +12, +24 and +48 hours after first IVM dose for which values were recorded. The mean increase in SpO2 value as a percentage of full normalization to SpO2=97 was 55.1% at +12 hours and 62.3% at +24 hours after first IVM dose. These results closely parallel the mean SpO2 normalization of 65.2% as calculated from SpO2 values reported by Hazan et al. for 19 RT-qPCR confirmed COVID-19 patients having pre-treatment SpO2 $\leq$ 90, with all SpO2 values on room air.

The marked, rapid normalizations of blood oxygenation, $p<0.0000001$ for the 34-patient SpO2 tracking series in each time period analyzed (paired t-test), stand in sharp contrast to the well-established typical decline in SpO2 during at least the first week after onset of moderate or severe COVID-19 symptoms and establish a cause-and-effect clinical benefit for IVM-based combination treatment of this disease. Furthermore, for the larger set of 92 severe COVID-19 patients treated with IVM and other adjunct agents, all having pre-treatment SpO2 values of 90 and below, all but two recovered, and only two of those recovering patients experienced deterioration before recovery. These two deaths and four deteriorations (including the two deaths) are much less than the expected seven deaths and 17 deteriorations predicted using the well-regarded 4C COVID-19 risk assessment model.

For the patients of this Zimbabwe study and the Hazan critical series, treatment at home or in clinics with basic facilities freed up hospital resources for other patients, and the treatment approach modeled in these studies could significantly relieve the pressure on overwhelmed health facilities. IVM is widely available worldwide, inexpensive, and one of the safest drugs in modern medicine, with its safety in "improving the health and wellbeing of millions" noted explicitly by the Nobel Committee in awarding its 2015 prize for the discovery of IVM.[54] These study results, therefore, support the extended deployment of IVM for COVID-19 treatment, complementary to immunizations for prevention.

Figures

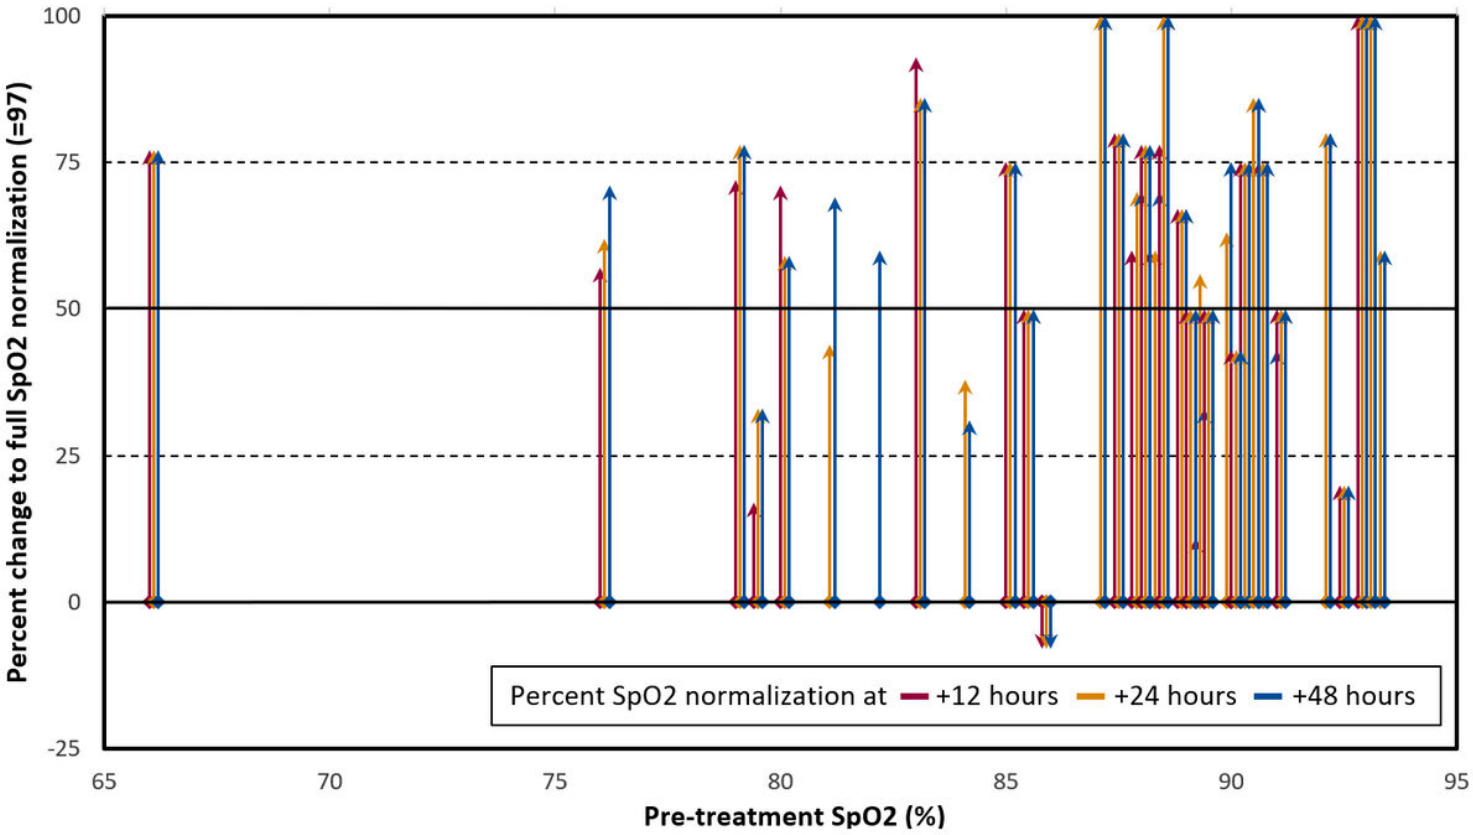

Figure 1

Changes in pre- to post-treatment SpO2 values, all on room air, for 34 severe COVID-19 patients treated with ivermectin (IVM), doxycycline and zinc, as percentages of optimal normalization to SpO2=97. Red, orange and blue lines represent, respectively, changes in SpO2 values at +12, +24 and +48 hours after first dose of IVM. X values were increased slightly (<1.5) as needed to accommodate clusters of values. For pre-and post-treatment SpO2 values S0 and S1, the y axis is the percent of optimal normalization to SpO2=97, that is: 100* (S1-S0)/(97-S0), capped at 100%. Mean (±SD) SpO2 changes (y values) were 55.1% ± 28.0% at +12 hours, 62.3% ± 26.3% at +24 hours and 64.3% ± 24.5% at +48 hours. These results closely parallel changes in SpO2, all on room air, reported by Hazan et al. for 19 RT-qPCR confirmed COVID-19 patients having pre-treatment SpO2 ≤ 90.40 At 24 hours after treatment with IVM, doxycycline and zinc, the mean SpO2 increase as a percentage of normalization to SpO2=97 was 65.2%, as calculated from the SpO2 values reported, close to the 62.3% at +24 hours for this 34-patient series. All patients in both of these IVM-treated cohorts recovered.

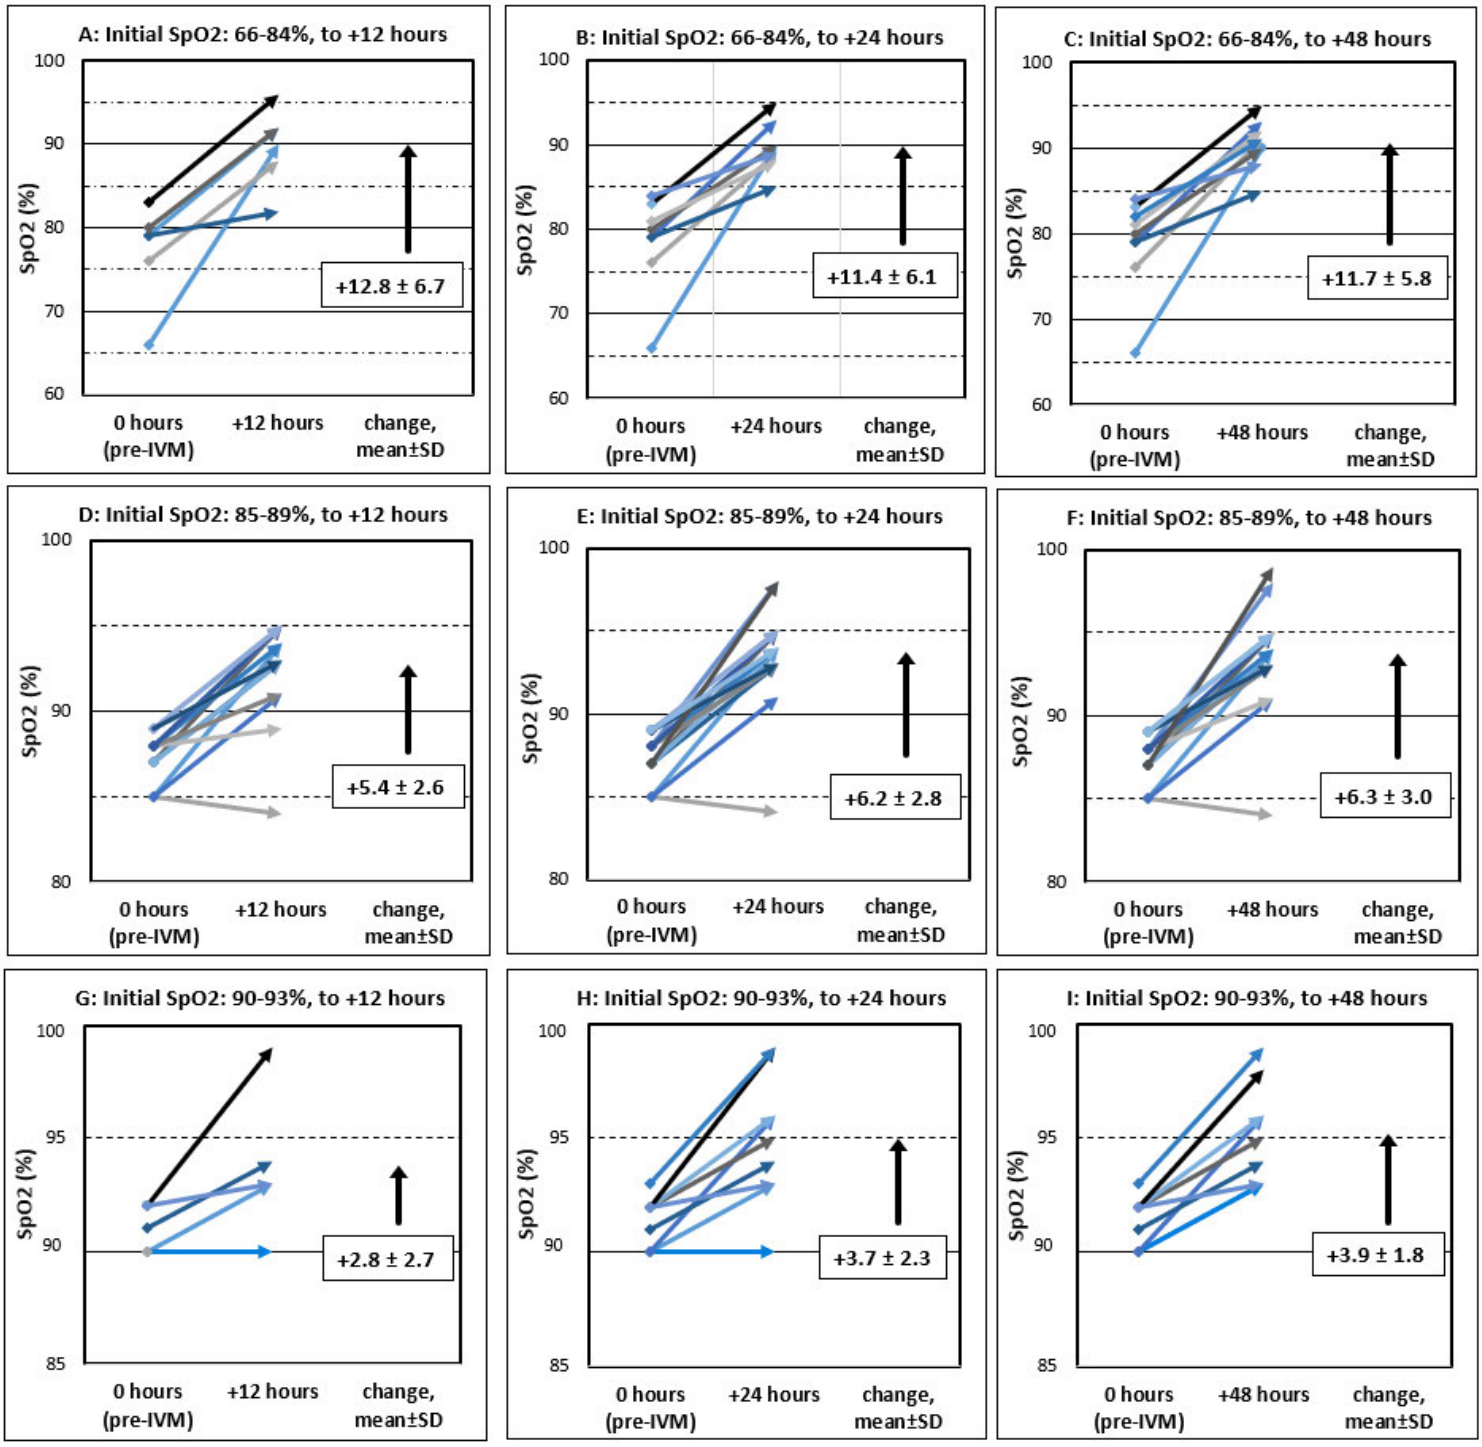

Figure 2

Pre- and post-treatment SpO2 values, all on room air, for 34 severe COVID-19 patients treated with IVM, doxycycline and zinc. Graphs A-I are in horizontal groupings by the range of pre-treatment SpO2 value and in vertical groupings by elapsed time after first dose of IVM. (The lowest SpO2 value in the stipulated range of 51-93% was 66%.) For these elapsed times of x=12, 24, and 48 hours, the SpO2 value shown for a given patient is at the latest post-treatment time ≤ x. All pre-treatment SpO2 values are from within one hour before the start of treatment.

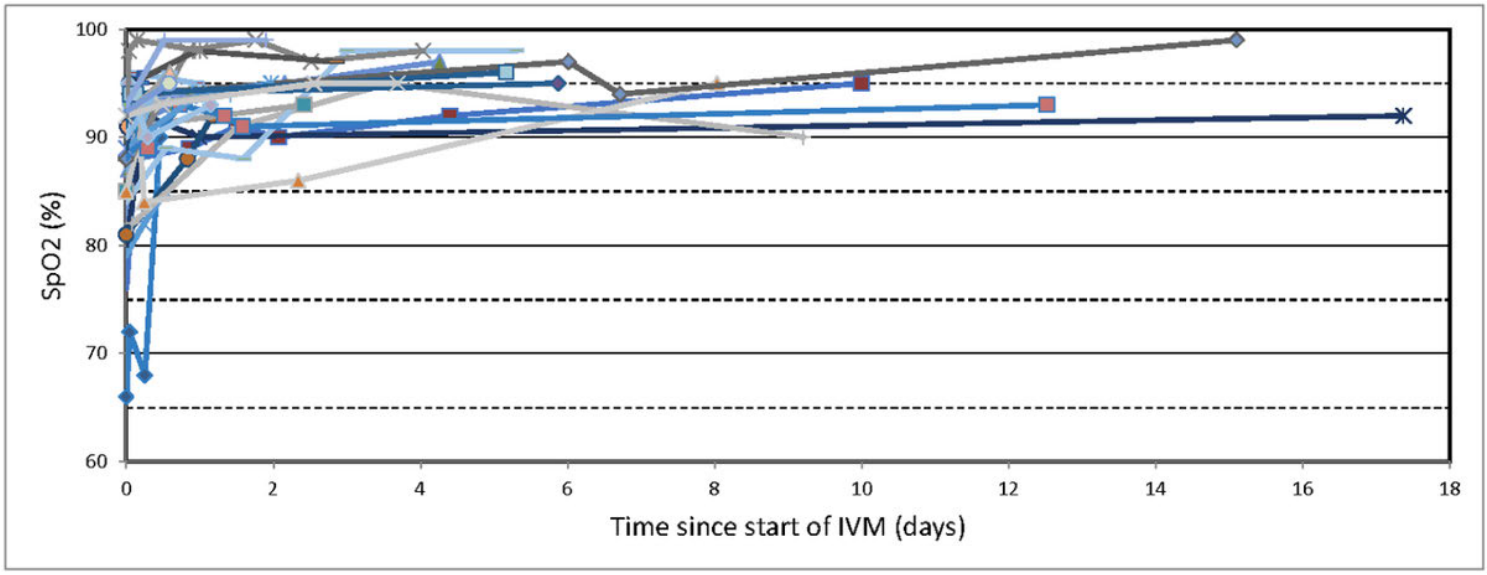

Figure 3

SpO2 values, all on room air, tracked for 34 severe COVID-19 patients treated with IVM, doxycycline and zinc.

Figure 4

Changes in SpO2 over 3 hours for a COVID-19 patient after administration of IVM. SpO2 values are shown (all on room air), with pulse rates (bpm) below those, at pre-treatment (A) and for 45 minutes (B), 90 minutes (C), and 3 hours (D) after first dose of IVM. This patient was diagnosed with COVID-19 by a positive result from a rapid antigen test and treated with combination therapy including IVM, doxycycline and zinc plus other oral and nebulized adjunct agents from among those itemized above.

Abstract: The emergence of COVID-19 in March 2020 challenged Zimbabwe to respond with limited medical facilities and therapeutic options. Based on early clinical indications of efficacy for the macrocyclic lactone, Ivermectin (IVM), against COVID-19, IVM-based combination treatments were deployed to treat it. Oxygen saturation (SpO2) data were retrospectively analyzed for 34 severe, hypoxic COVID-19 patients all on room air (without supplemental oxygen). The patients, median age 56.5, were treated at clinics or at home between August 2020 and May 2021. All but three of these 34 patients had significantly increased SpO2 values within 24 h after the first IVM dose. The mean increase in SpO2 as a percentage of full normalization to SpO2 = 97 was 55.1% at +12 h and 62.3% at +24 h after the first IVM dose (paired *t*-test, $p < 0.0000001$). These results parallel similar sharp, rapid increases in SpO2, all on room air, for 24 mostly severe COVID-19 patients in the USA (California) who were given an IVM-based combination treatment. All patients in both of these critical series recovered. These rapid increases in SpO2 values after IVM treatment stand in sharp contrast to declines in SpO2 and associated pulmonary function through the second week following the onset of moderate or severe COVID-19 symptoms under standard care.

1. Introduction

Evaluating the efficacy of COVID-19 therapeutics is challenging, since most patients typically recover; the worldwide cumulative case fatality rate was 2% as of September 2021 [1]. Thus, randomized clinical trial (RCT) results are important, yet interpretations, for example, of the mixed results from more than 25 RCTs for COVID-19 treatment with the drug Ivermectin (IVM) [2–5], including three recent studies with negative results [6–8], have been controversial. Yet, such conflicting results have emerged even among RCTs having large patient cohorts, for example those for remdesivir, for which opposite conclusions were drawn by the U.S. FDA (positive) [9] and the World Health Organization (negative) [10] as to efficacy against COVID-19.

Against the backdrop of these mixed RCT results for IVM, a quantifiable determination of whether rapid, major improvements in pulmonary function are achieved shortly after IVM administration to COVID-19 patients can provide an additional means to study efficacy. Such a route of investigation offers additional potential insights when conducted in conjunction with important new studies that indicate potential biological mechanisms by

FOI 26-3132 - Document 5

which IVM could rapidly neutralize the morbidity of a SARS-CoV-2 infection [11,12]. The simplest indicator of lung function is blood oxygen saturation level, SpO2, measured with a pulse oximeter. However, the administration of supplemental oxygen to any COVID-19 patient would preclude meaningful pre- and post-treatment comparisons of SpO2 values. For this retrospective study conducted in Zimbabwe, ironically, challenges that constrained treatment capabilities also provided the opportunity to track changes in SpO2 values, all recorded on room air (without supplemental oxygen), for 34 hypoxic, severe COVID-19 patients within 12 to 48 h after beginning IVM-based combination treatment (see Figure 1). Details of the inclusion and exclusion criteria applied that resulted in the selection of these 34 patients are provided in the Materials and Methods Section below. It should be noted that while inferences can be drawn as to these changes in SpO2 values over a 48 h period following administration of ivermectin, as detailed below, other conclusions are limited by a lack of control groups, randomization, or follow-up.

Zimbabwe, a landlocked country in Southern Africa that shares a border with South Africa, had its first reported case of COVID-19 in March 2020 [13]. Eight cases and one death from COVID-19 followed in the same month [14]. COVID-19 wards were created at a general practice clinic by converting two staff rooms into a four-bed ward and a storeroom into a two-bed ward. Available equipment included several oxygen cylinders, an oxygen concentrator, six beds, and three monitors for SpO2 and blood flow parameters. The staff consisted of the lead author, another primary care physician, and either one or two nurses at different times, each on 12 h shifts. During the initial months of the pandemic, in the absence of proven therapies and protocols, the standard of care evolved through early August 2020 to include corticosteroids, anticoagulants, and antibiotics, as used elsewhere in the world during this period.

However, the efficacy of these treatments was found to be limited, and by the end of July 2020, several COVID-19 deaths were recorded in the country. Based on reports of initial success using IVM for COVID-19 treatment from colleagues in Johannesburg, South Africa, the College of Primary Care Physicians of Zimbabwe (CPCPZ) adopted and included IVM in their COVID-19 treatment protocol from 8 August 2020, starting initially with a 10–12 mg stat dose. Treatment of COVID-19 with IVM continued after the first patients showed improved outcomes, with more rapid recoveries achieved at doses higher than the standard of 200 ug/kg, as initially used. In August 2020, after it became apparent that IVM added to standard of care was significantly reducing the death rate, together with the hospital system being overwhelmed, CPCPZ physicians decided to treat COVID-19 patients where an IVM-based protocol could be administered, including at local general practice clinics that had nursing care and oxygen and at some patients' homes with nursing support and oxygen supplementation as available.

IVM for COVID-19 Treatment

The decision to include IVM in COVID-19 treatment protocols in Zimbabwe was made as the pandemic swept through that nation, overwhelming limited clinical care facilities, with no drug developed to treat COVID-19 being generally accepted as effective. A published case–control study of IVM treatment for COVID-19 conducted at four U.S. hospitals [15] that had been initially released in a preprint in June 2020 found a 40% reduction in mortality among 173 patients treated with low-dose IVM vs. 107 case-matched controls (15% vs. 25.2% deaths). Interest in IVM was supported by its Nobel prize-honored pedigree and its extensive use to treat a variety of human diseases in over 3.7 billion doses worldwide since 1987 [2,16,17]. Another favorable characteristic of this drug is its extraordinary record of safety, well tolerated at high doses [18,19], including in studies for COVID-19 treatment [6,20]. It is generally non-toxic even at doses far exceeding the therapeutic range [21,22]. Since August 2020, inpatient and outpatient treatments of COVID-19 with IVM have been applied across 25 countries [2], with more than 20 RCTs conducted for IVM treatment regimens [2–5].

FOI 26-3132 - Document 5

A comprehensive review of clinical studies for IVM treatment of COVID-19 by the Nobel co-laureate for IVM, Dr Satoshi Omura, and colleagues, concluded that IVM yielded major reductions in mortality [2]. As noted above, however, three recent RCTs for IVM treatment of COVID-19 had negative results [6–8]. However, one of these had multiple protocol violations, with 38 doses of IVM mistakenly substituted for placebo and blinding violated with a glucose placebo [6,23], while related concerns were raised for another [7,24]. Two animal studies of IVM treatment at low human-equivalent doses, one for the SARS-CoV-2 virus in golden hamsters [25] and another for a related betacoronavirus (MHV-A59) in mice [26], found statistically significant treatment benefits. An indicated key biological mechanism of IVM, competitive binding with the SARS-CoV-2 spike protein [11,12], is likely non-epitope-specific, possibly yielding full efficacy against emerging viral mutant strains.

The demonstrated safety of IVM at much higher than standard doses [6,18–20] allowed the latitude for dose escalation for IVM treatment of COVID-19 over time, and combination therapy centered around IVM plus doxycycline and zinc became the standard COVID-19 treatment protocol used by the CPCPZ. This application of multiple drugs against COVID-19 was based on Zimbabwe's experience with prior infectious diseases, for which early, aggressive use of multiple drugs has been a core treatment principle. The potential efficacy of these adjuncts was later supported by successful clinical trial results with treatments using IVM in combination with doxycycline [27] or with doxycycline and zinc [28]. This combination therapy for COVID-19 has been researched and advanced by Thomas Borody [5], who, in 1990, published the first clinical trial of using a triple therapy of three inexpensive repurposed drugs for *H. pylori* [29], the underlying bacterial cause of peptic ulcers. This triple therapy of repurposed drugs became the worldwide standard of care for peptic ulcers a decade later, after the patents for the palliative drugs Tagamet and Zantac expired, and the discovery of *H. pylori* as the cause of peptic ulcers was honored with the Nobel Prize for Medicine in 2005 [5].

2. Results

Table 1 shows the age group, sex, and range of SpO2 values prior to treatment for the 34 patients in this study. Figures 1 and 2 and Table S1 show the progression of pre-treatment and post-treatment SpO2 values within 48 h after the start of treatment (including first dose of IVM) for the 34 COVID-19 patients of this study, all of whom were treated with IVM, doxycycline, and zinc. All of these patients recovered. SpO2 values are shown at pre-treatment, all recorded within one hour before the start of treatment (first dose of IVM) and within 12, 24, and 48 h after start of treatment. The SpO2 value shown for a given patient at time x is that for the latest post-treatment time $\leq$ x (thus, for example, for a patient having an SpO2 measurement at Hour 17 as the only one in the first 48 h after initial treatment, which would be used as their +24 and +48 h values).

Table 1. Patient age group, sex, and range of pre-treatment SpO2 values.

Age * Group	Sex	Initial SpO2 (%) 66–84	85–89	90–93	Total
25–49					
	Female	2	2	1	5
	Male	2	2	2	6

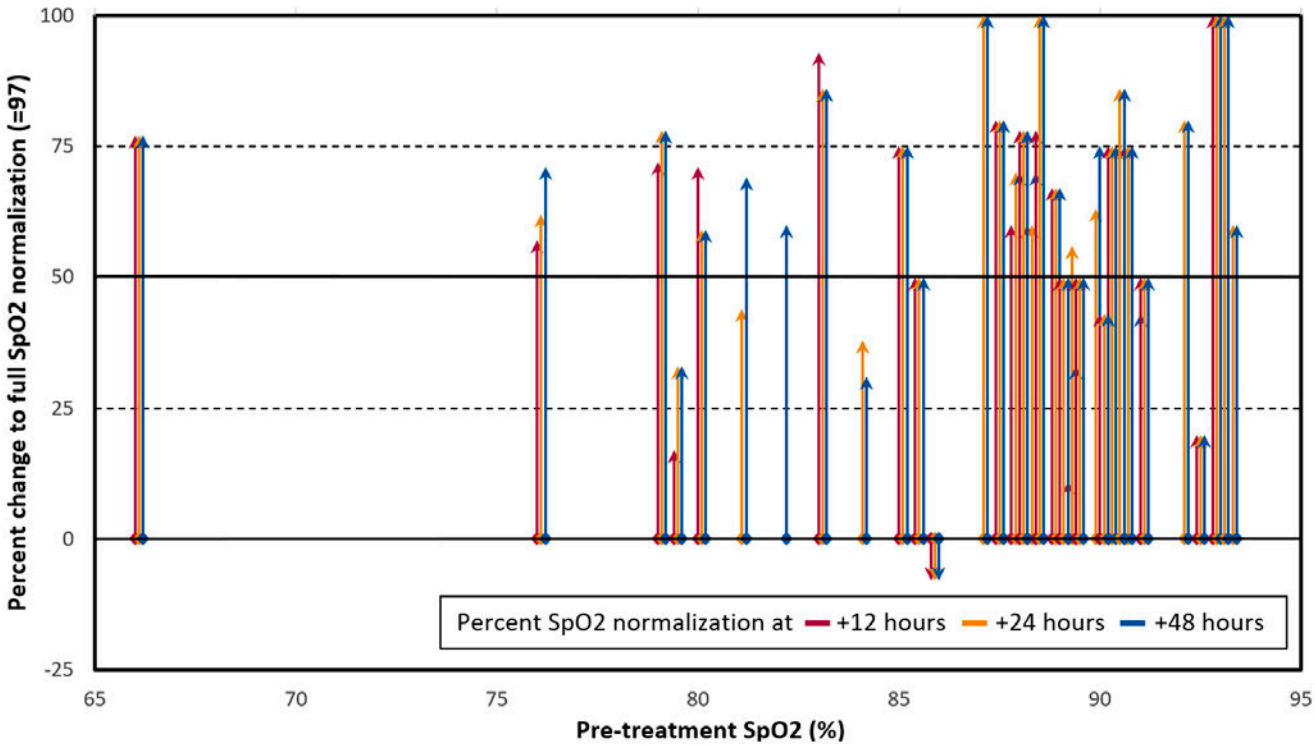

Figure 1. Changes in pre- to post-treatment SpO2 values, all on room air, for 34 severe COVID-19 patients treated with Ivermectin (IVM), doxycycline, and zinc, as percentages of optimal normalization to SpO2 = 97. Red, orange, and blue lines represent, respectively, changes in SpO2 values at +12, +24, and +48 h after the first dose of IVM. Arrows were shifted to the right slightly (<1.5 × axis units), as needed for clarity. For pre- and post-treatment SpO2 values S_0 and S_1, the y axis is the percent of optimal normalization to SpO2 = 97, that is: $100 \times (S_1 - S_0)/(97 - S_0)$, capped at 100%. Mean (±SD) SpO2 changes (y values) were 55.1% ± 28.0% at +12 h, 62.3% ± 26.3% at +24 h, and 64.3% ± 24.5% at +48 h.

Figure 1 shows, for all 34 patients, SpO2 value changes from before IVM administration to post-treatment as percentages of full normalization to an optimal SpO2 value of 97 (95 is considered the minimum normal SpO2 value for a healthy child or adult by the U.S. CDC [30]). Red, orange, and blue lines show, respectively, SpO2 values at +12, +24, and +48 h post-treatment. The mean (±SD) SpO2 changes as this specified percent of optimal normalization were 55.1% ± 28.0% at +12 h, 62.3% ± 26.3% at +24 h, and 64.3% ± 24.5% at +48 h. As shown in Figure 1, the bulk of the patients had 50% or more SpO2 normalization within 48 h, while the sickest 3 (pre-treatment SpO2 ranging from 66 to 78%) improved by over 70%.

Figure 2 shows all pre- and post-treatment SpO2 values grouped into nine graphs (A–I) by the range of pre-treatment SpO2 values and post-treatment times (after first IVM dose) of +12, +24, and +48 h. As shown in Figure 2 and identically in Table 2, those patients with the lowest, mid-range, and highest pre-treatment SpO2 values had mean SpO2 increases at +12 h of 12.8, 5.4, and 2.8, respectively (all SpO2 values in percentage units). Figure 3 shows all pre- and post-treatment SpO2 values throughout the entire observation period for each of the 34 patients. Note that these values were recorded less frequently after a patient's SpO2 value had increased above severe COVID-19 levels (≤93) and general condition had improved.

FOI 26-3132 - Document 5

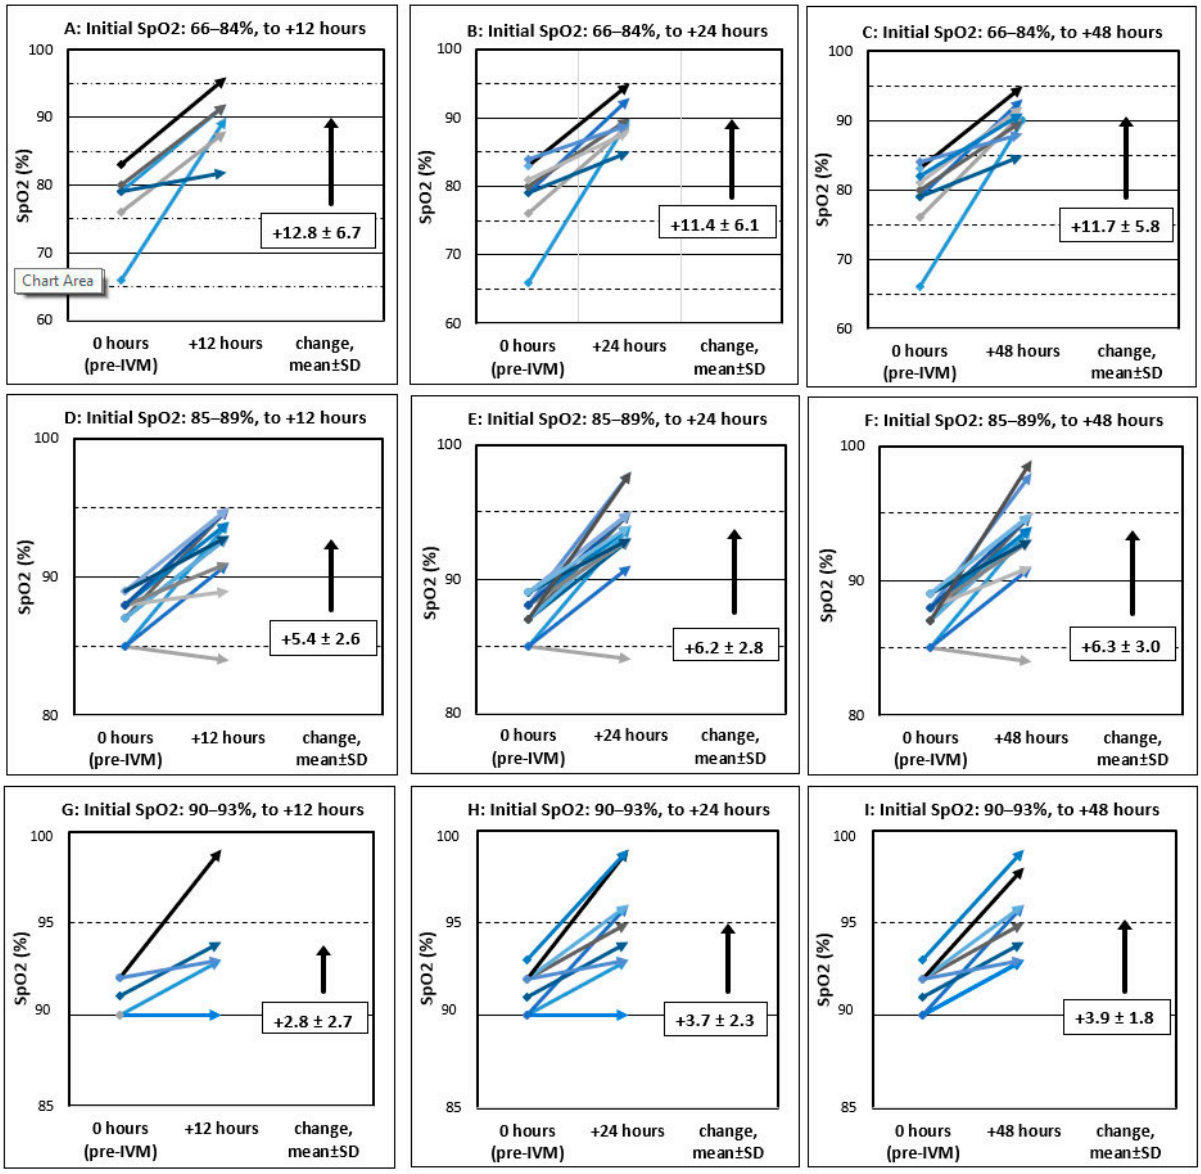

Figure 2. Pre- and post-treatment SpO2 values, all on room air, for 34 severe COVID-19 patients treated with IVM, doxycycline, and zinc. Graphs A–I are in horizontal groupings by the range of pre-treatment SpO2 values and in vertical groupings by elapsed time after first dose of IVM. (The lowest SpO2 value in the stipulated range of 51–93% was 66%.) For these elapsed times of x = 12, 24, and 48 h, the SpO2 value shown for a given patient is at the latest post-treatment time $\leq x$. All pre-treatment SpO2 values are from within one hour before the start of treatment.

Table 2. Mean (± SD) changes in SpO2 values from pre- to post-treatment with IVM-based combination therapy.

	SpO2 (%)		
Pre-Treatment	**at +12 h**	**at +24 h**	**at +48 h**
66–84%	+12.8 ± 6.7	+11.4 ± 6.1	+11.7 ± 5.8
85–89%	+5.4 ± 2.6	+6.2 ± 2.8	+6.3 ± 3.0
90–93%	+2.8 ± 2.7	+3.7 ± 2.3	+3.9 ± 1.8

FOI 26-3132 - Document 5

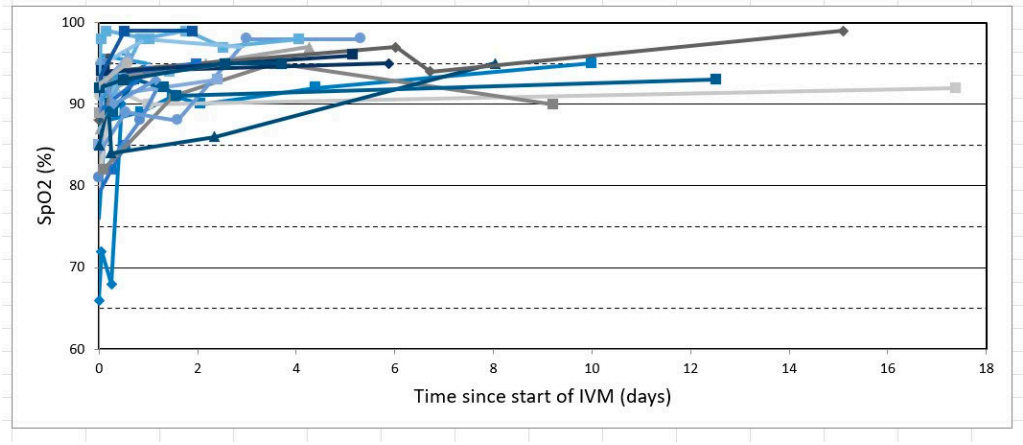

Figure 3. All SpO2 values (on room air) for the 34 severe COVID-19 patients of this study, all treated with IVM-based combination therapy including IVM, doxycycline, and zinc. Each patient is represented by joined line segments of a different color, with markers designating SpO2 values recorded.

Figure 4 shows successive SpO2 values for one patient who had a particularly rapid increase in these values after his first dose of IVM. This patient was a 25-year-old male, treated by a CPCPZ physician at a GP clinic without a supplemental oxygen capability. He received his first 12 mg IVM dose (repeated over the next four days) immediately after entering the clinic with respiratory distress and bilateral pneumonia indicated by stethoscopic examination. His COVID-19 diagnosis was confirmed by a positive result from a rapid antigen test. As shown, his SpO2 values increased from that recorded immediately before treatment (79%) to values at 45 min (87%), 90 min (92%), and 3 h (95%) post-treatment. He was discharged later that same day, and his home SpO2 readings then fluctuated between 92% and 95% over the next three days. By the fourth day after discharge, his SpO2 stabilized at 97%, his pulse dropped to 77 from prior values over 100, and he resumed working from home. Several other patients in this series likewise experienced some degree of tachycardia; however, these were generally manifested prior to the administration of IVM and did not become more pronounced after IVM dosing. While the increases in SpO2 for most of these 34 patients occurred less rapidly, over 48 h, than for this case, as shown in Figures 1–3 and Table S1, several other patients had SpO2 increases of 12% or more within 12 h after the first IVM dose (Table S1): SpO2 76% to 88% for a 38-year-old female; 83% to 96% for a 45-year-old male; 66% to 90% for a 49-year-old female; and 80% to 92% for a 75-year-old male.

Figure 4. Changes in SpO2 over 3 h for a COVID-19 patient after administration of IVM. SpO2 values are shown (all on room air), with pulse rates (bpm) below those, at pre-treatment (**A**) and for 45 min (**B**), 90 min (**C**), and 3 h (**D**) after first dose of IVM. This patient, a 25-year-old male, was diagnosed with COVID-19 by a positive result from a rapid antigen test and treated with combination therapy including IVM, doxycycline, and zinc plus other oral and nebulized adjunct agents from among those itemized above.

FOI 26-3132 - Document 5

As shown in Figure 2, all but two of the 34 patients in this study had increases in SpO2 within the first 48 h after the first dose of IVM. This overall increase in SpO2 continued throughout the entire observation period (Figure 3). Because SpO2 values that are at best stable and typically decreasing for several days after onset of disease symptoms are a well-established norm for moderate and severe COVID-19 patients under standard care, as discussed and shown in Figure 5 and Figure 6 in the Discussion Section below, these sharp, rapid SpO2 increases for all but two of the 34 patients in this study are noteworthy. Furthermore, given this expected change in SpO2 of ≤ 0 within 12, 24, or 48 h after the first IVM dose in the absence of an efficacious intervention against COVID-19, one-tailed paired *t*-test calculations can be performed to assess whether the change in SpO2 values was significantly greater than zero at each time period tracked. Taking into account some missing post-treatment values (see Table S1), there are 25, 33, and 34 pairs of pre- and post-treatment SpO2 values at +12 h, +24, and +48 h, respectively. Applying these paired *t*-test calculations, the SpO2 increases were highly significant for each time period: t = 6.28, $p = 8.5 \times 10^{-7}$ at +12 h; t = 8.42, $p = 6.36 \times 10^{-10}$ at +24 h, and t = 8.81, $p = 3.47 \times 10^{-10}$ at +48 h.

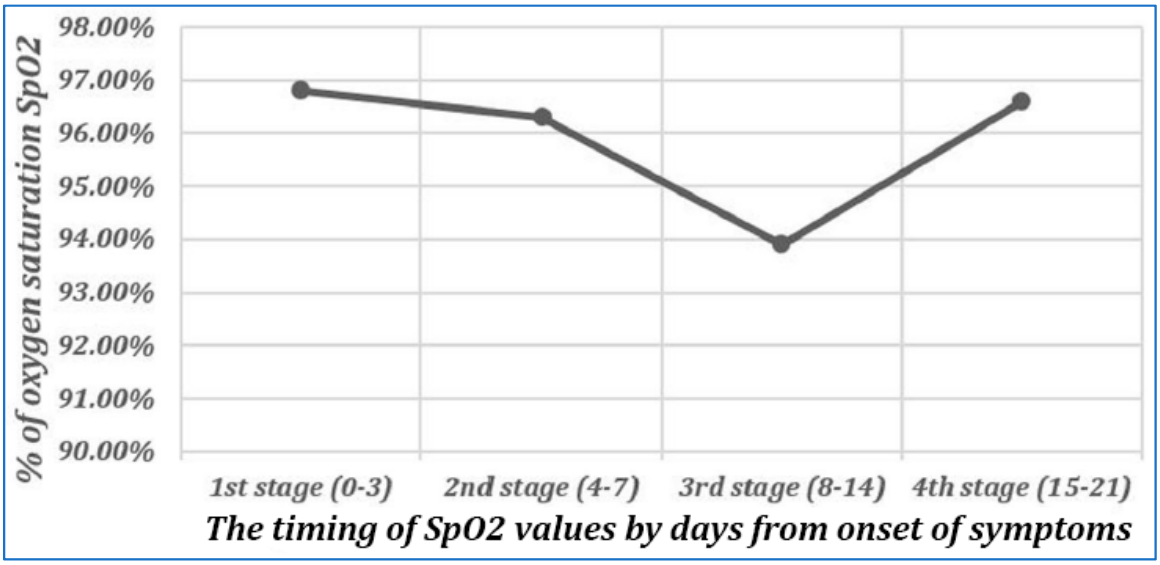

Figure 5. Changes in oxygen saturation during different stages of follow-up of cases with COVID-19 infection. Reproduced from Osman et al., 2020 [31] (CC-BY 4.0). These values were obtained from 125 PCR-confirmed COVID-19 inpatients, March-August 2020, with all values obtained on room air except for 3 patients in Stages 1 and 2, 13 in Stage 3, and 1 in Stage 4. As shown, the mean value of SPO2 decreases from Days 0–3 to Days 8–14; it is inversely correlated with the severity of pulmonary CT abnormalities in these patients throughout the full period of observation.

No serious adverse effects (AEs) from IVM treatment were observed in any patient, although transient AEs such as blurred vision characteristic of higher-dose IVM administration were observed in some patients given doses as high as 100 mg. While comparative results using higher vs. lower doses were not systematically tracked, the practice of increasing IVM doses for patients not initially responding to treatment had generally successful outcomes and became the standard protocol after December 2020.

3. Discussion

This study is a retrospective review of clinical data collected amid the challenges of providing treatment with limited facilities and resources to COVID-19 patients with severe disease. Under such conditions, it was not possible to obtain blood test values for all patients, including values for lymphocyte count, LDH, D-Dimer, and CRP, which were thus not analyzed. On the other hand, the lack of availability of oxygen supplementation for

FOI 26-3132 - Document 5

many of the patients treated in Zimbabwe provided the rare opportunity to track changes in SpO2 values all recorded on room air before and after administration of IVM for this group of 34 severe COVID-19 patients, 74% of them presenting with SpO2 values below 90% and 29% presenting with SpO2 85% and below.

It should be noted that this retrospective review is limited in its conclusions by the lack of control groups, randomization, or follow-up. Although, as noted, all of these 34 severe COVID-19 patients in this series survived, no conclusions as to mortality benefits can be drawn due to the absence of randomized controls. The one clinical parameter for which conclusions can be reasonably drawn is for the change in SpO2 values during the course of a 48 h period following IVM administration, since as detailed below, there is an extensive set of consistent baseline data on changes in SpO2 during the course of a COVID-19 infection under standard care.

The mean ($\pm$SD) SpO2 normalization, as reported above, was 55.1% $\pm$ 28.0% at +12 h, which rose to 62.3% $\pm$ 26.3% at +24 h and then to 64.3% $\pm$ 24.5% at +48 h after the first IVM dose. Paired *t*-test calculations yield $p < 0.0000001$ for each of the SpO2 increases, at +12, +24, or +48 h, having occurred by chance if the IVM-based combination therapy applied had no clinical activity against COVID-19. These highly significant p-values are based on the well-grounded assumption of expected change in SpO2 values of $\leq$0 during this time period. Moderate and severe COVID-19 patients under standard care typically manifest decreasing SpO2 values in tandem with increasing pulmonary CT abnormalities from the day of onset of disease symptoms through the second week following, as established in several studies that tracked SpO2 values, pulmonary abnormalities, or both [31–37]. For example, Figure 5 shows SpO2 values recorded over three weeks for COVID-19 patients under standard care [31], with decreasing SpO2 values through Stage 3, 8–14 days after the onset of symptoms.

The most useful baseline of SpO2 values for comparison would be those on room air for COVID-19 patients having pre-treatment SpO2 values $\leq$ 93% (severe COVID-19), as obtained in this study. Yet such SpO2 data are rarely obtained, since severe COVID-19 patients would typically receive supplemental oxygen. However, results without supplemental oxygen were provided in one study of COVID-19 patients in Nigeria (Thairu et al., 2022), which tracked SpO2 values prior to standard treatment and for ten days following [38] as compared with results of a prior study in which IVM treatment was provided in a similarly scheduled regimen [39]. The patients in the standard treatment series were given varying combinations of lopinavir/ritonavir (Alluvia), remdesivir, azithromycin, and enoxaparin (low-molecular-weight heparin, administered to all patients), along with zinc sulfate and vitamin C. The standard treatment regimen used by Thairu et al., 2022, was aggressive; some studies using just heparin as a mainstay of COVID-19 treatment reported successful results [40–42]. In a molecular modeling study that screened 100 agents [43], heparin was found to have binding affinity to the SARS-CoV-2 spike protein second highest to that of IVM, indicating the potential for heparin, like IVM, to inhibit virally caused morbidities affecting blood oxygenation efficiency [12].

The results for Thairu et al., 2022, its standard treatment group, as shown in Figure 6, are for those 26 COVID-19 patients who had pre-treatment SpO2 values $\leq$ 93% (severe COVID-19), and who were tracked only on room air per limitations on availability of supplemental oxygen [38,44]. Mean SpO2 remained at or below its pre-treatment value through Day 4 and then began to increase at Day 5. Despite the potentially greater than typical improvements in SpO2 for patients under standard care in Thairu et al., 2022, given use of enoxaparin, mean SpO2 did not increase through Day 4, as shown in Figure 6, in contrast to the sharp increases of SpO2 values through Day 2 for our study's 34 patients.

FOI 26-3132 - Document 5

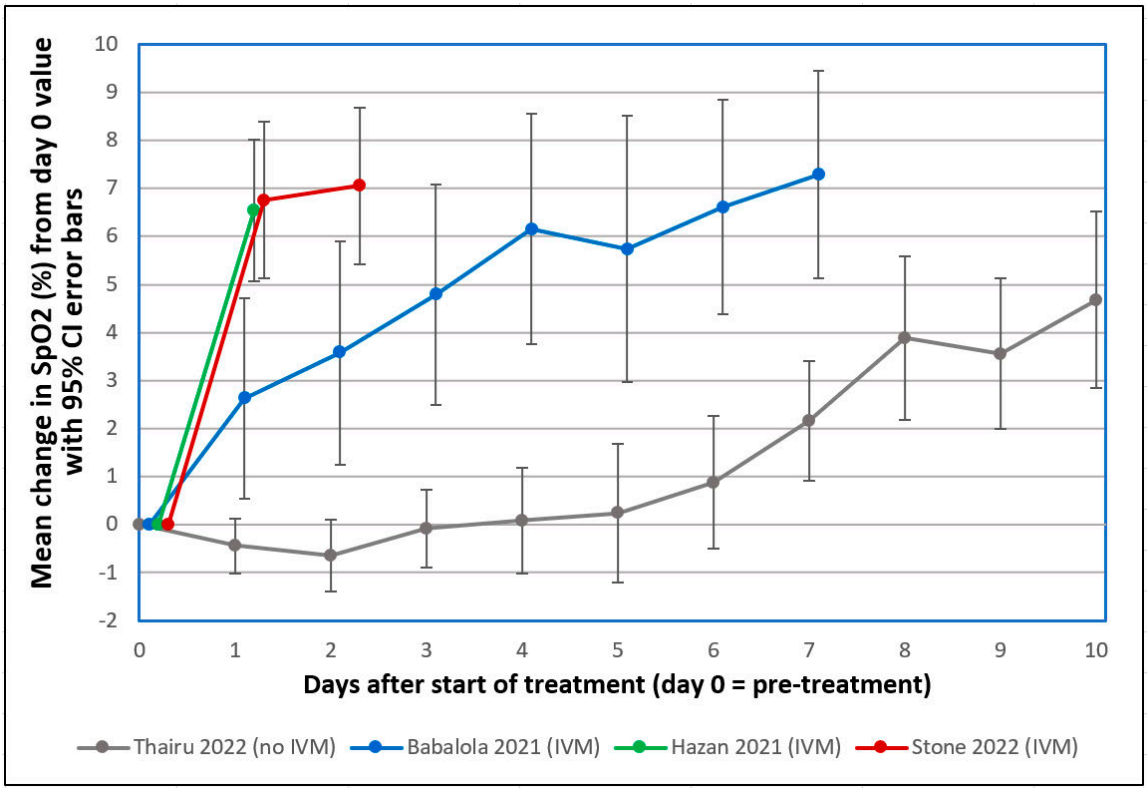

Figure 6. Mean changes in oxygen saturation (SpO2) for severe COVID-19 patients following treatments including or excluding IVM. Patients tracked over various time periods from each regimen were those with SpO2 values all recorded on room air, having pre-treatment (day 0) values $\leq$ 93%. The y axis value at day n is the mean of changes in SpO2 values from day 0 to day n, with error bars designating 95% confidence intervals. • Thairu et al., 2022 [38,44]: 26 patients, median age 45, treated with varying combinations of lopinavir/ritonavir (Alluvia), remdesivir, azithromycin, and enoxaparin plus zinc sulfate and vitamin C. • Babalola et al., 2021 [39,44]: 19 patients, median age 33, treated with IVM, zinc and vitamin C, with some also given azithromycin and hydroxychloroquine. • Hazan et al., 2021 [45]: 19 patients, median age 63, treated with IVM, doxycycline and zinc. • Stone et al., 2022 (this study): 34 patients, median age 56.5, treated with IVM, doxycycline and zinc, as described.

Our study's results, including the recoveries of all 34 patients, parallel those recently reported by Hazan et al., 2022, for which SpO2 values all on room air for 24 RT-qPCR confirmed COVID-19 patients in California (USA) who were tracked before and +24 h after treatment with IVM, doxycycline, and zinc [45]. For the 19 severe COVID-19 patients in that series who had pre-treatment SpO2 values of 90% or below (minimum = 77%) and had post-treatment SpO2 values recorded at +24 h (see Table S2), the mean ($\pm$SD) SpO2 values rose from 86.7% $\pm$ 4.5% pre-treatment to 93.3% $\pm$ 2.6% at +24 h after the first IVM dose. Per our calculation of the percentage of normalization to SpO2 = 97, the mean ($\pm$SD) relative SpO2 increase at 24 h post-treatment for these 19 patients was 65.2% $\pm$ 17.5%, which is close to the mean ($\pm$SD) of 62.3% $\pm$ 26.3% for the 34 patients in our study. The one-tailed paired *t*-test for these increased SpO2 values in these 19 patients yielded t = 9.34, $p < 0.0000001$, which, as for our Zimbabwe study, is highly significant.

In a third study, Babalola et al., 2021, for 19 severe COVID-19 patients in Nigeria, SpO2 values increased significantly one day after the first dose of IVM ($p < 0.008$, one-tailed paired *t*-test) [39,44]. SpO2 values increased even more markedly at two days after the first dose of IVM ($p < 0.0023$, one-tailed paired *t*-test). All of the patients in the Hazan and Babalola studies recovered (38 of these 43 total patients having severe COVID-19 status, as noted), as did all our Zimbabwe patients.

FOI 26-3132 - Document 5

The similar results for the 34 severe COVID-19 patients in our Zimbabwe SpO2 series and the 19 severe COVID-19 patients of Hazan et al., 2022 [45], are both sharper than the significant SpO2 increases obtained by Babalola et al., 2021 [39] and suggest that the triple therapy of IVM, doxycycline, and zinc provides enhanced efficacy with respect to IVM used with other adjuncts. One limitation of our study is that except for nebulized nano-silver, used for all patients at the start of the treatment regimen, other adjuncts were deployed on a case-by-case basis, per the patient's condition. Furthermore, IVM dosages were increased during the study period based on the observations that no serious AEs were observed at higher doses, and higher doses appeared to be more effective for the patients with the most severe symptoms. A follow-up clinical study of IVM-based combination treatment of COVID-19 would benefit from a more structured specification and tracking of dosages and adjuncts used.

The distinct improvements in respiratory function for our study parallel those reported by Hazan et al., 2022, and Babalola et al., 2021, and provide a quantifiable demonstration of rapid clinical improvement in severe COVID-19 patients after IVM treatment. Such rapid improvements had been observed since the first major clinical trial in Florida, USA, of IVM treatment of COVID-19 [15]. The lead investigator of that clinical trial had observed that stabilization and then improvement in breathing function along with blood oxygenation as tracked by SpO2 frequently occurred within 12–48 h after IVM treatment, even for patients who had been deteriorating rapidly and had required supplemental oxygen at up to a 50% mixture [46]. That Florida study also reported a 40% reduction in mortality in the IVM-treated group compared with propensity-matched case controls. Likewise, for a larger series of 92 severe COVID-19 patients treated in Zimbabwe with IVM, doxycycline, and zinc and other agents, the number of case fatalities (two) and deteriorations followed by recoveries (two) were much lower than predicted for a comparable set of patients using a well-regarded risk assessment model [47]. Yet, this risk model assessment is suggestive only, and as stated earlier, no conclusions regarding mortality or deteriorations can be drawn given the lack of controls in this study.

The SpO2 increases within a day after IVM treatment observed in this study and by Hazan et al., 2022, and Babalola et al., 2021, offer a distinct indication that IVM yields rapid, directly observable resolution of pulmonary dysfunction as tracked by SpO2 values for COVID-19 patients. This finding offers clues as to the potential biological mechanism of IVM activity against SARS-CoV-2 since, for example, even an effective freeze on viral replication or rapid repair of damaged pulmonary alveoli would be unlikely to yield such rapid clinical improvements. One indicated biological mechanism of IVM activity, competitive binding with the SARS-CoV-2 spike protein [11,12,48], may act quickly, through a reversal of virally induced blood cell clumping, to increase pulmonary capillary flow and, in turn, account for normalization of blood oxygenation. Another plausible mechanism of IVM activity, based on strong binding affinity of IVM to the alpha 7 cholinergic receptor a7nAChR, as shown in silico [11], is the activation of the cholinergic anti-inflammatory pathway under the control of the vagus nerve [49], which is regulated by acetylcholine and potentiated by the high-affinity binding of IVM (a positive allosteric modulator) to a7nAChR [50] expressed on bronchial, vascular, as well as to cytokine-producing cells (i.e., TNF, IL1- and IL6-secreting macrophages, lymphocytes, and mast cells) [11,51]. Through the stimulation of a related a7nAChR pathway, IVM may also be able to induce vasodilation [11].

It should be noted that similar rapid normalizations of SpO2 deficits were observed in this study and Hazan et al., 2022 [45], which both used IVM, doxycycline, and zinc; and in Rajter et al., 2020, conducted in Florida [15], which used IVM added to the standard of care, compared with controls using the standard of care without IVM. In Babalola et al., 2021 [39], similar rapid increases in SpO2 were observed using IVM, zinc, and vitamin C, as well as hydroxychloroquine and azithromycin for some patients (no significant differences in outcomes were found with or without those two additional agents; the results with and without those two added agents are combined in Figure 6). Although it is reasonable to deduce that since IVM was the common agent in all these studies and the biological

FOI 26-3132 - Document 5

mechanisms noted provide a reasonable explanation for their reported rapid increases in SpO2, without appropriate controls, it is impossible to positively conclude that it was IVM and not various combinations of other adjuncts that caused the SpO2 increases observed.

For our study, rapid increases in SpO2 values after the start of IVM-based combination treatment occurred for all but two of these 34 patients and resulted in recoveries for all of them. As noted above, no serious adverse effects (AEs) from IVM treatment were observed in any patient, and while comparative results using higher vs. lower doses were not systematically tracked, the practice of increasing IVM doses for patients not initially responding to treatment had generally successful outcomes.

4. Materials and Methods

This study is a retrospective review of clinical data collected for 34 severe COVID-19 patients for whom SpO2 values were monitored, all on room air, during the course of their treatment, with therapeutic agents selected by their physicians to offer the greatest chances for clinical benefits and recovery. Clinical data were collected for additional patients in Zimbabwe for whom SpO2 values on room air were not recorded, thus not fitting the inclusion criteria of this analysis, with mortality and deterioration outcomes for that larger patient series having been previously reported [47].

4.1. Outcomes

Outcomes tracked were changes in SpO2 values from within one hour before treatment to 12, 24, and 48 h after start of treatment (first dose of IVM), for 34 COVID-19 patients for whom a pre-treatment SpO2 value and at least one SpO2 value up to +48 h after start of treatment were available, all obtained on room air.

4.2. Participants

The 34 COVID-19 patients of this study were from Harare, treated by CPCPZ physicians either at local clinics or at patients' homes.

4.3. Inclusion and Exclusion Criteria

Patients selected for analysis were of age 18 or older and had treatment start dates between 8 August 2020 and 31 May 2021. Patients selected had an SpO2 value on intake of 51–93%, with all SpO2 values recorded and documented to have been obtained on room air (in almost every case because oxygen was not available), and at least one SpO2 value obtained within 48 h after IVM administration. These patients thus fit the U.S. National Institutes of Health's definition of severe COVID-19, a sufficient condition of which is an SpO2 value of 93% or below [52]. Patients were required to have been found COVID-19 positive either by a positive PCR test (real-time PCR, nasal-pharyngeal swabs) or a clinical diagnosis made by criteria including exposure to a COVID-19 patient, hypoxia, lymphopenia, monocytosis, elevated LDH, elevated dimer, and/or radiology consistent with pulmonary abnormalities caused by the virus. PCR testing was not performed for all patients because, in addition to having significantly depressed SpO2 values $\leq$ 93%, several patients had other symptoms of serious concern and required immediate treatment before the results of a PCR test could be obtained.

4.4. Treatment

All patients were administered an IVM-based combination therapy also including doxycycline and zinc plus selected other agents from the standard of care used prior to August 2020. These agents used in combination with IVM included corticosteroids, clopidogrel, aspirin, enoxaparin, a nebulized nano-silver preparation (applied for all patients), rivaroxaban, zinc sulfate, azithromycin, doxycycline, and, in some cases, an IV antibiotic. Patients treated in a clinic were assessed by a nurse upon admittance, with blood drawn and PCR tests conducted as feasible given the patient's condition and with severe symptoms necessitating immediate treatment. For those patients who contacted a CPCPZ physician

FOI 26-3132 - Document 5

from home requesting treatment, an online questionnaire was first completed by the patient, after which, if COVID-19 was still a suspected diagnosis, a nurse visit to the home was conducted, with associated follow-up per the procedures described for in-clinic patients.

As evidence of IVM safety and tolerability accrued following its use beginning in August 2020, its stat dose of 10 mg as used for the earliest patients was increased on 11 September 2020 to 10–12 mg every four days for three doses. Subsequently, the dosage was further increased to 12 mg IVM on the day of admission and then on Days 4 and 8 plus doxycycline (100 mg b.i.d.) and zinc sulfate (60 mg/day). The latter regimen was used up through December 2020, when the second pandemic wave emerged in Zimbabwe. At that time, additional evidence of the safety and tolerability of this regimen supported further dose escalation to a standard IVM dose regimen of 12 mg daily for five consecutive days, with adjunct use of doxycycline and zinc sulfate continued at the doses noted. In some cases, for which this standard treatment regimen did not yield significant clinical gains within a few days, even higher doses of IVM were used, in some cases as high as 100 mg for a single dose. Transient adverse effects (AEs) such as blurred vision characteristic of high-dose IVM often occurred at those dose levels, but no serious AEs associated with IVM were manifested in any patient.

4.5. Data Collection

SpO2 values were tracked using monitors that continually displayed readings for pulse rate and blood pressure and waveform images of blood pulses. For those patients treated at home, the intake nurse provided a pulse oximeter to the patient, unless the patient had one that the nurse deemed of reliable quality. The patient or a family member took SpO2 readings regularly, using the same oximeter as used for the pre-treatment reading. In most cases, these readings were taken daily, with much lower frequency after SpO2 values had risen significantly and the patient's clinical condition had correspondingly improved. Patients were instructed to message the nurse immediately if SpO2 ever decreased from a higher value to 93% or below or if any new clinical symptoms of concern developed.

4.6. Analytical Methods

For the 34-patient severe COVID-19 patients of this study, a measure of percent normalization toward a fully optimal SpO2 value of 97 was applied, which for pre- and post-treatment SpO2 values S_0 and S_1, was: $100 \times (S_1 - S_0)/(97 - S_0)$, capped at 100%. Pre- and post-treatment SpO2 values are plotted for all 34 patients using this percent normalization measure in Figure 1 and are also presented directly in Figures 2 and 3 and Table S1.

5. Conclusions

Marked, rapid normalizations of blood oxygenation, $p < 0.0000001$ (paired *t*-test), were obtained in each time period analyzed for the 34 severe COVID-19 patients in this study, all treated with IVM-based combination therapy. These results parallel similar rapid SpO2 increases reported by Hazan et al., 2022, for 19 severe COVID-19 patients having pre-treatment SpO2 ≤ 90, also at $p < 0.0000001$, with all SpO2 values likewise on room air. Similar results for IVM treatment were also obtained by Babalola et al., 2021, for 19 severe COVID-19 patients, with paired *t*-test values of $p < 0.008$ at Day 1 and $p < 0.0023$ at Day 2. These sharp, rapid increases in SpO2, accompanied by the survival of all patients in this Zimbabwe study and the California (Hazan) and Nigeria (Babalola) clinical series stand in sharp contrast to the, at best, stable and typically decreasing SpO2 values for several days after the onset of moderate or severe COVID-19 symptoms, even under aggressive non-IVM-based treatment regimens. These SpO2 increases rapidly following the first IVM dose establish a cause-and-effect clinical benefit for IVM-based combination treatment of this disease.

For the 34 patients of this study, treatment at home or in clinics with basic facilities freed up hospital resources for other patients, and the treatment approach modeled in these

FOI 26-3132 - Document 5

studies could significantly relieve the pressure on overwhelmed health facilities. IVM is widely available worldwide, inexpensive, and one of the safest drugs in modern medicine, with its safety in "improving the health and wellbeing of millions" noted explicitly by the Nobel Committee in awarding its 2015 prize for the discovery of IVM [53]. These study results, therefore, support the extended deployment of IVM-based combination treatment for COVID-19, complementary to immunizations for prevention.

DERMATOLOGIC THERAPY WILEY

LETTER

Further aspects of doxycycline therapy in COVID-19

Dear Editor,

In their work, Conforti et al urge experts to broadly investigate the combination of doxycycline and hydroxychloroquine in treating coronavirus disease (COVID-19).[1] The tetracycline antibiotic doxycycline is a nontoxic inhibitor of mitochondrial biogenesis and cellular respiration[2] besides other known pleiotropic properties.[1] Now that the World Health Organization has just halted hydroxychloroquine trials for COVID-19 because of safety reasons, the time has come to find auxiliary compounds so as to give additional benefit to doxycycline.

We also need to take into account that quite a lot of similarities in metabolic pathways of virally infected and cancer cells have been observed.[3] Viruses usually target mitochondria as cellular power houses and various interplays have been detected between viruses and mitochondrial dynamics.[4] Most viruses require aerobic glycolysis as the energy source for replication and its inhibition could attenuate this process.[4]

Vitamin C is a broad-spectrum antiviral agent[5] and an inhibitor of aerobic glycolysis.[2] The combined administration of doxycycline with vitamin C resulted in a robust eradication of cancer stem cells (CSCs) in in vitro experiments by blocking mitochondrial protein translation and ATP production from glycolysis.[2] The addition of azithromycin further boosted CSC clearance.[2]

Sargiacomo et al also proposed the use of doxycycline or azithromycin in COVID-19.[6] Their concept assumes that SARS-CoV-2 prefers chronologically aged, senescent lung cells for binding and replication causing stormy inflammation and subsequent fibrosis, suggesting the application of senolytic drugs such as doxycycline to prevent fibrotic transformation.[6]

I believe that a combined approach regarding CSC elimination[2] may be transmissible into antiviral therapy. Supplementation of doxycycline with the amplifier vitamin C may result in mitochondrial damage of virally compromised cells, the attenuation of immune response by the inhibition of glycolysis in pro-inflammatory immune cells,[7] and a stronger suppression on postinflammatory fibrosis[8] than with doxycycline alone.

In vitro very low concentration of doxycycline is able to block mitochondria,[2] and this antiinflammatory dose is approved up to a 12-month use in rosacea[9] so a prolonged course together with vitamin C may also be an inexpensive, safe, and promising approach in antiviral prophylaxis and treatment.

Meeting Report

Doxycycline for Malaria Chemoprophylaxis and Treatment: Report from the CDC Expert Meeting on Malaria Chemoprophylaxis

Kathrine R. Tan,* Alan J. Magill, Monica E. Parise, and Paul M. Arguin

Division of Parasitic Diseases and Malaria, Center for Global Health, Centers for Disease Control and Prevention, Atlanta, Georgia; Walter Reed Army Institute for Research, Silver Spring, Maryland

Abstract. Doxycycline, a synthetically derived tetracycline, is a partially efficacious causal prophylactic (liver stage of *Plasmodium*) drug and a slow acting blood schizontocidal agent highly effective for the prevention of malaria. When used in conjunction with a fast acting schizontocidal agent, it is also highly effective for malaria treatment. Doxycycline is especially useful as a prophylaxis in areas with chloroquine and multidrug-resistant *Plasmodium falciparum* malaria. Although not recommended for pregnant women and children < 8 years of age, severe adverse events are rarely reported for doxycycline. This report examines the evidence behind current recommendations for the use of doxycycline for malaria and summarizes the available literature on its safety and tolerability.

SUMMARY

Indications. The only U.S. Food and Drug Administration (FDA)-approved indication for the use of doxycycline for malaria is for prophylaxis of *Plasmodium falciparum* in short-term travelers (< 4 months) to areas with chloroquine and/or pyrimethamine-sulfadoxine-resistant strains. Although not FDA approved, doxycycline is recommended for prophylaxis of other species of malaria[1] and may be used long term. When used in conjunction with other medications, doxycycline can be used for the treatment of malaria in non-pregnant adults and children ≥ 8 years of age: with quinine sulfate for uncomplicated, chloroquine-resistant *P. falciparum*; with both quinine sulfate and primaquine for uncomplicated chloroquine-resistant *Plasmodium vivax*; and with parenteral quinidine for severe malaria.[2]

Dosing. Available in multiple dosage forms and strengths, doxycycline tablets or capsules of 100 mg are most often used for malaria prophylaxis or treatment. Tablets or capsules should be swallowed with an adequate amount of fluid and should be taken with food. Intravenous (IV) formulation is available for patients unable to take oral medications for treatment. For IV, avoid rapid administration.

Adults. Prophylaxis: 100 mg base once daily starting 1–2 days before travel, then daily during travel, and daily for 4 weeks after leaving the malarious area.

Treatment: 100 mg twice a day for 7 days; must be used in conjunction with a fast acting schizontocide. Primaquine is also required if treating *P. vivax* or *Plasmodium ovale*.

Children. For children ≥ 8 years of age.

Prophylaxis: 2.2 mg/kg (up to adult dose of 100 mg) daily starting 1–2 days before travel, daily during travel, and daily for 4 weeks after leaving the malarious area.

Treatment: 2.2 mg/kg (up to adult dose of 100 mg) twice a day for 7 days; must be used in conjunction with a fast acting schizontocide. Primaquine is also required if treating *P. vivax* or *P. ovale*.

Efficacy. Prophylaxis: Protective efficacy of doxycycline has been shown in three randomized placebo-controlled trials to be between 92% and 96% for *P. falciparum* and 98% for primary *P. vivax* infection.

Treatment: When used in combination with a fast acting schizontocide, treatment efficacy of doxycycline has been shown to be 96–100% in three open-label trials.

Pharmacokinetics. Limited data suggest that milk and other dairy products may limit the bioavailability of doxycycline. It is recommended to separate doxycycline and ingestion of dairy products by 2–3 hours.

Adverse drug reactions. Most common mild/moderate adverse drug reactions (ADRs): nausea, vomiting, abdominal pain, photosensitivity, and vaginitis. Women prone to candidal vaginitis should consider carrying a self-treatment course of an anti-fungal. Severe ADRs are uncommon and include esophagitis and esophageal ulcerations. Doxycycline monohydrate has been observed to have less gastrointestinal side effects than doxycycline hyclate.

Contraindications. Doxycycline is contraindicated in those who have known hypersensitivity to tetracyclines.

Drug interactions. Decreased absorption of doxycycline can occur if taken concurrently with medications with divalent or trivalent cations such as antacids, laxatives, and oral iron preparations. Although the current FDA label states "concurrent use of tetracycline may render oral contraceptives less effective," recent studies have failed to show a significant association between oral contraceptive failure and tetracyclines. Tetracyclines may potentiate the effect of oral anticoagulants, therefore patients on oral anticoagulants should have prothrombin times monitored closely and dose adjusted as needed. Concurrent use of tetracyclines and methoxyflurane anesthesia is not recommended. Barbiturates, carbamazepine, and phenytoin decrease the half-life of doxycycline.

Warnings. Pregnancy category D: Do not use in pregnancy except for the treatment of life-threatening multidrug-resistant *P. falciparum* when no other treatment options are available. Not recommended for children < 8 years of age.

Use during breastfeeding. Excreted in low concentrations in breast milk; noted to be compatible with breastfeeding by the American Academy of Pediatrics.

INTRODUCTION

Doxycycline is a broad-spectrum bacteriostatic agent synthetically derived from naturally occurring tetracyclines produced

FOI 26-3132 - Document 5

by *Streptomyces* sp. bacteria.[3] Doxycycline was invented and clinically developed in the early 1960s by Pfizer Inc., New York, NY, and marketed under the brand name Vibramycin. Vibramycin received FDA approval in 1967, becoming Pfizer's first once-a-day broad-spectrum antibiotic. The additional indication for malaria prophylaxis was obtained in 1994 with a supplemental New Drug Application. Tetracyclines were first reported efficacious against drug-resistant malaria in the 1970s.[4,5] Early studies examined the effectiveness of tetracycline, minocycline, and doxycycline as antimalarials.[4–8] The evidence for minocycline beyond these early studies is limited, and the four times per day dosing of tetracycline may make adherence difficult. Of the tetracyclines, doxycycline has the most evidence for its effectiveness as an antimalarial.

RECOMMENDED USES AND DOSING OF DOXYCYCLINE

Doxycycline can be used by travelers to all malaria-endemic areas for malaria prophylaxis. When used in conjunction with other medications, doxycycline can also be used to treat malaria.

Prophylaxis. Doxycycline can be used for the prevention of malaria in travelers to malaria-endemic areas and is a good option for areas with chloroquine or multidrug-resistant *P. falciparum*. For prophylaxis, doxycycline is taken once daily beginning 1–2 days before travel, while in malarious areas, and for 4 weeks after leaving. Daily dosage for children ≥ 8 years of age is 2.2 mg/kg (not to exceed the adult dose of 100 mg) and for adults 100 mg.

Treatment. Doxycycline should always be used in conjunction with another drug for treatment of malaria. Quinine with doxycycline can be used for uncomplicated malaria caused by chloroquine-resistant *P. falciparum* or *P. vivax*. When used for severe malaria doxycycline should be used with intravenous quinidine. The treatment dose of doxcycyline in adults is 100 mg twice a day and for children 2.2 mg/kg twice a day up to a maximum of 100 mg twice daily. For those unable to tolerate oral medications, doxycycline is available in a parenteral form and can be made in concentrations between 0.1 and 10 mg/mL. If pain occurs while receiving doxycycline intravenously, it is recommended to use more dilute concentrations (no lower than 0.1 mg/mL) infused at rates no higher than 1 mg/min[9]; switch to an oral formulation once the patient is able to tolerate medications by mouth. If treating *P. vivax* or *P. ovale*, in addition to the aforementioned drugs, primaquine must also be given to prevent relapses (see Pharmacodynamics section).

EFFICACY AND EFFECTIVENESS

The emergence of chloroquine-resistant *P. falciparum* in the 1960s spurred efforts to examine alternative medications such as tetracyclines with antimalarial activity. Early studies examined the treatment and prophylactic efficacy of tetracyclines such as doxycycline, tetracycline, and minocycline against chloroquine-resistant *P. falciparum*. Since these earlier studies, the preponderance of literature on efficacy of tetracyclines as antimalarials has focused on doxycycline.

Overall, studies have showed that doxycycline is a slow-acting blood schizontocidal agent, had partial causal effects and no sporontocidal or gametocytocidal effects, and is effective in the treatment and prevention of malaria (prophylaxis Table 1).[10–18] Doxycycline 100 mg daily has been shown to be highly effective as a blood schizonticidal agent, meaning that it kills the asexual, erythrocytic stages of the malaria parasite.[10,12–21] Three randomized, double-blinded, placebo-controlled studies showed that in semi-immune patients, 100 mg of doxycycline daily had a protective efficacy of 84% (95% confidence interval [CI] = 79.9–97.5%), 92.6% (95% CI = 79.9–97.5%), and 96% (95% CI = 85.4–99.6%) for *P. falciparum* infections.[10,11,18] One of these studies found that doxycycline had a 98% (95% CI = 88.0–99.9%) protective efficacy against primary *P. vivax* infection,[18] but did not examine protective efficacy against relapses. Another randomized, double-blinded, placebo-controlled study showed a 99% (95% CI = 94–100%) protective efficacy of doxycycline 100 mg daily for *P. falciparum* in 67 non-immune Indonesian soldiers.[13] However, in two of these studies, participants were not followed up after leaving the malaria-endemic areas, and it was unclear if prophylactic medications were continued after leaving. One open-label trial followed non-immune patients for 3 months after returning from a malaria-endemic country. Patients had received 100 mg of daily doxycycline while abroad. Of these 171 patients, only 5 (0.6%) developed *P. falciparum* malaria during the follow-up period. Of these 5, one developed malaria while on prophylaxis and 4 developed symptoms after discontinuation of prophylaxis during the 3 months of observation upon returning to a malaria-free country.[12]

Other studies have also shown doxycycline to have inadequate causal activity, or activity against the liver stage of the malaria parasite, which has implications for doxycycline's post-exposure course.[5,22–24] One randomized, double-blinded, placebo-controlled trial examined the efficacy of doxycycline prophylaxis for *P. falciparum* malaria when taken by individuals exposed to mosquitoes infected with *P. falciparum*. Doxycycline was taken daily 3 days before exposure and for 6 days post exposure. Four of 12 persons taking that preventive regimen developed falciparum malaria 15–24 days after completing medications; the protective efficacy was 67% (95% CI = 35–90%).[23] Another study found that of 60 soldiers who received 100 mg of doxycycline a day before deployment, 6 weeks during their deployment, and for 3 days after their return, none had falciparum malaria, whereas two developed vivax malaria.[16] These studies suggest that doxycycline has some tissue schizontocidal activity for *P. falciparum*, but is insufficient for causal prophylaxis. Doxycycline would therefore have to be continued for a sufficient amount of time post exposure for successful suppression of parasites that emerge from the liver. Studies have observed that[5,22–24] malaria developed within 3–4 weeks post exposure. It is therefore recommended that doxycycline prophylaxis be continued for 4 weeks post exposure.

Doxycycline's limited activity in the liver stages of *Plasmodium* also means that it does not kill *P. vivax* hypnozoites. Although very effective for preventing primary *P. vivax* infections, doxycycline is not effective at preventing relapses.

The dose of doxycycline required to achieve successful malaria prophylaxis was also examined. The efficacy of half-dose doxycycline (50 mg/day, $N = 67$) was compared with full-dose doxycycline (100 mg/day, $N = 77$). One open-label, randomized, controlled trial found that full-dose doxycycline was significantly more effective in prevention of *P. vivax,*

TABLE 1
Efficacy of doxycycline for prophylaxis*

Country (population)	Study type	Sample size on doxycycline	Duration of prophylaxis	Efficacy (95% CI, if reported)
Kenya (semi-immune)[10]	Randomized, double-blind, comparators = azithromycin daily ($N = 59$), azithromycin weekly ($N = 58$), and placebo	55	10 weeks	Doxycycline: 92.6% (79.9–97.5%) Azithromycin daily: 82.7% (68.5–91.1%) Azithromycin weekly: 64.2% (47.1–77.1%) azithromycin weekly
Kenya (semi-immune, children aged 9–14)[11]	Randomized, double-blind, comparators = primaquine daily ($N = 32$), proguanil daily plus chloroquine weekly ($N = 37$), vitamin daily plus weekly mefloquine ($N = 30$), vitamin alone ($N = 34$)	32	11 weeks	Doxycycline: 84% (66–92%) Primaquine: 85% (68–93%) Mefloquine: 77% (55–88%) Chloroquine plus proguanil: 54% (25–72%)
Gabon and Central African Republic (non-immune)[12]	Randomized, open-label, comparator = CP ($N = 270$)	171	Travel: 4 months	Doxycycline: 97.0% CP: 98.9%
Irian Jaya (non-immune)[13]	Randomized, double-blind, comparator = MQ ($N = 68$) and placebo	67	13 weeks	Doxycycline: 99% (94–100%) overall, 98% (88–100%) for *P. falciparum*, 100% (90–100%) for *P. vivax* MQ: 100% (96–100%) overall, 100% (93–100%) for *P. falciparum*, 100% (91–100%) for *P. vivax*
Thai–Burmese border (semi-immune children aged 10–16 years)[14]	Randomized, open-label, comparators = half-dose doxycycline ($N = 77$), placebo	67	5 months	Full-dose: 5 cases/1070 person-weeks Half-dose: 20 cases/1176 person-weeks
Thai-Burmese border (semi-immune children aged 19015 years)[15]	Randomized, open-label, comparator = CQ ($N = 93$)	95	9 weeks	Doxycycline: 5 cases/597 person-weeks CQ: 31 cases/488 man-weeks
Papua New Guinea (PNG), Malaysia, Thailand (non-immune)[16]	Open-label, comparators = MQ ($N = 40$, PNG), doxycycline + PQ ($N = 69$, PNG), doxycycline + CQ ($N = 125$, Malaysia and Thailand)	60 55	6 weeks 3 weeks	Doxycycline ($N = 60$): 100% for *P. falciparum*, 96.7% for *P. vivax* Doxycycline ($N = 55$): 100% for *P. falciparum*, 76.4% for *P. vivax* MQ: 100% for *P. falciparum*, 90% for *P. vivax* Doxycycline + PQ: 100% for both *P. falciparum* and *P. vivax*
Thai-Kampuchean border (non-immune)[17]	Randomized, open-label, comparators = half-dose doxycycline ($N = 243$) or phyrimethamine + dapsone ($N = 123$), adherence observed but not enforced	243	17 weeks	Doxycycline + CQ: 81% (Adherence 73% for both doxycycline groups)
Irian Jaya, Indonesia (non-immune)[18]	Randomized, double-blind, placebo-controlled, comparators: azithromycin ($N = 148$), placebo	75	20 weeks	Doxycycline: 97.1% (91.2–99.4%) overall, 96.3% (85.4–99.6%) *P. falciparum*, 98.0% (88.0–99.9%) *P. vivax* Azithromycin: 84.7% (75.5–90.7%) overall, 71.6% (50.3–83.8%) *P. falciparum*, 98.9% (93.1–99.9%) *P. vivax*

* CI = confidence interval; CP = chloroquine-proguanil; MQ = mefloquine; PQ = primaquine; CQ = chloroquine.

however the study was not powered to detect a difference between the two doses of doxycycline in preventing *P. falciparum* infections.[14] Another study examined the effectiveness of full-dose and half-dose doxycycline under operational conditions; adherence to medications was not enforced. Although adherence to full versus half-dose doxycycline was not examined, the study found that on average 73% of the doxycycline regimen was taken and that half-dose (33% infected) was significantly less effective than full-dose doxycycline (19% infected) at preventing both *P. falciparum* and primary *P. vivax* infection.[17]

Treatment (Table 2).[5,26–29] Doxycycline has been shown to be a slower acting blood schizonticide during the course of an acute *Plasmodium* infection relative to other antimalarials.[30] However, doxycycline achieves good treatment efficacy when given with rapidly acting shizontocidal drugs such as quinine or quinidine. Studies have reported parasite clearance times (*P. falciparum*) between 3.8 and 6.0 days and fever clearance times between 3.6 and 4.0 days in patients treated with only tetracycline or doxycycline.[4,7,25,26] These clearance times are longer than those observed in patients given quinine alone with parasite and fever clearance times of 2.6 days and 1.9–2.6 days, respectively.[31,32] In terms of treatment efficacy, in patients given doxycycline or tetracycline alone for *P. falciparum*, cure rates between 75% and 100% have been reported.[5,7] Therefore, the slowness with which tetracyclines act make them of limited usefulness as a monotherapy in *P. falciparum* infections.[5,7] The usefulness of tetracycline when given with a faster acting schizontocidal drug, quinine, was studied when decreased effectiveness of quinine was observed in Southeast Asia.[7,32,33] Two open-label trials, one non-randomized and the other randomized, gave subjects quinine (640 mg three times daily for 3 days, and 600 mg four times daily for 7 days, respectively) and tetracycline (250 mg four times daily for 10 days) and found treatment efficacies between 96% and 98% with average parasite clearance times between 3 and

FOI 26-3132 - Document 5

TABLE 2
Efficacy of doxycycline with or without quinine for treatment of *P. falciparum* malaria

Country (population)	Study type	Sample size/doxycycline dose	Duration of treatment	Cure rate (95% CI)
United States (mixture of immune and non-immune)[5]	Challenge, open-label	*P. vivax:* 1/100 mg twice a day 1/100 mg twice a day *P. falciparum:* 4/100 mg twice a day 9/100 mg twice a day	4 days 5 days 7 days	0 0 0 100%
West Malaysia (varied, children aged 2 months–8 years)[27]	Challenge, open-label	9/4 mg/kg daily 26/4 mg/kg daily	4 days 7 days	44.4% 84.6%
Irian Jaya, Indonesia (non-immune)[26]	Randomized, open-label, comparator = CQ (N = 30) and doxycycline + CQ (N = 39)	20/100 mg twice a day	7 days	*P. falciparum*: 64.7% (42.0–87.4%) *P. vivax*: 33.3% (6.6–59.5%)
Brazil (semi-immune)[28]	Randomized, open-label, comparator = AL (N = 28)	31/100 mg twice a day + 500 mg quinine every 8 hours	5 days doxycycline 3 days quinine	100%
Pakistan (unknown immune status)[29]	Challenge, open-label	100/100 mg twice a day + 10mg/kg quinine every 8 hours	7 days doxycycline 3 days	100%

3.6 days and a fever clearance time of 2.6 days.[7,34] Furthermore, one study observed that tetracycline contributed to the maintenance of plasma quinine levels above the minimum inhibitory concentration during the treatment period.[35] It was then extrapolated from these studies that quinine plus doxycycline would also be an effective malaria treatment regimen. More recently, an open-label trial showed 100% cure of all subjects given quinine (10 mg/kg three times a day for 3 to 7 days) and doxycycline (100 mg twice a day for 7 days) for treatment of uncomplicated *P. falciparum* malaria.[29] Therefore, doxycycline should be given with a rapidly acting schizontocide for timely and effective malaria treatment.

PHARMACOKINETICS AND PHARMACODYNAMICS

Pharmacokinetics. An oral dose of 100–200 mg of doxycycline is almost completely absorbed in the duodenum and stomach and is detectable in the blood 15–30 minutes after administration. Following a 200 mg oral dose, peak concentrations of ~2.6 µg/mL are reached at ~2 hours, but this may vary as gastrointestinal (GI) absorption rates can differ among individuals.[3,36,37] Doxycycline, being highly lipophilic, is readily transported across cell membranes, resulting in widespread distribution in body tissues and fluids.[37] Doxycycline binds to serum proteins, localizes in the bone marrow, liver, and spleen, crosses the placenta, and is excreted in breast milk.[3] Tetracyclines also form tetracycline-calcium orthophosphate complexes in sites of calcification such as developing teeth and bone.[3] The bioavailabililty of the doxycycline derivatives, the monohydrate free base and the hydrochloride salt (hyclate), has been shown to be equivalent.[37]

According to the FDA, the absorption of doxycycline "is not markedly influenced by simultaneous ingestion of food and milk," despite the reduced absorption observed with other tetracyclines. However, more recent studies on this subject, while limited, have shown that the absorption of doxycyline is affected to some degree by food and milk, but the clinical consequence of this is not well understood. Food has been shown to decrease serum levels of doxycycline from 4.4 to 4.0 µg/mL, but this has not been shown to be clinically significant.[3,37] Milk decreases the absorption of tetracyclines because of chelation between the calcium in the milk and tetracyclines, however the magnitude of this decrease varies between different tetracycline preparations, and the data for doxycycline is limited.[38,39] One single-dose, cross-over study administered doxycycline with either water or milk to nine volunteers and found that milk decreased the peak plasma drug concentration by 24% and that the area under the plasma concentration-time curve from 0 to 32 hours decreased by 35%.[39] How this decrease in bioavailability translates clinically is not known. Furthermore, doxycycline is a lipophilic drug and it is not known if the fat content of the food or drink affects its absorption. In these studies, the fat content of the food and milk ingested was not discussed. Therefore, food taken with doxycycline to prevent gastrointestinal side effects is not expected to decrease efficacy of the drug; however, there is some limited data that suggests that milk reduces the bioavailability of doxycycline, which may have a negative impact on drug efficacy as in other tetracyclines. Because of absent better data, it would seem prudent to caution individuals to avoid milk and other dairy products when ingesting their daily doxycycline. Separation of the ingestion of doxycycline and ingestion of milk by 2–3 hours (time for absorption and peak concentration) should be satisfactory.

Unlike other tetracyclines, excretion of doxycycline occurs primarily by the gastrointestinal tract and to a much lesser extent by the kidneys.[40–42] Most of a doxycycline dose diffuses from the serosal to the mucosal side of the small bowel. Doxycycline is chelated to an inactive form intraluminally and is excreted.[41,43] A very small portion is also concentrated by the liver in bile for excretion in feces.[41,43] Serum half-life of doxycycline (15–25 hours) is not affected by impaired renal function or hemodialysis, and in patients with renal failure, all excretion of doxycyline occurs by the gastrointestinal route of excretion.[42,43]

There are limited to no data on sex, age, body weight, or race differences in the pharmacokinetics of doxycycline. One study found no differences between males and females (N = 14 males and 14 females).[44]

Pharmacodynamics. Although it is known that doxycyline is a blood schizontocide,[45] the exact mechanism of action is not well defined. In *P. falciparum*, doxycycline has been

FOI 26-3132 - Document 5

observed to block the expression of apicoplast genes, leading to nonfunctional apicoplasts in subsequent progeny, and impeding the development of viable parasites.[46] It is also thought that doxycycline's antimalarial actions may be similar to its bacteriostatic actions of binding to ribosomal subunits and inhibiting protein synthesis, but this has only been observed in supra-pharmacologic doses.[47] Doxycycline has also been observed to have some degree of pre-erythrocytic activity in *P. falciparum*.[16] Of 55 men given a doxycycline prophylaxis regimen that ended 3 days after travel, 13 developed *P. vivax* and none developed *P. falciparum*.[16] Two other studies observed breakthroughs to doxycycline prophylaxis for *P. falciparum* between 2 and 12 weeks after administration of medication and for *P. vivax* between 4 and 9 weeks.[14,15] There are no data on the causal activity of doxycycline for the other species of malaria. On the basis of these studies, the recommended duration of the post-exposure course of doxycycline is 4 weeks. Doxycycline has no effect on the hypnozoites of the *Plasmodium* species.[16,45] Because of this, when treating patients infected with species such as *P. vivax* and *P. ovale* with quinine and doxycycline, a 2-week course of primaquine must be added to kill hypnozoites.[48] There is very limited evidence on doxycycline's effect on gametocytes. Only one study was found that looked at gametocytemia and doxycycline. In this study, *P. vivax* gametocytemia increased after treatment with doxycycline (from 32% pre-treatment to 44% immediately post-treatment) with a median gametocyte clearance time of 62 hours.[49] Although gametocytemia has no clinical implications, malaria in an individual being treated with doxycycline may still be transmitted through mosquitoes.

There is no global consensus on the threshold of susceptibility for use in *in vitro* susceptibility testing for doxycycline. Traditionally, culture-derived or field *P. falciparum* isolates are incubated with varying concentrations of drug and inhibition of replication is measured by several methods to yield a 50% inhibitory concentration (IC50) at 48, 72, or 96 hours. The assay conditions and the drug mechanism of action can markedly affect results.[50] Frequently, the incubation time for these assays is one cycle of parasite replication or 48 hours, but for doxycycline at least 72 hours and preferably 96 hours is needed, depending on the assay method, to obtain accurate results. The increased incubation time is required because doxycyline has been shown to exert its effect during the first 48 hours, but is only detectable in second generation parasites near the 96 hour time point.[46,51,52] However, most studies have been limited to 48-hour assays. One study in French Guiana suggested an IC_{50} cutoff level of 9.6 μM for a 48-hour assay and noted that after both quinine and doxycycline were recommended as first-line malaria treatment in 1995, there was an increase of mean IC_{50s} from 9.6 μM in 1996–1999 to 13.1 μM in 2005.[53] Another study examined *P. falciparum* samples of French patients who traveled to various African countries between 1997 and 2006 using a 42-hour assay and found an overall mean IC_{50} of 9.3 μM with country-specific means ranging between 6.2 and 11.1 μM.[54] The findings of these two studies found many samples with IC_{50s} above the suggested 9.6 μM threshold. However, these findings are not consistent with the relative dearth of reporting of doxycycline failure (when taken appropriately either as prophylaxis or treatment) in the literature. Another study further identified possible molecular markers for decreased *in vitro* susceptibility to doxycycline defined as an IC_{50} of 35 μM.[55]

Resistance of *P. falciparum* to doxycycline is not described but breakthroughs in prophylaxis have been associated with inadequate doses,[14] possibly inadequate serum levels,[11] and poor compliance.[56,57] A clear relationship between the development of clinical symptoms with confirmed *P. falciparum* parasitemia and a serum or plasma level of doxycycline or a predictive IC_{50} in a well-qualified *in vitro* susceptibility assay remains to be determined. More studies are needed to examine emergence of doxycycline resistance and establish a clinically relevant susceptibility threshold.

ADHERENCE

Adherence to daily doxycycline throughout the period of exposure to malaria and for 4 weeks following exposure is vital in achieving full effectiveness of doxycycline as a malaria prophylactic agent. The effectiveness of doxycycline among persons in whom adherence was not enforced was compared with persons in whom compliance was enforced. Effectiveness was only 89% (78–96%) for all types of malaria compared with 99% (94–100%) in soldiers in whom adherence was enforced.[13] Because of doxycycline's short half-life and the mechanism of action (asexual parasite killing at the end of two cycles of erythrocytic replication or 96 hours) relative to that of weekly medications, missing a few doses of doxycycline would have greater consequences than being a few days late for a medication with a long half-life.

Most studies suggest that adherence to daily doxycyline is more challenging than adherence to a weekly medication. One study reported that full adherence to doxycycline daily (81%, $N = 52$) was lower than that for weekly mefloquine (98%, $N = 344$) among United States troops in Somalia; however, it was not discussed whether administration of one or both medications was supervised.[19] Another study in Thai soldiers did not enforce or observe drug administration and reported that adherence (at least 75% of the time) occurred in more than 70% of men given a weekly drug (Maloprim) and in only 50% given doxycycline daily.[17] Survey-based studies of travelers or military personnel have found adherence rates for doxycycline prophylaxis to be between 70% and 84%. A decrease in adherence over time has also been demonstrated. In Australian troops, adherence to daily doxycycline decreased from 60% at 2 months to 44% at 4 months.[21] Only one study of French soldiers in sub-Saharan Africa comparing daily doxycycline to weekly chloroquine-proguanil (CP) found that a decrease in adherence occurred over time in both groups regardless of regimen.[58] Therefore, studies seem to show that short-term adherence to daily prophylaxis is more challenging than for a weekly medication, but long-term adherence decreases for both daily and weekly prophylactic regimens.

SAFETY AND TOLERABILITY

General (Tables 3[10,13–16,19,20,28,57,58,61–64] and 4[10,12–15,19,21,28,57,58,61–64]). Doxycycline is generally well tolerated with GI complaints and photosensitivity among the most common adverse events (AEs). Most available information on AEs in doxycycline are from studies examining doxycycline at prophylactic doses (100 mg/day), and there is limited information on AEs in doxycycline at treatment doses. At prophylactic doses of doxycycline, reports of mild and moderate AEs vary widely among studies from 0.6% to 84% of the study population.[13,20,21,59–61] This variation can be

FOI 26-3132 - Document 5

TABLE 3
Mild to moderate adverse events (AEs) associated with doxycycline prophylaxis and treatment*

Study location (design)	Sample size, dose, duration	Most frequent AE	Comparator	AE risk with doxycyline
Prophylaxis				
Kenya (RDBPC, semi-immune)[10]	55, 100 mg doxycycline hyclate daily, 10 weeks	Events: Abdominal pain 49 Diarrhea 9 Vomiting 6 Vaginitis 5	Azithromycin daily Azithromycin weekly Placebo	No difference between doxycycline and comparators
Thailand (RDB, non-immune)[62]	119, 100 mg doxycycline daily, 5 weeks	Nausea 16.7% Headache 10.7% Skin rash 10.7% Dizziness 6.3% Vomiting 4.4%	MQ	No difference between doxycycline and MQ
Africa (observational, non-immune)[63]	188, 100 mg doxycycline daily, 4 days	Nausea 33.0% Abdominal pain 22.9% Drowsiness 23.9% Headache 19.7% Vomiting 8.5% Dizziness 7.4% Rash 0.5%	MQ	Doxycycline group had significantly more nausea, abdominal pain, vomiting, drowsiness, headache, and dizziness than MQ goup.
Irian Jaya, Indonesia (RDBPC, non-immune)[13]	67, 100 mg doxycycline daily, 13 weeks	Skin-related 33% Cough 31% GI symptoms 24% Headache 16% Dizziness 9% Insomnia 6%	MQ Placebo	Doxycycline group had significantly fewer AE relative to MQ and placebo.
Thai-Burmese border (RPC, open-label, semi-immune, children aged 10–16 years)[14]	67, > 40 kg 100 mg doxycycline daily, < 40 kg 50 mg doxycycline daily, 5 months	Abdominal pain 16% Nausea 12% Diarrhea 8% Vomiting 4% Headache 34.3% Dizziness 26.8%	Doxycycline half-dose	Full-dose doxycycline more likely to have GI symptoms than half dose. Full-dose doxycyline less likely to have headache and dizziness than placebo.
Thai-Burmese border (R, open-label, semi-immune, children aged 10–16 years)[15]	95, > 40 kg 100 mg doxycycline daily, < 40 kg 50 mg doxycycline daily, 9 weeks	Dizziness 27% Nausea 20% Headache 17% Fever 15% Abdominal pain 8% Vomiting 7% Diarrhea 7%	CQ	No difference between doxycycline and CQ
Papua New Guinea (open-label, non-immune)[16]	55, 100 mg doxycycline daily, 3 weeks	Gastrointestinal 24% Photosensitivity 7.3%	Doxycycline + PQ	No difference between doxycycline and doxycycline + PQ
Somalia (observational, non-immune)[19]	52, 100 mg doxycycline daily, 7 weeks	Gastrointestinal 34.6% Photosensitivity 21.2% Lightheadedness 19.2%	MQ	Doxycycline had significantly higher rates of photosensitivity and gastrointestinal events than MQ.
Rwanda (observational, non-immune)[20]	28, 100 mg doxycycline daily, 2 months	Abdominal pain 33.3% Fatigue 23.8%	MQ	Doxycyline had higher rates of AE compared with MQ.
Somalia (observational, non-immune)[57]	499, 100 mg doxycycline daily, varied time periods	Gastrointestinal 17% Dizziness 10% Insomnia or nightmares 9% Sunburn 5%	MQ	No significant difference between doxycycline and MQ, except MQ had more insomnia or nightmares.
Sub-Saharan Africa (RDB, placebo run-in phase, non-immune)[61]	153, 100 mg doxycycline	Neuropsychological 24% Gastrointestinal 14% Skin itching, reddening 5% Skin and vaginal itching, abnormal discharge 9%	MQ CP Atovaquone and Proguanil	Doxycycline had less neuropsychological events than mefloquine, and less adverse skin events than CQ + proguanil. No increased risk of vaginal candidiases with doxycycline.
Chad and Gabon (randomized groups, non-immune)[58]	275, 100 mg doxycycline monohydrate daily, 5 months	Events: Diarrhea 52 Epigastralgia 46 Nausea 30 Vertigo 14 Mouth ulcers 11 Pruritis 11 Skin rash 9 Sun sensitization 4	CP	Doxycycline had significantly less diarrhea, epigastralgia, mouth ulcers, urticaria, pruritis, rash, and sun sensitization than CP. No statistical difference in nausea and vertigo.
Varied countries (observational, non-immune)[64]	228, 100 mg doxycycline daily, at least 6 months	Gastrointestinal 35% Skin and vaginal 34% Neuropsychologic 30%	MQ CQ	Doxycycline had a higher proportion of skin, vaginal, and gastrointestinal events than MQ and CQ.
Treatment				
Brazil (R, open-label, semi-immune)[28]	31, 100 mg doxycycline twice a day for 5 days + 500 mg quinine every 8 hours for 3 days	Upper abdominal pain 41.4% Nausea 34.5% Vomiting 27.6% Asthenia 27.6% Headache 27.6%	AL	Frequency of AE were similar for both doxycycline and AL.

* MQ = mefloquine; GI = gastrointestinal; CQ = chloroquine; PQ = primaquine; CP = chloroquine-proguanil; AL = artemether/lumefantrine.

TABLE 4
Severe adverse events (AE) associated with doxycycline prophylaxis and treatment

Study location (design)	Sample size, dose, duration	Severe AE	Discontinued because of AE
Prophylaxis			
Kenya (RDBPC, semi-immune)[10]	55, 100 mg doxycycline hyclate daily, 10 weeks	Recurrent vaginitis 1	1 withdrew
Thailand (RDB, non-immune)[62]	119, 100 mg doxycycline daily, 5 weeks	None	None
Gabon and Central African Republic (non-immune)[12]	171, 100 mg doxycyline hyclate daily, 4 months	Gastrointestinal side effects 11	11 withdrew
Africa (observational, non-immune)[63]	188, 100 mg doxycycline daily, 4 days	Esophagitis 1	1 discontinued, requiring further evaluation and treatment
Irian Jaya, Indonesia (RDBPC, non-immune)[13]	67, 100 mg doxycycline daily, 13 weeks	None	None
Thai-Burmese border (semi-immune, children aged 10–16 years)[14]	67, 100 mg doxycycline daily, 5 months	None	None
Thai-Burmese border (R, open-label, semi-immune, children aged 10–16 years)[15]	95, > 40 kg 100 mg doxycycline daily, < 40 kg 50 mg doxycycline daily, 9 weeks	None	None
Rwanda (observational, non-immune)[19]	28, 100 mg doxycycline daily, 2 months	Abdominal pain 1	1 discontinued
Somalia, Cambodia (observational, non-immune)[21]	900, 100 mg daily, 4 months, all received primaquine eradication course after travel	Sun sensitization 13 Gastroinestinal problems 2	15 discontinued
Somalia (Observational, non-immune)[57]	499, 100 mg doxycycline daily, varied time periods	Odynophagia 4	4 discontinued, required hospitalization because of dehydration
sub-Saharan Africa (RDB, placebo run-in phase, non-immune)[61]	153, 100 mg monohydrate daily, 7–9 weeks	Skin and vaginal itching, abnormal discharge 4 Skin itching, reddening 3 Gastrointestinal 3 Neuropsychological 1	5 withdrew, did not specify which AE
Chad and Gabon (randomized groups, non-immune)[58]	275, 100 mg doxycycline monohydrate daily, 5 months	Gastrointestinal effects 9 Headache 5 Sun sensitization 1	15 withdrew
Varied countries (observational, non-immune)[64]	228, 100 mg doxycycline daily, at least 6 months	Gastrointestinal 11 Skin and vaginal 9 Neuropsychologic 5	Did not specify. Regimen changes caused by AE was lower among those taking doxycycline than those taking CQ or MQ.
Treatment			
Brazil (R, open-lab,[28] semi-immune)[61]	31, 100 mg doxycycline twice a day for 5 days + 500 mg quinine every 8 hours for 3 days	Vomiting 1	1 withdrew

explained in part because of a high background rate of non-specific symptoms experienced by both non-immune travelers and semi-immune study subjects in malaria endemic areas, differing definitions of mild and moderate AEs, use of different salts and formulations of doxycycline, and different study populations.

Reports of AEs of doxycycline at treatment doses (100 mg twice a day) are very limited because studies often examine malaria treatment with doxycycline in combination with another drug such as quinine, and it is difficult to determine if symptoms are related to doxycycline alone, malaria, the accompanying drug, or because of a drug-drug interaction. One randomized, open-label study comparing treatment of malaria with doxycycline and quinine versus artemether-lumefantrine found that at least one AE was reported in 93.5% of patients treated with quinine-doxycycline and 89.2% of those treated with artemether-lumefantrine; statistically similar proportions.[28] No serious AEs were noted in both groups.[28]

Gastrointestinal adverse events. Gastrointestinal symptoms are usually mild to moderate and include nausea (4–33%) and abdominal pain (12–33%).[13–15,19,20,58,62,63] Nausea has been noted to be more common when doxycycline is ingested without food.[13,21] Vomiting (4–8%) and diarrhea (6–7.5%) are less commonly reported.[13–15,62,63] The GI symptoms requiring a change in medication have been reported infrequently (0.2–6.4%).[12,20,21]

Doxycycline and other tetracyclines are believed to be the most common cause of drug-induced esophageal disorders.[64,65] It is thought that long transit times of the pills in the esophagus contributes to mucosal inflammation and that ingestion of a sufficient amount of fluid, taking the pill while in an upright position, and avoiding taking the pill before bedtime could decrease the transit time and prevent inflammation.[65,66] Doxycycline has been implicated in esophagitis; among United States military personnel returning from Somalia, 4 of 499 (0.8%) who took daily doxycycline developed odynophagia with dehydration requiring hospitalization.[57] One other study, a shipboard survey, found esophagitis in 1 of 188 persons taking doxycyline prophylaxis.[63]

The effect of various doxycycline salts and formulations such as oral suspensions, tablets, capsules, and enteric-coated tablets are likely quite significant in their ability to cause GI adverse events. Gelatin capsules have been observed to be more sticky than tablets, delaying transit time or even adhering to the esophageal lining, and this is affected by the amount of fluids ingested with the pills.[65,67] Enteric-coated formulations are available

FOI 26-3132 - Document 5

and may decrease GI side effects. One double-blind, placebo-controlled, multiple-dose cross-over study compared the incidence of GI side effects of enteric-coated doxycycline hyclate pellets in capsules (Doryx, Parke-Davis, Morris-Plains, NJ) and doxycycline hyclate powder in capsules (Vibramycin, Pfizer, New York), the enteric-coated capsule formulation produced statistically significantly fewer episodes of nausea, vomiting, abdominal discomfort, and decreased appetite than did the non-enteric-coated capsules.[68] Differences in GI adverse events between doxycycline salts may exist. In the majority of studies in which doxycycline has been used for malaria prophylaxis, the source of doxycycline, the salts used, and the formulation was not reported. Because the exact active drug ingredient and the formulation used seems to affect the incidence and severity of GI adverse events, rates between studies are difficult to compare. However, one study[12] examining efficacy of doxycycline hyclate in the French Army noted a 6% withdrawal rate caused by GI AEs and attributed this to the hyclate salt acidity and capsule form. Fewer withdrawals caused by GI AEs (1.5% and 4.9% at two study sites) were observed in a follow-up study[58] looking at tolerability of doxycycline monohydrate. Although data are limited, it appears that enteric-coated hyclate formulations and monohydrate salts are better tolerated in terms of GI AEs than standard hyclate capsules or tablets.

Photosensitivity. An erythematous rash in sun-exposed areas has been reported to occur in 7.3–21.2% of persons[16,19,57] taking doxycycline for malaria prophylaxis. One study examined the tolerability of various malaria prophylactic regimens and found that doxycycline did not cause a significantly higher percentage of all skin events (photosensitivity not specified) when compared with other antimalarials. The rash resolves upon discontinuation of the drug. A study of 106 acne patients taking daily doxycycline found a high incidence (35.8%) of light-sensitive rash and suggested that the phenomenon is dose related; 20% of patients taking 150 mg/day of doxycycline developed a light-sensitive rash, whereas 42% of those taking 200 mg/day were affected.[69] It is suggested that patients with lighter complexions (Fitzpatrick skin types 1 and 2) may be more susceptible to doxycycline photosensitivity than patients with darker skin pigmentation.[70] Both ultraviolet A (UV-A) and ultraviolet B (UV-B) radiation have been implicated.[71] Although the mechanism of the phototoxic reaction has not been fully elucidated, it is believed to be mediated by excited-state singlet oxygen and free radicals after irradiation with UV-A radiation, thereby causing selective injury to mitochondria, within which doxycycline and other tetracyclines are localized.[72] Patients developing photosensitivity should be advised to stop taking doxycycline. Avoiding sun exposure, wearing protective clothing, and using a broad spectrum (protection against both UV-A and UV-B radiation) sunscreen can lower the risk of photosensitivity.[73,74]

Vulvovaginitis. Antibiotics such as tetracyclines are believed to suppress vaginal bacterial flora, resulting in overgrowth of candida.[75] A recent *in vitro* study found that tetracycline may also enhance *Candida albicans* virulence factors, but the authors note that it is still unclear as to what degree this contributes to clinical vaginitis.[76] Increased colonization with *C. albicans* after taking tetracyclines has been shown.[75,77,78] After a 3-week course of tetracycline, one study observed that the percentage of women with vaginal cultures positive for *C. albicans* increased from 7% to 24%.[77] Another study had similar findings for both tetracycline and minocycline.[78] Despite this increase in yeast colonization, both studies found that only a small percentage of women with positive candidal vaginal cultures had symptoms of vulvovaginitis.[77,78] In fact, other studies have found that only a small percentage of women develop clinical vulvovaginitis after taking tetracyclines.[10,79] In women taking tetracycline for acne, symptomatic vaginitis was observed in 5%.[79] In another study, only one of 21 (4.8%) women on daily doxycycline withdrew from the study because of repeated episodes of vaginitis.[10] Another study did not find an increased risk for vaginal candidiasis with doxcycyline.[61] Of note, reporting of vaginitis as an adverse drug reaction specifically to doxycycline when taken as malaria prophylaxis is limited because vaginitis is often included under the category of non-specific skin reactions and many of the early studies were done in male military personnel. Women taking doxycycline who have a predisposition to candidal vulvovaginitis, such as those with diabetes mellitus, past history of recurring vulvovaginitis, and those taking oral contraceptives, should consider carrying a self-treatment course of antifungals.

Other AEs. There are other AEs that have been reported in association with tetracyclines. These include case reports of benign intracranial hypertension with tetracycline, minocycline, and doxycycline, but this has been observed to resolve upon discontinuation of the medication and has not been described in someone taking doxycycyline for malaria prevention.[80–82] Skin hyper-pigmentation has been reported in the dermatological literature associated primarily with minocycline, and seems to mainly occur with long-term use and usually fades slowly after discontinuing treatment.[83–88] Only one case report mentions skin hyper-pigmentation associated with doxycycline in a patient who had taken 1 g dose of doxycycline daily for 12 years.[89] Other AEs mentioned in case reports associated with tetracyclines include postinflammatory elastolysis and tooth discoloration in an adult with long-term use (12 years).[90,91] Central nervous system symptoms such as vertigo and ataxia have been more frequently associated with minocycline as compared with doxycycline because of minocycline's greater lipid solubility.[92] *Clostridium difficile*-associated diarrhea (CDAD) has been reported in three patients taking doxycycline for malaria prophylaxis for between 2 and 6 weeks.[93] A more recent case-control study examining antibiotic use and subsequent CDAD found doxycycline to be protective, however, this study did not examine the duration and dose of antibiotic therapy.[94]

Comparative tolerability. There are varying reports of the comparative tolerability of doxycycline. Several non-randomized survey-based studies in military personnel have found a higher occurrence of photosensitivity, GI symptoms, headache, and light-headedness with doxycycline as compared with mefloquine, whereas others have found that doxycycline is better tolerated than mefloquine.[19,20,57,63,64] The type of doxycycline salt and formulation used in these studies were rarely reported, making it difficult to distinguish if the comparative tolerability of doxycycline to other antimalarials was affected by the type of doxycycline preparation used. One randomized, open-label trial found that while more participants taking doxycycline monohydrate withdrew from the study, their rates of adherence were higher compared with those taking chloroquine/progruanil.[58] However, another randomized, open-label trial found doxycycline (unspecified salt) to be tolerated as well as chloroquine.[15]

FOI 26-3132 - Document 5

The strongest evidence for doxycycline's relatively good tolerability is found in three randomized, double-blinded trials. Two of the studies found little or no difference in the frequency of AEs between doxycycline (unspecified salt) and mefloquine, and all AEs were mild and transient.[13,62] In the third study, doxycycline monohydrate, atovaquone/proguanil, mefloquine, and chloroquine plus proguanil were compared ($N = 623$ evaluable persons).[61] Severity of AEs was graded on a scale of 1–4 with 1 being trivial and 4 requiring hospitalization. Although no significant differences were seen between groups for mild (grade 1) or severe (grade ≥ 3) AEs, moderate AEs (grade = 2) differed significantly between groups. Moderate AEs were reported by 45% of chloroquine/proguanil users, 42% of mefloquine users, 33% of doxycycline monohydrate users, and 32% of atovaquone/proguanil users. Although not statistically significant, doxycycline monohydrate had the lowest incidence of severe adverse events (6%) of all regimens. Of these severe events, one-third was skin reactions. There were no significant differences in the rates of skin reaction or GI events between any of the regimens. When compared with the other medications, doxycycline monohydrate had an intermediate proportion of withdrawals, but this proportion did not differ significantly between the treatment arms. The authors concluded that of all four regimens, doxycycline monohydrate was one of the best tolerated.[61] Overall, the evidence suggests that doxycycline is tolerated as well as other malaria prophylactic regimens.

CONTRAINDICATIONS

Doxycycline is contraindicated in anyone with a history of hypersensitivity to any of the tetracyclines.

Duration of Use. There are very limited studies on the use of doxycycline for malaria prophylaxis for a prolonged period of time. The current FDA product insert approves use for up to 4 months.[95] One study surveyed 600 military personnel in Cambodia who took prophylactic doses of doxycycline for 12 months and 900 men deployed to Somalia for 4 months.[21] Doxycycline was well tolerated; only 7 (0.6%) in Cambodia and 15 (1.7%) in Somalia discontinued medication because of adverse events related to GI problems and photosensitivity. Another study surveyed 228 U.S. Peace Corps volunteers who had taken doxycycline prophylaxis for an average of 19 months.[64] Of these, 45 (20%) changed medications caused by adverse events such as GI symptoms, pruritic skin reactions, photosensitivity, and vaginal yeast infection. Compared with mefloquine in which 28% of respondents changed medication caused by adverse events, doxycycline was better tolerated. Of note, in these two studies, the types of adverse events reported were the same as those in persons using doxycycline for shorter periods of time. However, both studies used post-trip surveys and did not have information on adherence for all participants.

Although long-term safety and tolerability studies have not been performed with doxycycline as a malaria chemoprophylaxis, similar drugs in the same class, tetracycline and minocycline, have been used in equivalent doses (less than 1 g/day for tetracycline, 50 mg/day to 100 mg twice a day for minocycline) for a few months to several years in the treatment of various dermatological conditions. This suggests that doxycycline can be used for long-term malaria chemoprophylaxis. When used at this dosage, tetracyclines were found in some studies to cause no abnormalities in renal and hepatic function when taken for as long as 5 years and in one study, for as long as 13 years.[96–98] There have, however, been several case reports of minocycline-associated autoimmune hepatitis and systemic lupus erythematosus-like syndrome in persons who used minocycline at 100 mg or more daily for more than 1 year.[99–103] Of note, doxycycline users were not found to have an increased risk of hepatotoxicity in one matched case-control study.[104] Scleral, dental, and dermal hyperpigmentation has also been reported in patients taking long-term minocycline as early as 1 month after initiation of treatment,[86,87,105,106] but this hyperpigmentation has been shown to fade after discontinuation of the medication.[86,87,105,106] In a 2-year, double-blind comparison of minocycline (100 mg twice a day) and hydroxychloroquine for the treatment of rheumatoid arthritis, only 10% of patients withdrew because of rash or GI symptoms.[106] Overall, these case reports and studies observed rare to occasional adverse events associated with long-term use of other tetracyclines.

THERAPEUTIC INDEX AND OVERDOSE

Tetracycline antibiotics are relatively non-toxic. Exceeding the recommended dosage of doxycycline may result in increased incidence of ADRs. There has been one case report of an individual who took 1 g of doxycycline/day for 12 years.[89] He was found to have hepatocellular necrosis with cholestasis, nephrotoxicity, leucopenia with anemia, skin hyperpigmentaion, and intermittent supraventricular tachycardia with sporadic Wenckebach heart block. He was not found to have any of the common doxycycline side effects such as GI symptoms or photosensitivity. After discontinuation of the drug, most of these symptoms resolved with the exception of residual cutaneous hyperpigmentation, relapsing cardiac arrythmias, and increased bilirubin.[89] In the case of overdosage, the medication should be discontinued and supportive measures and symptomatic treatment instituted.[95]

DRUG INTERACTIONS

Doxycycline was introduced into clinical practice long before the recognition of drug-drug interactions and without currently required pre-licensure *in vitro* or *in vivo* studies.[107] The potential for drug-drug interactions with doxycycline based on a full panel of *in vitro* studies with phase I metabolizing enzymes (cytochrome P450), phase II enzymes, and transporter mediated drug interactions has not been reported. On the basis of a single *in vitro* study showing that doxycycline inhibits the metabolism of quinine to 3-hydroxyquinine, the major metabolic pathway known to be enzymatically catalyzed by CYP 3A4, doxycycline is thought to be a modest inhibitor of CYP 3A4. Because CYP 3A4 is the most common phase 1 enzyme involved in drug metabolism, the spectrum of potential drug-drug interactions is wide and is not well defined. Furthermore, *in vitro* interactions do not always predict clinically significant effects. Information on drug-drug interactions with doxycycline is based on clinical observations and predictions are based on limited data accumulated over the last 40 years of clinical use, as described below.

Tetracyclines can chelate divalent and trivalent cations in certain medications that may cause a decreased absorption of the tetracycline and the medication when given concurrently.[3] These medications include antacids with aluminum, calcium

FOI 26-3132 - Document 5

or magnesium, laxatives with magnesium, and oral iron preparations. Other medications decreasing absorption of tetracyclines include antidiarrheal agents containing kaolin, pectin, or bismuth subsalicylate. Medications such as these should be taken a few hours before doxycycline.[3,108]

Although a possible interaction with oral contraceptives (OCs) has been cited in older literature,[3] current evidence has not supported this information.[109–111] The overall OC failure rate in women who were also treated with antibiotics was found to be 1.2–1.6%, and this failure is thought to occur in individuals in whom plasma concentrations of ethinyl estradiol are decreased.[110] Furthermore, the failure rate observed in concurrent administration of OC and antibiotics is well within the 1–3% failure rate observed with typical OC use.[110,112] Therefore, recent evidence suggests that doxycycline can be used concurrently with OCs without leading to a higher rate of contraceptive failure than would be expected among OC users not currently taking antibiotics.

Tetracyclines may potentiate the effect of oral anticoagulants by impairing the use of prothrombin and decreasing vitamin K production by intestinal bacteria.[3] The literature is limited, and there has been only one case report of a woman well controlled on warfarin, who developed an increased international normalized ratio and retroperitoneal bleeding when doxycycline was administered.[113] It was hypothesized that in addition to the aforementioned mechanism, competition with protein binding or the occurrence of an inhibitory mechanism by the cytochrome P450 system could be factors.[113] Patients on oral anticoagulants should have their prothrombin times monitored closely and dosage adjusted as needed.[3]

As a bacteriostatic drug, tetracyclines may interfere with the bactericidal action of aminoglycosides and penicillin[3,36] but this has only been reported *in vitro*,[114] and may not be of clinical significance. Doxycycline can be used concurrently with ciprofloxacin and azithromycin, two antibiotics commonly given to travelers for self-treatment of traveler's diarrhea.

Fatal nephrotoxicity has been reported in patients receiving methoxyflurane anesthesia and tetracycline.[115–117] Although this has not been observed with doxycycline, specifically, concurrent use of tetracyclines and methoxyflurane anesthesia is not recommended.

Concurrent use of digoxin and oral antibiotics such as tetracyclines may increase serum digoxin concentrations in some individuals. It is believed that the tetracycline alters gut flora, diminishing digoxin conversion to inactive metabolites, resulting in increased serum digoxin concentrations.[118,119] However, the data is limited and there have been no reports of toxicity caused by concurrent administration of digoxin and tetracyclines.

Barbiturates, carbamazepine, and phenytoin are believed to decrease the half-life of doxycycline by inducing microsomal enzyme activity.[41,120] It has been suggested to double the doxycycline dosage (take twice daily) in those taking antiepileptics.[120]

Theoretically, antibiotics such as doxycycline could decrease the effectiveness of the oral typhoid vaccine Ty21a by preventing replication of the live attenuated *Salmonella* Ty21a bacteria used in the vaccine. However, there is no experimental data in animals or humans to support this position. Nevertheless, most experts advise not giving doxycycline within 24 hours of the oral typhoid vaccine.[1] Because the immunization schedule for oral typhoid vaccine is recommended to be completed at least 1 week before potential exposure to *Salmonella typhi*,[121] there should be no opportunity for interaction between the oral typhoid vaccine and doxycycline in most travelers.

There are no known drug interactions between doxycycline and antiretrovirals.

SPECIAL POPULATIONS

Children. Doxcycycline is not recommended for children < 8 years of age because tetracyclines have been shown to cause permanent discoloration of the teeth.[122,123] Tetracyclines form a complex with calcium orthophosphate that becomes incorporated into bones and teeth undergoing calcification.[124] Tooth discoloration is permanent because remodeling and calcium exchange do not occur after calcification is completed. Some believe teeth staining is related to the total dose of tetracycline[122,123] while others argue that it is caused by repeated courses.[125,126] It is also thought that timing of tetracycline administration during tooth development, especially during early dentin formation, determines the degree of discoloration.[126] By 8 years of age the dentin and calcium-rich enamel has formed on almost all teeth (except wisdom teeth), and therefore doxycycline can be taken after this age. There are some who recommend that the lower age limit for taking doxycycline should be 12, when most children have had their primary teeth replaced by their adult dentition. Doxycycline, however, may cause less tooth discoloration than other tetracyclines because it has a lower binding affinity to calcium.[127,128] In fact, one study found that a short course of doxycycline given to children for Rocky Mountain spotted fever did not cause clinically significant staining of teeth.[129]

Of note, doxycycline is considered the drug of choice for treatment of infections in which the risks of tooth discoloration is outweighed by the benefit of disease treatment, such as presumed or confirmed rickettsial infection, ehrlichiosis, murine typhus, or inhalational anthrax.[129–135] Because there are other drug alternatives for treatment and prophylaxis of malaria in children < 8 years of age, use of doxycycline is not recommended.

The formation of the tetracycline and calcium orthophosphate complex in developing bone is thought to cause growth retardation, but the evidence is limited. Decreased long bone growth rate has been observed in premature infants given tetracycline but is reversible upon discontinuation of the drug.[136,137] There are no studies showing tetracycline-induced growth retardation in term infants or older children.

Pregnant women. Doxycycline is a category D drug; therefore, the possibility of pregnancy in a woman of childbearing age must be addressed before administration of this drug.[124] Doxycycline is not recommended for malaria prevention or treatment in pregnancy, except for the treatment of life-threatening multidrug-resistant *P. falciparum* when no other treatment options are available. No congenital malformations have been associated with its use,[124,138,139] and some limited evidence suggests that use of doxycycline in the first trimester might not cause adverse events in the fetus.[140,141] However, tetracyclines cross the placenta and have been observed to cause discoloration of teeth when given during the second or third trimester of pregnancy.[142,143] Because deciduous teeth begin to calcify at 5–6 months gestation, use of tetracycline during this time can result in staining.[124] Additionally, on the basis of

FOI 26-3132 - Document 5

observed retardation of bone growth in premature infants,[137] there are concerns of inhibition of bone growth in the fetus.

Tetracyclines have also been associated with fatal liver necrosis in pregnancy.[138,144,145] These reports, however, are rare and have usually involved higher doses of doxycycline than those used for malaria prophylaxis and treatment.[146]

For women planning on becoming pregnant, there is no need to wait a specific period of time after doxycycline use before attempting to conceive, based on the short half-life (15–25 hours) of the drug.[3,36] If women or their health care providers wish to decrease the amount of doxycycline in the body before conception, after 6 half-lives (3–6 days) only 2% of the doxycycline remains in the body.[147]

Breastfeeding. Data are extremely limited on the use of doxycycline in breastfeeding women. Doxycycline is excreted in breast milk at concentrations 30–40% of that found in maternal blood,[138,148] and it is thought that the drug's absorption by infants is inhibited by the calcium in the breast milk. Furthermore, tetracycline was undetectable in breastfed infants whose mothers were taking tetracycline.[149] Tetracycline has also been assessed by the American Academy of Pediatrics to be compatible with breastfeeding.[149] Although data for doxycycline and breastfeeding are limited, most experts feel that the theoretical possibility of teeth discoloration and bone growth inhibition in the nursing baby would be remote. Concerned mothers or doctors may consider alternative drugs such as mefloquine, or for mothers nursing babies weighing more than 5 kg, atovaquone/proguanil.

Medical conditions. In patients with impaired renal or hepatic function, the dose of doxycycline does not have to be adjusted because it is excreted as an inactive chelated product by a complex process of back diffusion in the small intestine.[150] Additionally, the clearance of doxycycline has been shown to be similar to those with normal renal function and in those with renal failure.[151]

In patients with seizure disorders in whom mefloquine is contraindicated, doxycycline can be given as an alternative.[147] However, antiepileptics have been noted to shorten the half-life of doxycycline and dosing adjustments must be made accordingly (see Drug Interactions section).

Doxycyline (Vibramycin) syrup contains metabisulfite, which can cause allergic reactions, including anaphylaxis and asthmatic episodes in susceptible individuals.[3]

Persons being treated for skin conditions with minocycline and who are in need of malaria prophylaxis should stop minocycline and start doxycycline. There is more data on the antimalarial efficacy of doxycycline compared with minocycline, therefore minocycline is not recommended as a replacement for doxycycline. Additionally, there have been case reports of autoimmune hepatitis in persons taking 100 mg or more of minocycline daily, whereas doxycycline has been observed to have less hepatotoxicity than other tetracyclines and less adverse events than minocycline.[100,101,104,152] After completion of doxycycline for malaria prophylaxis, minocycline can be resumed.

COST

The drug cost for doxycycline varies by doxycycline salt, enteric formulation, or brand name versus generic. One article examining the cost considerations of malaria chemoprophylaxis looked at the average wholesale price (prices from 2006) of various antimalarial medications and found that generic doxycycline hyclate was much cheaper (100 mg, US $0.25 per dose) than generic doxycycline monohydrate (100 mg, $2.13 per dose) and that generic doxycycline monohydrate was much cheaper than the brand name (Vibratabs, doxycycline monohydrate 100 mg, $4.51 a dose).[153] In this same work, the direct costs of various malaria chemoprophylaxis regimens were compared. For a 14-day stay, including pre- and post-exposure doses, the drug cost for prophylaxis was $11.00 for generic doxycycline hyclate compared with $84.64 for mefloquine and $113.39 for atovaquone/proguanil.[153] Using generic doxycycline monohydrate brings up the cost of prophylaxis to that of mefloquine, and using brand name doxycycline monohydrate brings the costs up even further. To look at more recent costs, prices of antimalarials were examined online for the average wholesale price. A full course of malaria prophylaxis for a 14-day stay in a malaria-endemic area costs $18.49 for generic doxycycline hyclate capsules, $65.79 for generic doxycycline monohydrate capsules, $122.50 for Vibratabs, $406.35 for Doryx (enteric-coated doxycycline hyclate), $80.48 for mefloquine, and $159.94 for atovaquone/proguanil.[154]

EXCHANGING DOXYCYCLINE FOR OTHER ANTIMALARIALS

There is very limited information on the best regimen for changing from doxycycline to other antimalarials, and recommendations for doing so are based on considering several issues such as drug-drug interactions, half-life differences, and differences in mechanism of action. If changing between atovaquone/proguanil and doxycycline, note that the current atovaquone-proguanil label lists a pharmacokinetic interaction of "concomitant treatment (of *P. falciparum* malaria) with tetracycline (with atovaquone) has been associated with approximately a 40% reduction in plasma concentrations of atovaquone,"[155] however, there are no accessible published studies that support this. On the contrary, early *in vitro* studies of atovaquone plus doxycycline and atovaquone plus tetracycline showed potentiation between the two drugs, which was later confirmed in clinical studies by improved cure rates when compared with atovaquone alone.[156–158] Therefore, if changing from doxcycyline to atovaquone/proguanil for malaria treatment or prophylaxis, doxycycline can be stopped and atovaquone/proguanil started at the same time. However, the recommended length of the post-trip course of prophylactic medications may change because the drugs target different stages of the *Plasmodium* life cycle. The Centers for Disease Control and Prevention (CDC) currently recommends that the atovaquone/proguanil is continued for up to 4 weeks after leaving the endemic area depending on when the change was made.[1] If changing from atovaquone/proguanil to doxycycline at any time, a full prophylactic course of doxycycline should be taken (for the duration of the stay and 4 weeks after departure). Changing from doxycycline to other antimalarials such as chloroquine or mefloquine will be impacted by the difference in half-lives of these medications. Doxycycline's half-life of 15–25 hours is much shorter than that of chloroquine (6–60 days) and mefloquine (2–3 weeks).[1] A change from doxycycline to chloroquine or mefloquine before travel would still require that chloroquine and mefloquine are taken 1 and 2 weeks before exposure, respectively, to attain effective blood

FOI 26-3132 - Document 5

concentrations before travel. It is not recommended to change from doxycycline to chloroquine or mefloquine during or after travel because effective blood concentrations will not be achieved for a few weeks, leaving the traveler unprotected during this time.

DERMATOLOGIC THERAPY WILEY

LETTER

Further aspects of doxycycline therapy in COVID-19

Dear Editor,

In their work, Conforti et al urge experts to broadly investigate the combination of doxycycline and hydroxychloroquine in treating coronavirus disease (COVID-19).[1] The tetracycline antibiotic doxycycline is a nontoxic inhibitor of mitochondrial biogenesis and cellular respiration[2] besides other known pleiotropic properties.[1] Now that the World Health Organization has just halted hydroxychloroquine trials for COVID-19 because of safety reasons, the time has come to find auxiliary compounds so as to give additional benefit to doxycycline.

We also need to take into account that quite a lot of similarities in metabolic pathways of virally infected and cancer cells have been observed.[3] Viruses usually target mitochondria as cellular power houses and various interplays have been detected between viruses and mitochondrial dynamics.[4] Most viruses require aerobic glycolysis as the energy source for replication and its inhibition could attenuate this process.[4]

Vitamin C is a broad-spectrum antiviral agent[5] and an inhibitor of aerobic glycolysis.[2] The combined administration of doxycycline with vitamin C resulted in a robust eradication of cancer stem cells (CSCs) in in vitro experiments by blocking mitochondrial protein translation and ATP production from glycolysis.[2] The addition of azithromycin further boosted CSC clearance.[2]

Sargiacomo et al also proposed the use of doxycycline or azithromycin in COVID-19.[6] Their concept assumes that SARS-CoV-2 prefers chronologically aged, senescent lung cells for binding and replication causing stormy inflammation and subsequent fibrosis, suggesting the application of senolytic drugs such as doxycycline to prevent fibrotic transformation.[6]

I believe that a combined approach regarding CSC elimination[2] may be transmissible into antiviral therapy. Supplementation of doxycycline with the amplifier vitamin C may result in mitochondrial damage of virally compromised cells, the attenuation of immune response by the inhibition of glycolysis in pro-inflammatory immune cells,[7] and a stronger suppression on postinflammatory fibrosis[8] than with doxycycline alone.

In vitro very low concentration of doxycycline is able to block mitochondria,[2] and this antiinflammatory dose is approved up to a 12-month use in rosacea[9] so a prolonged course together with vitamin C may also be an inexpensive, safe, and promising approach in antiviral prophylaxis and treatment.

Zn^{2+} Inhibits Coronavirus and Arterivirus RNA Polymerase Activity *In Vitro* and Zinc Ionophores Block the Replication of These Viruses in Cell Culture

Abstract

Increasing the intracellular Zn^{2+} concentration with zinc-ionophores like pyrithione (PT) can efficiently impair the replication of a variety of RNA viruses, including poliovirus and influenza virus. For some viruses this effect has been attributed to interference with viral polyprotein processing. In this study we demonstrate that the combination of Zn^{2+} and PT at low concentrations (2 μM Zn^{2+} and 2 μM PT) inhibits the replication of SARS-coronavirus (SARS-CoV) and equine arteritis virus (EAV) in cell culture. The RNA synthesis of these two distantly related nidoviruses is catalyzed by an RNA-dependent RNA polymerase (RdRp), which is the core enzyme of their multiprotein replication and transcription complex (RTC). Using an activity assay for RTCs isolated from cells infected with SARS-CoV or EAV—thus eliminating the need for PT to transport Zn^{2+} across the plasma membrane—we show that Zn^{2+} efficiently inhibits the RNA-synthesizing activity of the RTCs of both viruses. Enzymatic studies using recombinant RdRps (SARS-CoV nsp12 and EAV nsp9) purified from *E. coli* subsequently revealed that Zn^{2+} directly inhibited the *in vitro* activity of both nidovirus polymerases. More specifically, Zn^{2+} was found to block the initiation step of EAV RNA synthesis, whereas in the case of the SARS-CoV RdRp elongation was inhibited and template binding reduced. By chelating Zn^{2+} with MgEDTA, the inhibitory effect of the divalent cation could be reversed, which provides a novel experimental tool for *in vitro* studies of the molecular details of nidovirus replication and transcription.

Introduction

Zinc ions are involved in many different cellular processes and have proven crucial for the proper folding and activity of various cellular enzymes and transcription factors. Zn^{2+} is probably an important cofactor for numerous viral proteins as well. Nevertheless, the intracellular concentration of free Zn^{2+} is maintained at a relatively low level by metallothioneins, likely due to the fact that Zn^{2+} can serve as intracellular second messenger and may trigger apoptosis or a decrease in protein synthesis at elevated concentrations [1,2,3]. Interestingly, in cell culture studies, high Zn^{2+} concentrations and the addition of compounds that stimulate cellular import of Zn^{2+}, such as hinokitol (HK), pyrrolidine dithiocarbamate (PDTC) and pyrithione (PT), were found to inhibit the replication of various RNA viruses, including influenza virus [4], respiratory syncytial virus [5] and several picornaviruses [6,7,8,9,10,11]. Although these previous studies provided limited mechanistic information, this suggests that intracellular Zn^{2+} levels affect a common step in the replicative cycle of these viruses.

In cell culture, PT stimulates Zn^{2+} uptake within minutes and inhibits RNA virus replication through a mechanism that has only been studied in reasonable detail for picornaviruses [11,12]. *In vitro* studies with purified rhinovirus and poliovirus 3C proteases revealed that protease activity was inhibited by Zn^{2+} [13,14], which is in line with the inhibition of polyprotein processing by zinc ions that was observed in cells infected with human rhinovirus and coxsackievirus B3 [11]. The replication of segmented negative-strand RNA viruses such as influenza virus, however, does not depend on polyprotein processing and the effect of PDTC-mediated Zn^{2+} import was therefore hypothesized to result from inhibition of the viral RNA-dependent RNA polymerase (RdRp) and cellular cofactors [4]. Moreover, an inhibitory effect of Zn^{2+} on the activity of purified RdRps from rhinoviruses and hepatitis C virus was noted, but not investigated in any detail [15,16].

Details on the effect of zinc ions are currently largely unknown for nidoviruses. This large group of positive-strand RNA (+RNA) viruses includes major pathogens of humans and livestock, such as severe acute respiratory syndrome coronavirus (SARS-CoV), other human coronaviruses, the arteriviruses equine arteritis virus (EAV), and porcine reproductive and respiratory syndrome virus (PRRSV) [17,18]. The common ancestry of nidoviruses is reflected in their similar genome organization and expression strategy, and in the conservation of a number of key enzymatic functions in their

Author Summary

Positive-stranded RNA (+RNA) viruses include many important pathogens. They have evolved a variety of replication strategies, but are unified in the fact that an RNA-dependent RNA polymerase (RdRp) functions as the core enzyme of their RNA-synthesizing machinery. The RdRp is commonly embedded in a membrane-associated replication complex that is assembled from viral RNA, and viral and host proteins. Given their crucial function in the viral replicative cycle, RdRps are key targets for antiviral research. Increased intracellular Zn^{2+} concentrations are known to efficiently impair replication of a number of RNA viruses, e.g. by interfering with correct proteolytic processing of viral polyproteins. Here, we not only show that corona- and arterivirus replication can be inhibited by increased Zn^{2+} levels, but also use both isolated replication complexes and purified recombinant RdRps to demonstrate that this effect may be based on direct inhibition of nidovirus RdRps. The combination of protocols described here will be valuable for future studies into the function of nidoviral enzyme complexes.

large replicase polyproteins [19]. A hallmark of the corona- and arterivirus replicative cycle is the transcription of a 5′- and 3′-coterminal nested set of subgenomic (sg) mRNAs from which the viral structural and accessory protein genes are expressed [20,21].

Analogous to picornaviruses [13,22], zinc ions were demonstrated to inhibit certain proteolytic cleavages in the processing of the coronavirus replicase polyproteins in infected cells and cell-free systems [23,24]. In this study we report that the zinc-ionophore pyrithione (PT) in combination with Zn^{2+} is a potent inhibitor of the replication of SARS-coronavirus (SARS-CoV) and equine arteritis virus (EAV) in cell culture. To assess whether - besides a possible effect on proteolytic processing - nidovirus RTC subunits and RNA synthesis are directly affected by Zn^{2+}, we employed *in vitro* systems for SARS-CoV and EAV RNA synthesis that are based on membrane-associated RTCs isolated from infected cells (from here on referred to as RTC assays) [25,26]. In addition, we used *in vitro* recombinant RdRp assays to directly study the effect of zinc ions on the RdRps of SARS-CoV and EAV [27,28].

Using these independent *in vitro* approaches, we were able to demonstrate that Zn^{2+} directly impairs nidovirus RNA synthesis, since it had a strong inhibitory effect in both RTC and RdRp assays. Interestingly, the Zn^{2+}-mediated inhibition could be reversed through the addition of a Zn^{2+} chelator (MgEDTA). We therefore applied this compound to stop and restart the *in vitro* RNA-synthesizing activity at will. This convenient tool allowed us to study various mechanistic aspects of arteri- and coronavirus RNA synthesis in more detail. Additionally, the zinc-mediated inhibition of nidovirus RNA synthesis described here may provide an interesting basis to further explore the use of zinc-ionophores in antiviral therapy.

Results

Zinc and pyrithione inhibit nidovirus replication *in vivo*

Zinc ions are involved in many different cellular processes, but the concentration of free Zn^{2+} is maintained at a relatively low level by metallothioneins [1]. Zn^{2+} and compounds that stimulate import of Zn^{2+} into cells, such as PT, were previously found to inhibit replication of several picornaviruses, including rhinoviruses, foot-and-mouth disease virus, coxsackievirus, and mengovirus in cell culture [6,7,8,9,10,11]. To determine whether Zn^{2+} has a similar effect on nidoviruses, we investigated the effect of PT and Zn^{2+} on the replication of EAV and SARS-CoV in Vero-E6 cells, using reporter viruses that express green fluorescent proteins (GFP), i.e., EAV-GFP [29] and SARS-CoV-GFP [30]. EAV-GFP encodes an N-terminal fusion of GFP to the viral nonstructural protein 2 (nsp2), one of the cleavage products of the replicase polyproteins, and thus provides a direct readout for translation of the replicase gene. In SARS-CoV-GFP, reporter expression occurs from sg mRNA 7, following the replacement of two accessory protein-coding genes (ORFs 7a and 7b) that are dispensable for replication in cell culture.

We first assessed the cytotoxicity of a range of PT concentrations (0–32 μM) in the presence of 0 to 8 μM $ZnOAc_2$. Treatment with PT of concentrations up to 32 μM in combination with <4 μM $ZnOAc_2$ did not reduce the viability of mock-infected cells after 18 h (Fig. 1A), as measured by the colorimetric MTS (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium) viability assay. As elevated Zn^{2+} concentrations are known to inhibit cellular translation, we also used metabolic labeling with ^{35}S-methionine to assess the effect of PT and Zn^{2+} on cellular protein synthesis. Incubation of Vero-E6 cells for 18 h with the combinations of PT and Zn^{2+} mentioned above, followed by a 2-h metabolic labeling, revealed no change in overall cellular protein synthesis when the concentration of $ZnOAc_2$ was <4 μM (data not shown).

Using these non-cytotoxic conditions we subsequently tested the effect of PT and $ZnOAc_2$ on EAV-GFP and SARS-CoV-GFP replication. To this end, Vero-E6 cells in 96-well plates were infected with a multiplicity of infection (m.o.i.) of 4. One hour post infection (h p.i.), between 0 and 32 μM of PT and 0, 1, or 2 μM $ZnOAc_2$ were added to the culture medium. At 17 h p.i., a time point at which GFP expression in untreated infected cells reaches its maximum for both viruses, cells were fixed, and GFP fluorescence was quantified.

The reporter gene expression of both SARS-CoV-GFP and EAV-GFP was already significantly inhibited in a dose-dependent manner by the addition of PT alone (Fig. 1B and C). This effect was significantly enhanced when 2 μM of Zn^{2+} was added to the medium. We found that addition of $ZnOAc_2$ alone also reduced virus replication, but only at levels that were close to the 50% cytotoxicity concentration (CC_{50}) of $ZnOAc_2$ in Vero-E6 cells (~70 μM, data not shown). This is likely due to the poor solubility of Zn^{2+} in phosphate-containing medium and the inefficient uptake of Zn^{2+} by cells in the absence of zinc-ionophores. The combination of 2 μM PT and 2 μM $ZnOAc_2$ resulted in a 98±1% and 85±3% reduction of the GFP signal for EAV-GFP and SARS-CoV-GFP, respectively. No cytotoxicity was observed for this combination of PT and $ZnOAc_2$ concentrations. From the dose-response curves in Fig. 1, a CC_{50} value of 82 μM was calculated for PT in the presence of 2 μM zinc. Half maximal inhibitory concentrations (IC_{50}) of 1.4 μM and 0.5 μM and selectivity indices of 59 and 164 were calculated for SARS-CoV and EAV, respectively.

Zn^{2+} reversibly inhibits the RNA-synthesizing activity of isolated nidovirus RTCs

We previously developed assays to study the *in vitro* RNA-synthesizing activity of RTCs isolated from cells infected with SARS-CoV or EAV [25,26]. In these RTC assays [α-^{32}P]CMP is incorporated into both genomic (replication) and sg mRNA (transcription) (Fig. 2). This allowed us to monitor the synthesis of the same viral RNA molecules that can be detected by hybridization of RNA from nidovirus-infected cells. A benefit of these assays is that the activity does not depend on continued protein synthesis and that it allows us to study viral RNA synthesis

independent of other aspects of the viral replicative cycle [26]. To investigate whether the inhibitory effect of PT and zinc ions on nidovirus replication in cell culture is reflected in a direct effect of

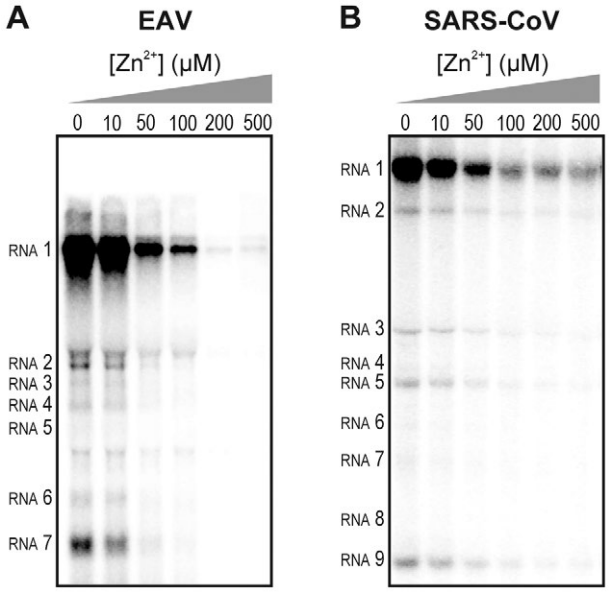

Figure 2. Inhibition of the *in vitro* RNA-synthesizing activity of isolated RTCs by Zn^{2+}. Incorporation of [α-^{32}P]CMP into viral RNA by EAV (**A**) and SARS-CoV (**B**) in RTC assays in the presence of various Zn^{2+} concentrations, as indicated above each lane.
doi:10.1371/journal.ppat.1001176.g002

Zn^{2+} on viral RNA synthesis, we tested the effect of Zn^{2+} addition on RTC activity. For both EAV (Fig. 2A) and SARS-CoV (Fig. 2B), a dose-dependent decrease in the amount of RNA synthesized was observed when $ZnOAc_2$ was present. For both viruses, a more than 50% reduction of overall RNA-synthesis was observed at a Zn^{2+} concentration of 50 μM, while less than 5% activity remained at a Zn^{2+} concentration of 500 μM. Both genome synthesis and sg mRNA production were equally affected.

To test whether the inhibition of RTC activity by Zn^{2+} was reversible, RTC reactions were started in the presence or absence of 500 μM Zn^{2+}. After 30 min, these reactions were split into two aliquots and magnesium-saturated EDTA (MgEDTA) was added to one of the tubes to a final concentration of 1 mM (Fig. 3A). We used MgEDTA as Zn^{2+} chelator in these *in vitro* assays, because it specifically chelates Zn^{2+} while releasing Mg^{2+}, due to the higher stability constant of the ZnEDTA complex. Uncomplexed EDTA inhibited RTC activity in all reactions (data not shown), most likely by chelating the Mg^{2+} that is crucial for RdRp activity [27,28], whereas MgEDTA had no effects on control reactions without Zn^{2+} (Fig. 3B, compare lane 1 and 2). As shown in Fig. 2, the EAV RTC activity that was inhibited by Zn^{2+} (Fig. 3B&C, lane 3) could be restored by the addition of MgEDTA (Fig. 3B, lane 4) to a level observed for control reactions without Zn^{2+} (Fig. 3B, lane 1). Compared to the untreated control, the EAV RTC assay produced approximately 30% less RNA, which was consistent with the 30% shorter reaction time after the addition of the MgEDTA (100 versus 70 min for lanes 1 and 4, respectively). Surprisingly, SARS-CoV RTC assays that were consecutively supplemented with Zn^{2+} and MgEDTA incorporated slightly more [α-^{32}P]CMP compared to untreated control reactions (Fig. 3C; compare lane 1 and 4). This effect was not due to chelation of the Zn^{2+} already present in the post-nuclear supernatant (PNS) of SARS-CoV-infected cells, as this increase was not observed when MgEDTA was added to a control reaction without additional Zn^{2+} (Fig. 3C, lane 2).

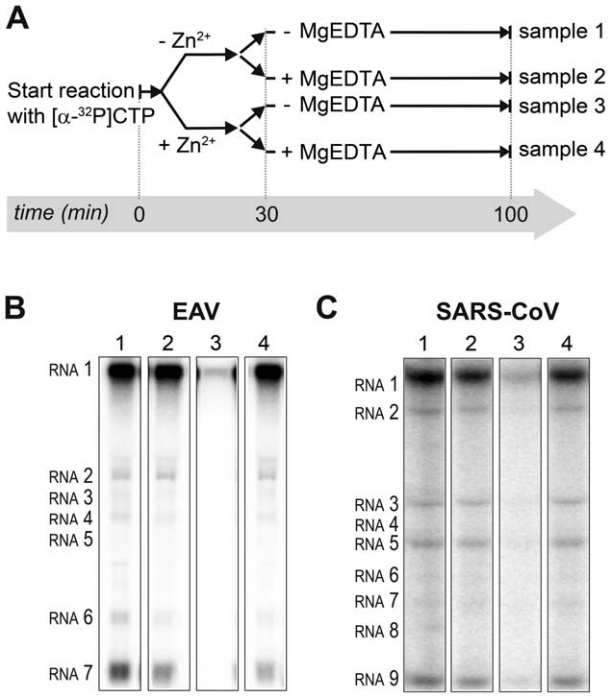

Figure 3. Inhibition of nidovirus RTC activity by Zn^{2+} can be reversed by chelation. (**A**) Schematic representation of the *in vitro* assays with isolated RTCs, which were initiated with [α-^{32}P]CTP, either in the absence (sample 1 and 2) or presence of 500 μM Zn^{2+}. After a 30-min incubation at 30°C, both the untreated and Zn^{2+}-treated samples were split into two aliquots, and 1 mM of the Zn^{2+} chelator MgEDTA was added to samples 2 and 4. All reactions were subsequently incubated for another 70 min before termination. (**B**) Analysis of RNA products synthesized in assays with EAV RTCs. doi:10.1371/journal.ppat.1001176.g003

Zinc ions affect the in vitro activity of recombinant nidovirus RdRps

To establish whether inhibition of RTC activity might be due to a direct effect of Zn^{2+} on nidovirus RdRp activity, we tested the effect of Zn^{2+} on the activity of the purified recombinant RdRps of SARS-CoV (nsp12) and EAV (nsp9) using previously developed RdRp assays [27,28]. Using an 18-mer polyU template, the EAV RdRp incorporated [α-^{32}P]AMP into RNA products of up to 18 nt in length (Fig. 4A). Initiation was *de novo*, which is in line with previous observations and the presence of a conserved priming loop in the nsp9 sequence [28]. Unlike the EAV RdRp nsp9, the *in vitro* activity of the SARS-CoV RdRp nsp12 - which lacks a priming loop - was shown to be strictly primer-dependent [27]. Thus, to study the RdRp activity of SARS-CoV nsp12, a primed polyU template was used (Fig. 4B), thereby allowing us to sample [α-^{32}P]AMP incorporation as described previously [27]. As specificity controls, we used the previously described SARS-CoV nsp12 mutant D618A [27], which contains an aspartate to alanine substitution in motif A of the RdRp active site, and EAV nsp9-D445A, in which we engineered an aspartate to alanine substitution at the corresponding site of EAV nsp9 [28,31]. Both mutant RdRps showed greatly reduced [α-^{32}P]AMP incorporation in our assays (Fig. 4), confirming once again that the radiolabeled RNA products derived from nidovirus RdRp activity.

Addition of $ZnOAc_2$ to RdRp assays resulted in a strong, dose-dependent inhibition of enzymatic activity for both the EAV and

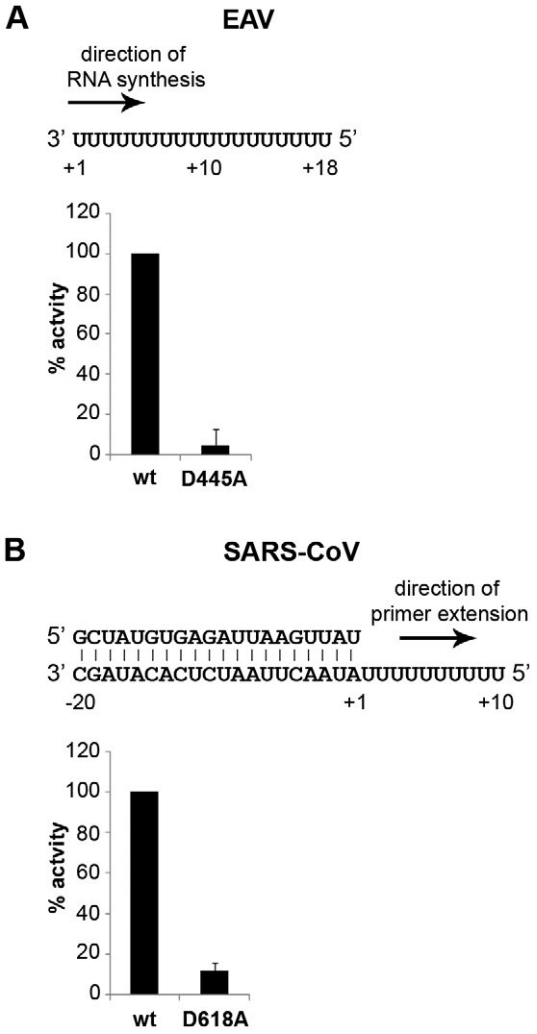

Figure 4. EAV and SARS-CoV RdRp assays with wild-type enzyme and active-site mutants. (**A**) The EAV polymerase was incapable of primer extension and required a free 3′ end and poly(U) residues to initiate. Nucleotide incorporating activity of the wild-type enzyme and D445A mutant of nsp9 on an 18-mer poly(U) template confirmed the specificity of our assay. (**B**) SARS-CoV nsp12 RdRp assays were performed with an RNA duplex with a 5′ U_{10} overhang as template. The bar graph shows the nucleotide incorporating activities of wild-type and D618A nsp12. Error bars represent standard error of the mean (n = 3).
doi:10.1371/journal.ppat.1001176.g004

SARS-CoV enzyme (Fig. 5A and B, respectively), similar to what was observed in RTC assays. In fact, compared to other divalent metal ions such Co^{2+} and Ca^{2+}, which typically bind to amino acid side chains containing oxygen atoms rather than sulfur groups, Zn^{2+} was the most efficient inhibitor of SARS-CoV nsp12 RdRp activity (Supplemental Fig. S1). To test whether, as in the RTC assay, the RdRp inhibition by zinc ions was reversible, RdRp assays were pre-incubated with 6 mM Zn^{2+}, a concentration that consistently gave >95% inhibition. After 30 min, 8 mM MgEDTA was added to both a control reaction and the reaction inhibited with $ZnOAc_2$, and samples were incubated for another 30 min (Fig. 5C). As shown in Fig. 5D, the inhibition of EAV RdRp activity by Zn^{2+} could be reversed by chelation of Zn^{2+} (Fig. 5D; compare lanes 3 and 4). The amount of product synthesized was consistently 60±5% of that synthesized in a 60-min control reaction (Fig. 5D; compare lanes 1 and 4), which was within the expected range given the shorter

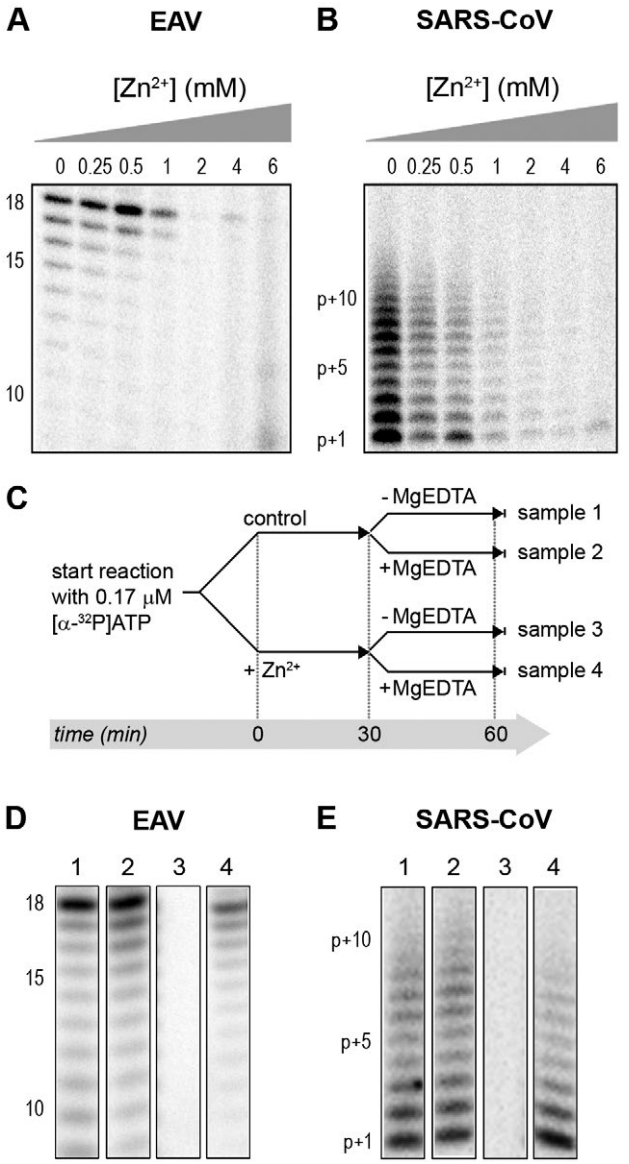

Figure 5. The activity of the RdRps of EAV and SARS-CoV is reversibly inhibited by Zn^{2+}. RdRp activity of purified EAV nsp9 (**A**) and SARS-CoV nsp12 (**B**) in the presence of various Zn^{2+} concentrations, as indicated above the lanes. (**C**) Schematic representation of the experiment to test whether Zn^{2+}-mediated inhibition of RdRp activity could be reversed with MgEDTA. RdRp reactions, either untreated controls (sample 1 and 2) or reactions containing 6 mM Zn^{2+} (samples 3 and 4) were incubated for 30 min. Both Zn^{2+}-containing and control samples were split into two aliquots and 6 mM MgEDTA was added to sample 2 and 4. All reactions were incubated for an additional 30 min and then terminated. Reaction products of the RdRp assays with EAV nsp9 and SARS-CoV nsp12 are shown in (**D**) and (**E**), respectively. Numbers above the lanes refer to the sample numbers described under (C).
doi:10.1371/journal.ppat.1001176.g005

reaction time. The inhibition of the SARS-CoV RdRp was reversible as well. During the 30-min incubation after the addition of MgEDTA, SARS-CoV nsp12 incorporated 40±5% of the label incorporated during a standard 60-min reaction (Fig. 5E). This was slightly lower than the expected yield and may be caused by the elevated Mg^{2+} concentration, which was shown to be suboptimal for nsp12 activity [27] and results from the release of Mg^{2+} from MgEDTA upon chelation of Zn^{2+}.

Differential effect of Zn^{2+} on the initiation and elongation phase of nidovirus RNA synthesis

For EAV, close inspection of the RdRp assays revealed a less pronounced effect of Zn^{2+} on the generation of full-length 18-nt products than on the synthesis of smaller reaction intermediates (Fig. 5A). This suggested that Zn^{2+} specifically inhibited the initiation step of EAV RNA synthesis. To test this hypothesis, an RTC assay was incubated for 30 min with unlabeled CTP (initiation), after which the reaction was split in two. Then, [α-^{32}P]CTP was added to both tubes (pulse), 500 μM Zn^{2+} was added to one of the tubes, and samples were taken at different time points during the reaction (Fig. 6A). Fig. 6B shows that in the presence of Zn^{2+} [α-^{32}P]CMP was predominantly incorporated into nascent RNA molecules that were already past the initiation phase at the moment that Zn^{2+} was added to the reaction. No new initiation occurred, as was indicated by the smear of short radiolabeled products that progressively shifted up towards the position of full-length genomic RNA. This suggested that Zn^{2+} does not affect the elongation phase of EAV RNA synthesis and that it specifically inhibits initiation. This also explains the relatively weak signal intensity of the smaller sg mRNA bands (*e.g.*, compare the relative change in signal of RNA2 to RNA7) produced in the presence of Zn^{2+}, since multiple initiation events are required on these short molecules to obtain signal intensities similar to those resulting from a single initiation event on the long genomic RNA, *e.g.*, 16 times more in the case of RNA7. In contrast to EAV, the effect of Zn^{2+} on RNA synthesis by SARS-CoV RTCs was not limited to initiation, but appeared to impair the elongation phase as well, given that the addition of Zn^{2+} completely blocked further incorporation of [α-^{32}P]CMP when added 40 min after the start of the reaction (Fig. 6C).

In the RdRp assays, the short templates used made it technically impossible to do experiments similar to those performed with complete RTCs. However, we previously noticed that at low concentrations of [α-^{32}P]ATP (~0.17 μM) SARS-CoV nsp12 RdRp activity was restricted to the addition of only a single nucleotide to the primer [27]. EAV nsp9 mainly produced very short (2–3 nt long) abortive RNA products and only a fraction of full length products, as is common for *de novo* initiating RdRps [28]. This allowed us to separately study the effect of Zn^{2+} on initiation and elongation by performing an experiment in which a pulse with a low concentration of [α-^{32}P]ATP was followed by a chase in the presence of 50 μM of unlabeled ATP, which increased processivity and allowed us to study elongation (Fig. 7A and C) as described previously [27]. The results of these experiments were in agreement with those obtained with isolated RTCs. For EAV, with initiation and dinucleotide synthesis completely inhibited by the presence of 6 mM Zn^{2+} (Supplemental Fig. S2A), the amount of reaction intermediates shorter than 18 nt diminished with time, while products from templates on which the RdRp had already initiated were elongated to full-length 18-nt molecules (Fig. 7B, right panel). This was consistent with the observation that the EAV RdRp remained capable of extending the synthetic dinucleotide ApA to trinucleotides in the presence of Zn^{2+} (Supplemental Fig. S2B). Likely due to the absence of reinitiation in the reactions shown in Fig. 7B, the low processivity of the EAV RdRp, and the substrate competition between the remaining [α-^{32}P]ATP and the >200 fold excess of unlabeled ATP, the differences between the 5- and 30-min time points were small. In the absence of Zn^{2+}, the RdRp continued to initiate as indicated by the ladder of smaller-sized RNA molecules below the full-length product (Fig. 7B, left panel) and the time course shown in Supplemental Fig. S2A. In contrast, the addition of Zn^{2+} to a SARS-CoV RdRp reaction also blocked elongation, since

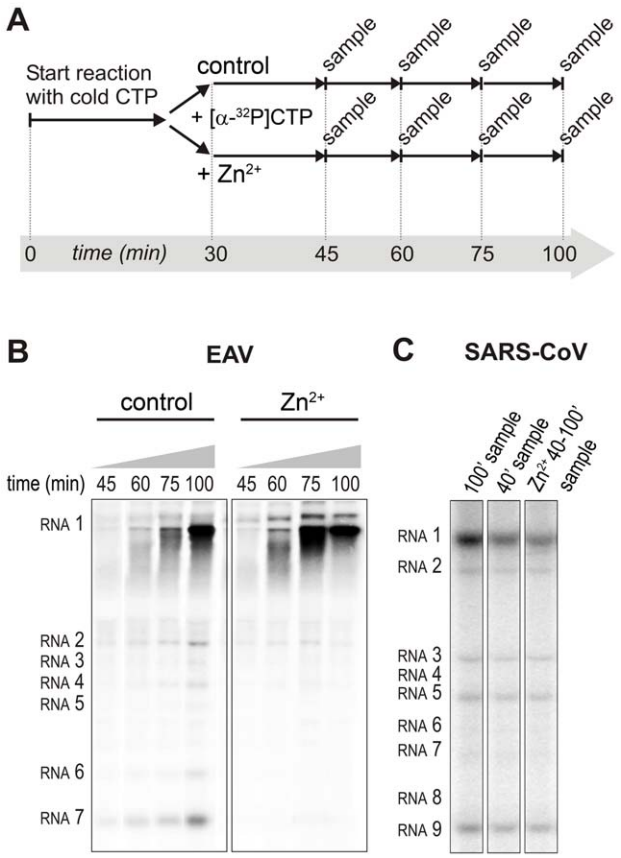

Figure 6. Effect of Zn^{2+} on initiation and elongation in *in vitro* assays with isolated EAV and SARS-CoV RTCs. (**A**) An *in vitro* RTC assay with isolated EAV RTCs was allowed to initiate with unlabeled NTPs (initiation). After 30 min, [α-^{32}P]CTP was added (pulse), the reaction was split into two equal volumes, and Zn^{2+} was added to a final concentration of 0.5 mM to one of the tubes. At the time points indicated, samples were taken and incorporation of [α-^{32}P]CMP into viral RNA was analyzed. (**B**) Radiolabeled EAV RNA synthesized at the time points indicated above the lanes in the presence and absence of Zn^{2+}. (**C**) Radiolabeled RNA synthesized by isolated SARS-CoV RTCs in reactions terminated after 100 (lane 1) and 40 (lane 2) min. Reaction products of a reaction to which 500 μM Zn^{2+} was added after 40 min, and that was terminated at t = 100 are shown in lane 3.
doi:10.1371/journal.ppat.1001176.g006

extension of the radiolabeled primer as observed in the absence of Zn^{2+} (Fig. 7D, left panel) no longer occurred (Fig. 7D, right panel).

Zinc affects SARS-CoV RdRp template binding

To assess whether Zn^{2+} affects the interaction of recombinant SARS-CoV nsp12 with the template used in our assays, we performed electromobility shift assays (EMSA) in the presence and absence of Zn^{2+} (Fig. 8A). To measure the binding affinity of the RdRp for the template, we determined the fraction of bound template at various protein concentrations and observed a 3–4 fold reduction in RNA binding when Zn^{2+} was present in the assay (Fig. 8B). We also assessed whether pre-incubation of the RdRp or RNA with Zn^{2+} was a requirement for this drop in binding affinity, but found no significant difference with experiments not involving such a preincubation (data not shown).

No binding was observed when a similar RNA binding assay was performed with purified EAV RdRp. Likewise, nsp9 did not bind RNA in pull-down experiments with Talon-beads, His_6-tagged nsp9, and radiolabeled EAV genomic RNA or various short RNA templates including polyU, whereas we were able to detect binding of a control protein (SARS-CoV nsp8, which has demonstrated RNA and DNA binding activity [32]) using this assay. It presently remains unclear why we are not able to detect the binding of recombinant EAV nsp9 to an RNA template.

Discussion

Although a variety of compounds have been studied, registered antivirals are currently still lacking for the effective treatment of SARS and other nidovirus-related diseases [33]. RdRps are suitable targets for antiviral drug development as their activity is strictly virus-specific and may be blocked without severely affecting key cellular functions. Several inhibitors developed against the polymerases of e.g. human immunodeficiency virus (HIV) and hepatitis C virus are currently being used in antiviral therapy or clinical trials [34,35,36]. Therefore, advancing our molecular knowledge of nidovirus RdRps and the larger enzyme complexes that they are part of, and utilizing the potential of recently developed *in vitro* RdRp assays [25,26,27,28] could ultimately aid in the development of effective antiviral strategies.

Zinc ions and zinc-ionophores, such as PT and PDTC, have previously been described as potent inhibitors of various RNA viruses. We therefore investigated whether PT-stimulated import of zinc ions into cells also inhibited the replication of nidoviruses in cell culture. Using GFP-expressing EAV and SARS-CoV [29,30], we found that the combination of 2 μM PT and 2 μM Zn^{2+} efficiently inhibited their replication, while not causing detectable cytoxicity (Fig. 1). Inhibition of replication by PT and Zn^{2+} at similar concentrations (2–10 μM) was previously observed for several picornaviruses such as rhinoviruses, foot-and-mouth disease virus, coxsackievirus, and mengovirus [6,7,8,9,10,11].

The inhibitory effect of Zn^{2+} on the replication of picornaviruses appeared to be due to interference with viral polyprotein processing. In infections with the coronavirus mouse hepatitis virus (MHV), Zn^{2+} also interfered with some of the replicase polyproteins cleavages [24], albeit at a much higher concentration (100 μM Zn^{2+}) than used in our studies. Since impaired replicase processing will indirectly affect viral RNA synthesis in the infected cell, we used two recently developed *in vitro* assays to investigate whether Zn^{2+} also affects nidovirus RNA synthesis directly. Our *in vitro* studies revealed a strong inhibitory effect of zinc ions on the RNA-synthesizing activity of isolated EAV and SARS-CoV RTCs. Assays with recombinant enzymes subsequently demonstrated that this was likely due to direct inhibition of RdRp function. The inhibitory effect could be reversed by chelating the zinc ions, which provides an interesting experimental (on/off) approach to study nidovirus RNA synthesis. Addition of Zn^{2+} following initiation of EAV RNA synthesis had little or no effect on NTP incorporation in molecules whose synthesis had already been initiated in the absence of Zn^{2+} (Fig. 6 and 7), indicating that Zn^{2+} does not affect elongation and does not increase the termination frequency, as was previously found for Mn^{2+} [25]. Therefore, Zn^{2+} appears to be a specific inhibitor of the initiation phase of EAV RNA synthesis. In contrast, Zn^{2+} inhibited SARS-CoV RdRp activity also during the elongation phase of RNA synthesis, probably by directly affecting template binding (Fig. 8). In coronaviruses, zinc ions thus appear to inhibit both the proper proteolytic processing of replicase polyproteins [23,24] and RdRp activity (this study). Contrary to the RTC assays, millimolar instead of micromolar concentrations of $ZnOAc_2$ were required for a nearly complete inhibition of nucleotide incorporation in RdRp assays.

It has been well established that DNA and RNA polymerases use a triad of conserved aspartate residues in motifs A and C to bind

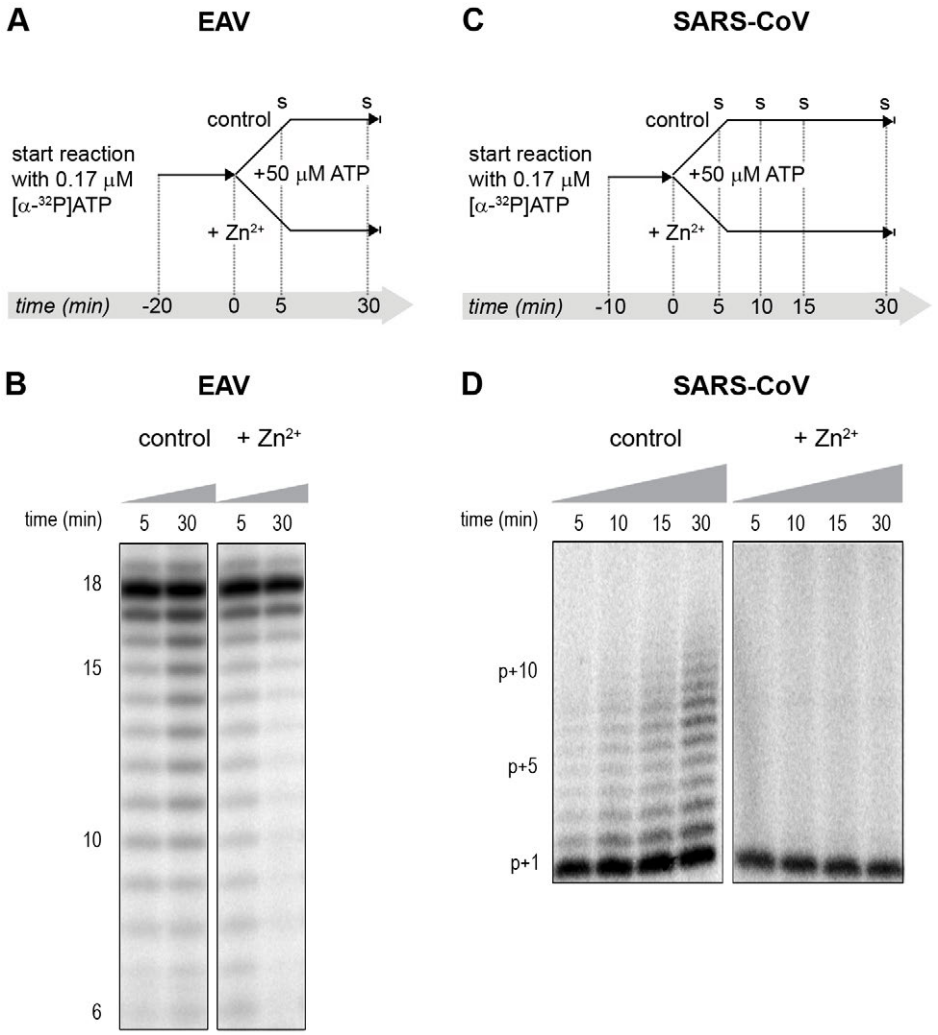

Figure 7. The effect of Zn^{2+} on initiation and elongation activity of purified EAV and SARS-CoV RdRps. (**A**) An EAV RdRp reaction was initiated in the presence of [α-^{32}P]ATP under conditions that do not allow elongation, *i.e.*, low ATP concentration. After 20 min, the reaction was split into two equal volumes, and Zn^{2+} was added to one of the tubes. A chase with 50 μM unlabeled ATP, which allows elongation, was performed on both reactions and samples were taken after 5 and 30 min. (**B**) EAV RdRp reaction products that accumulated in the presence and absence of Zn^{2+} (indicated above the lanes) after a 5- and 30-min chase with unlabeled ATP. The length of the reaction products in nt is indicated next to the gel. (**C**) A SARS-CoV RdRp reaction was initiated in the presence of 0.17 μM [α-^{32}P]ATP, which limits elongation. After 10 min, the reaction was split into two equal volumes, and Zn^{2+} was added to one of the tubes. A chase with 50 μM unlabeled ATP was performed on both reactions and samples were taken after 5, 10, 15, and 30 min. (**D**) SARS-CoV RdRp reaction products formed at the chase times indicated above the lanes in the presence and absence of Zn^{2+}. The length of the reaction products in nt is indicated next to the gel (p is the primer length).
doi:10.1371/journal.ppat.1001176.g007

divalent metal ions like Mg^{2+}, which subsequently coordinate incoming nucleotides during the polymerization reaction [37,38]. Mg^{2+} is also the divalent metal ion that is required for the *in vitro* activity of isolated SARS-CoV and EAV RTCs and recombinant RdRps [25,26,27,28], although *de novo* initiation of EAV nsp9 is primarily Mn^{2+}-dependent. Zn^{2+} could not substitute for Mg^{2+} or Mn^{2+} as cofactor as it was incapable of supporting the polymerase activity of nidovirus RTCs and RdRps in the absence of Mg^{2+} (data not shown), as was also reported for the poliovirus RdRp [39]. Moreover, inhibition of nidovirus RdRp activity by Zn^{2+} was even observed at low concentrations and in the presence of a more than 25-fold excess of Mg^{2+}, suggesting that either the affinity of the active site for Zn^{2+} is much higher or that Zn^{2+} does not compete for Mg^{2+}-binding and binds to another zinc(-specific) binding site in the protein.

Specific protein domains or pockets that contain zinc ions may be involved in protein-protein interactions, protein-RNA/DNA interactions, or conformational changes in enzyme structures. Zinc-binding domains commonly consist of at least three conserved cysteine and/or histidine residues within a stretch of ~10–30 amino acids, such as in zinc-finger motifs and metalloproteases [2,40,41]. However, in RdRps there are only few precedents for the presence of zinc-binding pockets, such as those identified in the crystal structure of the Dengue RdRp [42]. Sequence analysis of the EAV nsp9 amino acid sequence revealed that it lacks patches rich in conserved cysteines and/or histidines. In contrast, inspection of the SARS-CoV nsp12 amino acid sequence revealed two such patches, namely H295-C301-C306-H309-C310 and C799-H810-C813-H816. A crystal structure for nsp12 is presently unavailable, but a predicted structure that represents the C-terminal two-thirds of the enzyme has been published [31]. Interestingly, in this model, C799, H810, C813 and H816 are in a spatial arrangement resembling that of the Zn^{2+}

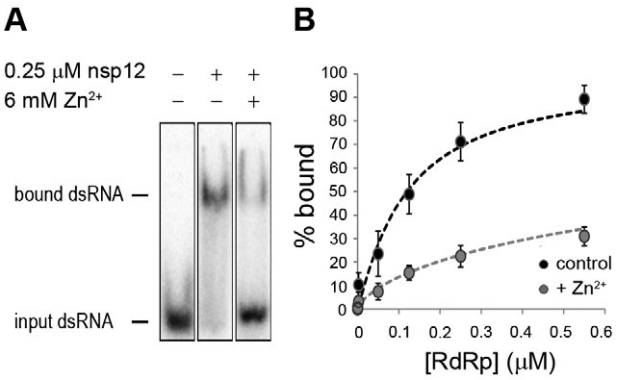

Figure 8. The effect of Zn^{2+} on SARS-CoV nsp12 template binding. (**A**) Electrophoretic mobility shift assay with radiolabeled dsRNA and nsp12 in the presence and absence of Zn^{2+} (indicated above the lanes). The position of unbound and nsp12-bound RNA in the gel is marked on the left of the panel. (**B**) Determination of the nsp12 affinity for RNA in the presence and absence of Zn^{2+}. A fixed amount of RNA was incubated with an increasing amount of nsp12. This revealed a 3–4 fold reduction in the percentage of bound RNA in the presence of zinc ions (grey) relative to the percentage of bound RNA in the absence of zinc ions (black). Error bars represent standard error of the mean (n = 3).
doi:10.1371/journal.ppat.1001176.g008

coordinating residues in the Zn2 zinc-binding pocket found in motif E of the Dengue virus RdRp (see Supplemental Fig. S3). Clearly, an in-depth analysis of nidovirus RdRps, e.g. through structural analysis and subsequent mutational studies targeting aforementioned cysteines and histidines, is required to provide further insight into and a structural basis for the Zn^{2+}-induced inhibitory effects on RdRp activity documented in this study. Such studies may, however, be complicated when Zn^{2+} binding proves to be very transient in nature and not detectable with currently available methods.

In summary, the combination of zinc ions and the zinc-ionophore PT efficiently inhibits nidovirus replication in cell culture. This provides an interesting basis for further studies into the use of zinc-ionophores as antiviral compounds, although systemic effects have to be considered [43,44] and a water-soluble zinc-ionophore may be better suited, given the apparent lack of systemic toxicity of such a compound at concentrations that were effective against tumors in a mouse xenograft model [45]. *In vitro*, the reversible inhibition of the RdRp by Zn^{2+} has also provided us with a convenient research tool to gain more insight into the molecular details of (nido)viral RNA synthesis, and revealed novel mechanistic differences between the RdRps of SARS-CoV and EAV.

Materials and Methods

Cells and viruses

Vero-E6 cells were cultured and infected with SARS-CoV (strain Frankfurt-1; accession nr. AY291315) or SARS-CoV-GFP as described previously [46]. All procedures involving live SARS-CoV were performed in the biosafety level 3 facility at Leiden University Medical Center. BHK-21 or Vero-E6 cells were cultured and infected with EAV (Bucyrus strain; accession nr. NC_002532) or EAV-GFP [29] as described elsewhere [25].

Effect of zinc ions on nidovirus replication in cell culture

One day prior to infection, Vero-E6 cells were seeded in transparent or black (low fluorescence) 96-well clusters at 10,000 cells per well. The next day, cells were infected with SARS-CoV-GFP or EAV-GFP with an m.o.i. of 4, and 1 h p.i. the inoculum was removed and 100 μl of medium containing 2% fetal calf serum (FCS) was added to each well. In some experiments 0–32 μM of pyrithione (Sigma) was added in addition to 0–2 μM $ZnOAc_2$. Infected cells were fixed at 17 h p.i. by aspirating the medium and adding 3% paraformaldehyde in PBS. After washing with PBS, GFP expression was quantified by measuring fluorescence with a LB940 Mithras plate reader (Berthold) at 485 nm. To determine toxicity of $ZnOAc_2$ and PT, cells were exposed to 0–32 μM PT and 0–8 μM $ZnOAc_2$. After 18 h incubation, cell viability was determined with the Cell Titer 96 AQ MTS assay (Promega). EC_{50} and CC_{50} values were calculated with Graphpad Prism 5 using the nonlinear regression model.

RNA templates and oligonucleotides

RNA oligonucleotides SAV557R (5′-GCUAUGUGAGAU-UAAGUUAU-3′), SAV481R (5′-UUUUUUUUUUAUAACUU-AAUCUCACAUAGC-3′) and poly$(U)_{18}$ (5′-UUUUUUUUU-UUUUUUUUU-3′) were purchased from Eurogentec, purified from 7 M Urea/15% PAGE gels and desalted through NAP-10 columns (GE healthcare). To anneal the RNA duplex SAV557R/SAV481R, oligonucleotides were mixed at equimolar ratios in annealing buffer (20 mM Tris-HCl pH 8.0, 50 mM NaCl and 5 mM EDTA), denatured by heating to 90°C and allowed to slowly cool to room temperature after which they were purified from 15% non-denaturing PAGE gels.

In vitro viral RNA synthesis assay with isolated RTCs

SARS-CoV and EAV RTCs were isolated from infected cells and assayed for activity *in vitro* as described previously [25,26]. To assess the effect of Zn^{2+}, 1 μl of a $ZnOAc_2$ stock solution was added to standard 28-μl reactions, resulting in final Zn^{2+} concentrations of 10–500 μM. When Zn^{2+} had to be chelated in the course of the reaction, magnesium-saturated EDTA (MgEDTA) was added to a final concentration of 1 mM. After RNA isolation, the ^{32}P-labeled reaction products were separated on denaturing 1% (SARS-CoV) or 1.5% (EAV) agarose formaldehyde gels. The incorporation of [α-^{32}P]CMP into viral RNA was quantified by phosphorimaging of the dried gels using a Typhoon scanner (GE Healthcare) and the ImageQuant TL 7 software (GE Healthcare).

Expression and purification of nidovirus RdRps

SARS-CoV nsp12 and EAV nsp9 were purified essentially as described elsewhere [27,28], but with modifications for nsp9. In short, *E. coli* BL21(DE3) with plasmid pDEST14-nsp9-CH was grown in auto-induction medium ZYM-5052 [47] for 6 hours at 37°C and a further 16 hours at 20°C. After lysis in buffer A (20 mM HEPES pH 7.4, 200 mM NaCl, 20 mM imidazole, and 0.05% Tween-20) the supernatant was applied to a HisTrap column (GE Healthcare). Elution was performed with a gradient of 20–250 mM imidazole in buffer A. The nsp9-containing fraction was further purified by gel filtration in 20 mM HEPES, 300 mM NaCl and 0.1% Tween-20 on a Superdex 200 column (GE Healthcare). The fractions containing nsp9-CH were pooled, dialyzed against 1000 volumes of buffer B (20 mM HEPES, 100 mM NaCl, 1 mM DTT and 50% glycerol) and stored at −20°C. RdRps with a D618A (SARS-CoV) or D445A (EAV) mutation were obtained by site-directed mutagenesis of the wild-type (wt) plasmid pDEST14-nsp9-CH [28] with oligonucleotides 5′-TACTGCCTTGAAACAGCCCTGGAGAGTTGTGAT-3′ and 5′-ATCACAACTCTCCAGGGCTGTTTCAAGGCAGTA-3′, and plasmid pASK3-Ub-nsp12-CHis$_6$ with oligonucleotides 5′-CCTTATGGGTTGGGCTTATCCAAAATGTG-3′ and 5′-CACATTTTGGATAAGCCCAACCCATAAGGA-3′, as described elsewhere [27]. Mutant proteins were purified parallel to the wt enzymes.

RdRp assays with purified enzymes

Standard reaction conditions for the RdRp assay with 0.1 μM of purified SARS-CoV nsp12 are described elsewhere [27]. To study the effect of Zn^{2+} in this assay, 0.5 μl of a dilution series of 0–80 mM $ZnOAc_2$ was added to the 5 μl reaction mixture, yielding final Zn^{2+} concentrations of 0–8 mM. The EAV RdRp assay contained 1 μM nsp9, 1 μM RNA template poly$(U)_{18}$, 0.17 μM [α-^{32}P]ATP (0.5 μCi/μl; Perkin-Elmer), 50 μM ATP, 20 mM Tris-HCl (pH 8.0), 10 mM NaCl, 10 mM KCl, 1 mM $MnCl_2$, 4 mM $MgOAc_2$, 5% glycerol, 0.1% Triton-X100, 1 mM DTT and 0.5 units RNaseOUT. $ZnOAc_2$ was added to the reaction to give a final concentration of 0–6 mM. To chelate Zn^{2+} during reactions, MgEDTA was added to a final concentration of 8 mM. Reactions were terminated after 1 hour and analyzed as described [27].

SARS-CoV nsp12 electrophoretic mobility shift assay

SARS-CoV RdRp was incubated with 0.2 nM 5′ ^{32}P-labeled SAV557R/SAV481R RNA duplex, for 10 minutes at 30°C either in presence or absence of 6 mM $ZnOAc_2$. Reactions were analyzed as described previously [27].

Supporting Information

Figure S1 Effect of various divalent cations on the RdRp activity of SARS-CoV nsp12. Purified recombinant SARS-CoV nsp12 was incubated with a primed template, ATP, and [α-^{32}P]ATP in the presence of either 6 mM Mg^{2+} only (lane 1), and with increasing concentrations of a second divalent metal (M^{2+}), specifically: 2–6 mM Ca^{2+} (lane 2–4), 2–6 mM Co^{2+} (lane 5–7), 2–6 mM Zn^{2+} (lane 8–10), or 2–6 mM Mn^{2+} (lane 11–13). The strongest inhibition was observed for Zn^{2+}. For more details on the SARS-CoV nsp12 RdRp assay, see the main text.

Figure S2 Effect of Zn^{2+} on the dinucleotide extension activity of EAV nsp9. Purified recombinant EAV nsp9 was incubated with a U^{18} template in the presence of [α-^{32}P]ATP, ATP, 4 mM Mg^{2+}, 1 mM Mn^{2+}, and 1 μM ApA. (**A**) Reaction mixtures were split into two aliquots, one of which was supplemented with 6 mM Zn^{2+}, and samples were taken at the time points (minutes) indicated above the lanes. In the absence of Zn^{2+}, EAV nsp9 initiates *de novo* and produces di- and trinucleotides, indicated with A2 and A3, respectively. A non-specific band, unrelated to RdRp activity, between A2 and A3 is indicated with an asterisk. In the presence of 6 mM Zn^{2+}, the synthesis of dinucleotides and trinucleotides was blocked. (**B**) When performing the assay described under (A) in the absence of Zn^{2+}, a full-length product of 18 nucleotides is formed. This product is not observed when the assay is performed in the presence of 6 mM Zn^{2+}, but nsp9 was capable of elongating the provided dinucleotide primer ApA into tri- (ApA*pA) and tetranucleotide ((ApA*pA*pA) products (the asterisk indicates radiolabeled phosphates). Due to the absence of a 5′ triphosphate group, these reaction products migrate much slower in the 20% acrylamide and 7 M urea gel used for this analysis. See the main text for additional experimental details on the EAV nsp9 RdRp assay.

Figure S3 Putative zinc-binding residues in the predicted structure of SARS-CoV nsp12 and comparison with the structure of the zinc-containing Dengue virus RdRp domain. (**A**) Sequence alignment of coronavirus RdRps showing conservation of four potential zinc-binding residues amino acids (C799-H810-C813-H816 in SARS-CoV; indicated with asterisks) in the C-terminal region of coronavirus nsp12. Black shading indicates complete conservation among coronaviruses. The coronavirus RdRp sequences were aligned with Muscle 3.6. The aligned sequences and NCBI accession numbers are the following: mouse hepatitis virus strain A59 (MHV_A59; NP_068668), human CoV 229E (HCoV_229E; NP_068668), infectious bronchitis virus strain Beaudette (IBV_B; P0C6Y1), bovine coronavirus (BCoV; NP_742138.1), feline coronavirus (FeCoV; YP_239353.1), and SARS-CoV strain Frankfurt-1 (SARS_Fr1; AAP33696). (**B**) Crystal structure of the Dengue virus RdRp domain showing the position of four cysteine and histidine residues that form Zn^{2+}-binding pocket Zn2, located close to motif E (depicted in red). A second Zn^{2+}-binding pocket (Zn1) and the two zinc ions identified in the crystal structure are indicated in blue-gray. (**C**) Predicted three-dimensional structure model of SARS-CoV nsp12 (Xu et al., Nucl. Acids Res. 31: 7117–7130), based on PDB code 1O5S, rendered with Swiss-PdbViewer 4.01 and POV-Ray 3.6. The positions of the conserved cysteine and histidine residues indicated in panel A (C799-H810-C813-H816) close to motif E (depicted in red) and RdRp active-site residues (D618, D760 and D761) are indicated. The spatial arrangement of these cysteines and histidines in this model strikingly resembles the positioning of the metal ion-coordinating residues of Zn-binding pocket Zn2 in the Dengue virus RdRp domain (see panel B).

Coronavirus biology and replication: implications for SARS-CoV-2

Philip V'kovski[1,2], *Annika Kratzel*[1,2,3], *Silvio Steiner*[1,2,3], *Hanspeter Stalder*[1,2] *and Volker Thiel*[1,2] ✉

Abstract | The SARS-CoV-2 pandemic and its unprecedented global societal and economic disruptive impact has marked the third zoonotic introduction of a highly pathogenic coronavirus into the human population. Although the previous coronavirus SARS-CoV and MERS-CoV epidemics raised awareness of the need for clinically available therapeutic or preventive interventions, to date, no treatments with proven efficacy are available. The development of effective intervention strategies relies on the knowledge of molecular and cellular mechanisms of coronavirus infections, which highlights the significance of studying virus–host interactions at the molecular level to identify targets for antiviral intervention and to elucidate critical viral and host determinants that are decisive for the development of severe disease. In this Review, we summarize the first discoveries that shape our current understanding of SARS-CoV-2 infection throughout the intracellular viral life cycle and relate that to our knowledge of coronavirus biology. The elucidation of similarities and differences between SARS-CoV-2 and other coronaviruses will support future preparedness and strategies to combat coronavirus infections.

Coronaviruses (CoVs) are a highly diverse family of enveloped positive-sense single-stranded RNA viruses. They infect humans, other mammals and avian species, including livestock and companion animals, and are therefore not only a challenge for public health but also a veterinary and economic concern. Within the order of *Nidovirales* and the suborder of *Coronavirineae* lies the family *Coronaviridae*. The latter is further specified into the subfamily of *Orthocoronavirinae*, which consists of four genera: *alphacoronavirus*, *betacoronavirus*, *gammacoronavirus* and *deltacoronavirus*. Whereas alphacoronaviruses and betacoronaviruses exclusively infect mammalian species, gammacoronaviruses and deltacoronaviruses have a wider host range that includes avian species. Human and animal coronavirus infections mainly result in respiratory and enteric diseases[1,2].

Human coronaviruses, such as HCoV-229E and HCoV-OC43, have long been known to circulate in the population and they, together with the more recently identified HCoV-NL63 and HCoV-HKU1, cause seasonal and usually mild respiratory tract infections associated with symptoms of the 'common cold'. In strong contrast, severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV) and SARS-CoV-2, which have emerged in the human population over the past 20 years, are highly pathogenic. By infecting bronchial epithelial cells, pneumocytes and upper respiratory tract cells in humans, SARS-CoV, MERS-CoV and SARS-CoV-2 infections can develop into severe, life-threatening respiratory pathologies and lung injuries for which no specific prophylactic or therapeutic treatment has been approved to date.

The initial steps of coronavirus infection involve the specific binding of the coronavirus spike (S) protein to the cellular entry receptors, which have been identified for several coronaviruses and include human aminopeptidase N (APN; HCoV-229E), angiotensin-converting enzyme 2 (ACE2; HCoV-NL63, SARS-CoV and SARS-CoV-2) and dipeptidyl peptidase 4 (DPP4; MERS-CoV). The expression and tissue distribution of entry receptors consequently influence viral tropism and pathogenicity. During the intracellular life cycle (FIG. 1), coronaviruses express and replicate their genomic RNA to produce full-length copies that are incorporated into newly produced viral particles. Coronaviruses possess remarkably large RNA genomes flanked by 5′ and 3′ untranslated regions that contain *cis*-acting secondary RNA structures essential for RNA synthesis. At the 5′ end, the genomic RNA features two large open reading frames (ORFs; ORF1a and ORF1b) that occupy two-thirds of the capped and polyadenylated genome. ORF1a and ORF1b encode 15–16 non-structural proteins (nsp), of which 15 compose the viral replication and transcription complex (RTC) that includes, amongst others, RNA-processing and RNA-modifying

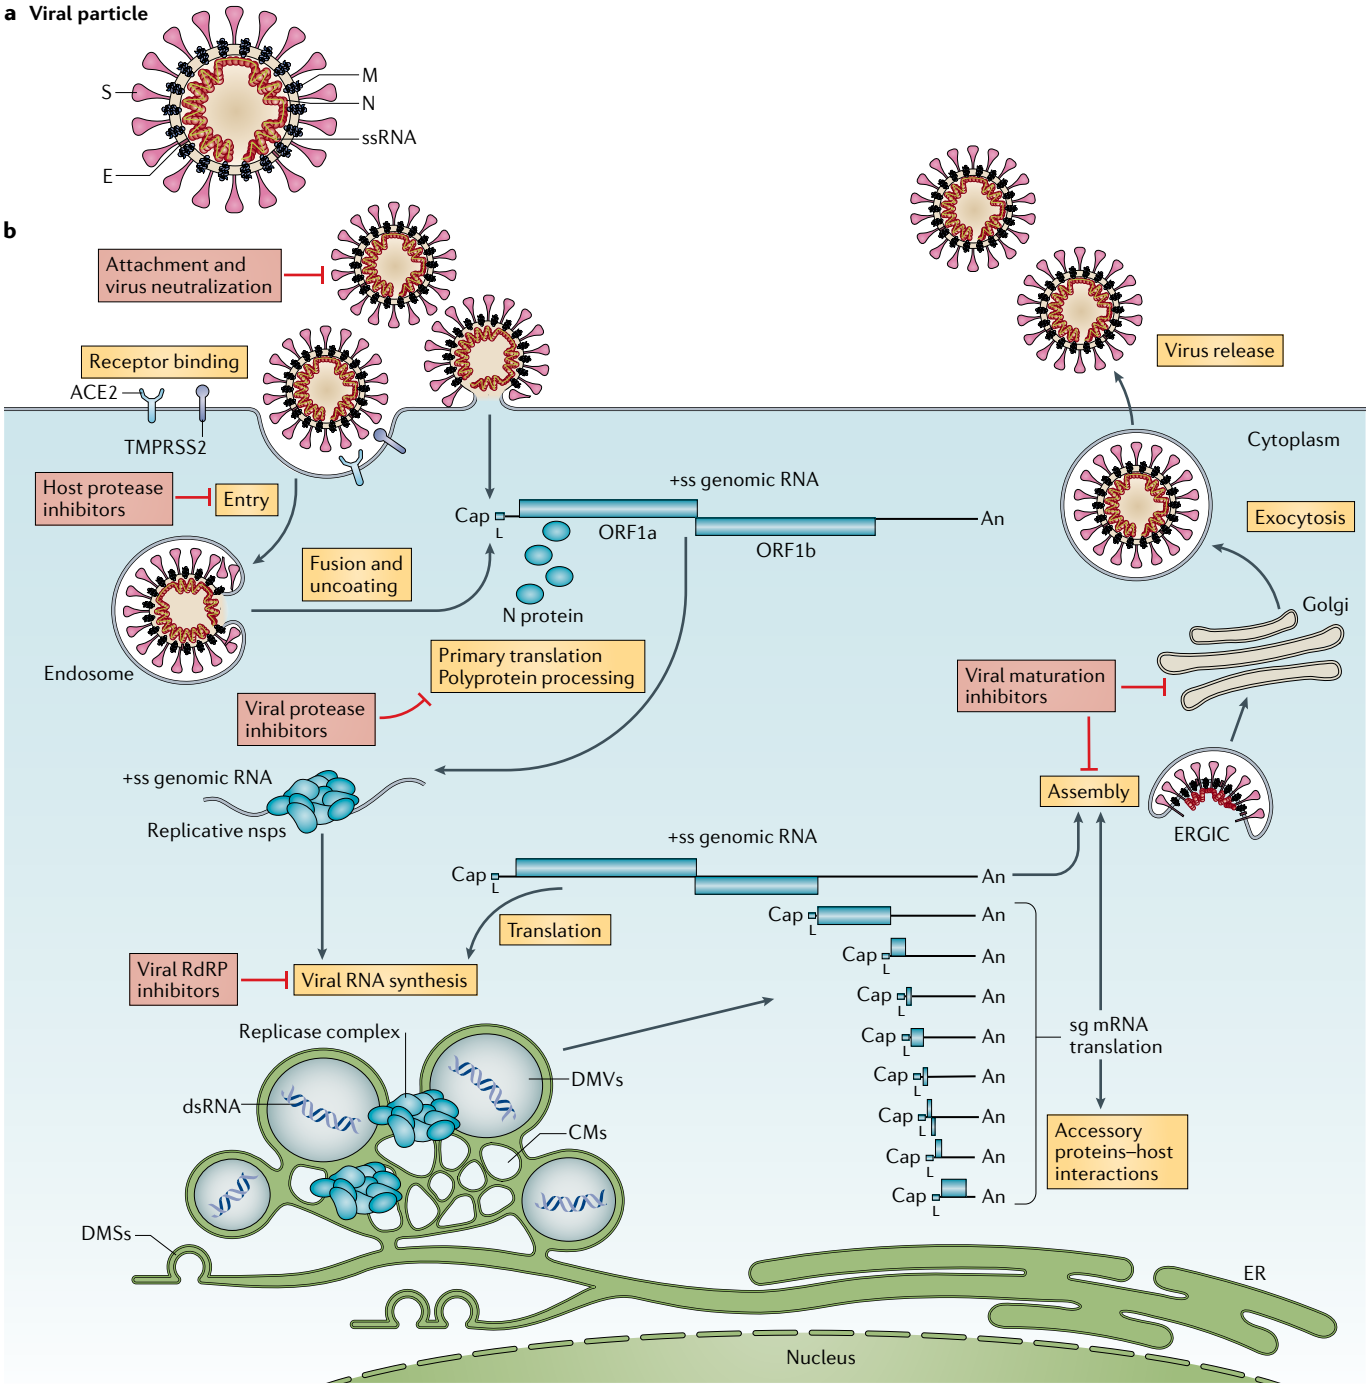

Fig. 1 | **The coronavirus virion and life cycle. a** | The coronavirus virion consists of structural proteins, namely spike (S), envelope (E), membrane (M), nucleocapsid (N) and, for some betacoronaviruses, haemagglutinin-esterase (not shown). The positive-sense, single-stranded RNA genome (+ssRNA) is encapsidated by N, whereas M and E ensure its incorporation in the viral particle during the assembly process. S trimers protrude from the host-derived viral envelope and provide specificity for cellular entry receptors. **b** | Coronavirus particles bind to cellular attachment factors and specific S interactions with the cellular receptors (such as angiotensin-converting enzyme 2 (ACE2)), together with host factors (such as the cell surface serine protease TMPRSS2), promote viral uptake and fusion at the cellular or endosomal membrane. Following entry, the release and uncoating of the incoming genomic RNA subject it to the immediate translation of two large open reading frames, ORF1a and ORF1b. The resulting polyproteins pp1a and pp1ab are co-translationally and post-translationally processed into the individual non-structural proteins (nsps) that form the viral replication and transcription complex. Concordant with the expression of nsps, the biogenesis of viral replication organelles consisting of characteristic perinuclear double-membrane vesicles (DMVs), convoluted membranes (CMs) and small open double-membrane spherules (DMSs) create a protective microenvironment for viral genomic RNA replication and transcription of subgenomic mRNAs (sg mRNAs) comprising the characteristic nested set of coronavirus mRNAs. Translated structural proteins translocate into endoplasmic reticulum (ER) membranes and transit through the ER-to-Golgi intermediate compartment (ERGIC), where interaction with N-encapsidated, newly produced genomic RNA results in budding into the lumen of secretory vesicular compartments. Finally, virions are secreted from the infected cell by exocytosis. Key steps inhibited by compounds that are currently being validated and which represent attractive antiviral targets are highlighted in red. Zoonotic pathogens
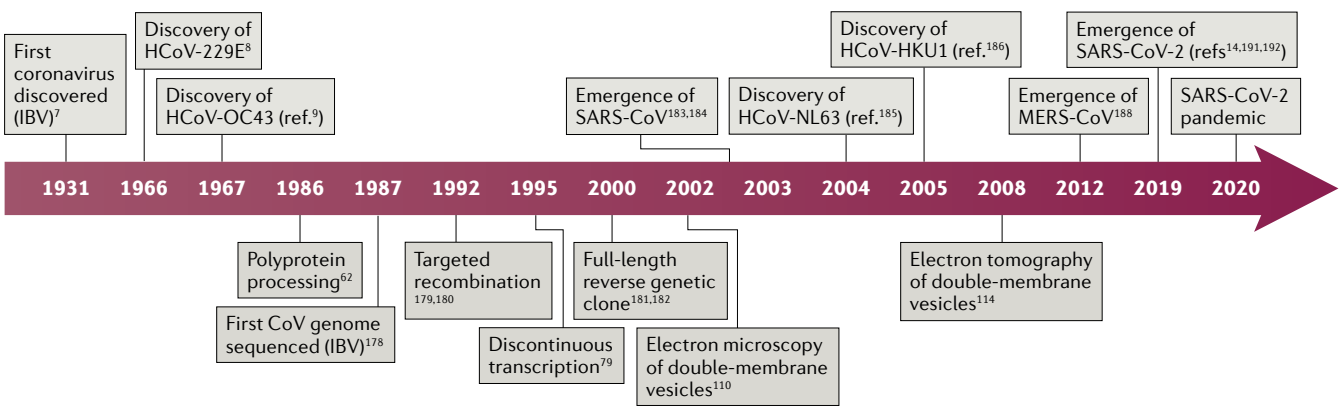
Animal pathogens that can infect and replicate in humans.

enzymes and an RNA proofreading function necessary for maintaining the integrity of the >30 kb coronavirus genome[3]. ORFs that encode structural proteins and interspersed ORFs that encode accessory proteins are transcribed from the 3′ one-third of the genome to form a nested set of subgenomic mRNAs (sg mRNAs). Coronavirus accessory proteins are highly variable sets of virus-specific proteins that display limited conservation even within individual species but they are principally thought to contribute to modulating host responses to infection and are determinants of viral pathogenicity[4,5]. Nevertheless, the molecular functions of many accessory proteins remain largely unknown owing to the lack of homologies to accessory proteins of other coronaviruses or to other known proteins[6].

Despite the previous public health emergencies caused by the SARS-CoV and MERS-CoV outbreaks and the impact of the ongoing SARS-CoV-2 pandemic on society and human health, intervention strategies to combat coronavirus infections are only in their early stages and await proof of clinical efficacy. Their development intimately relies on the deepened understanding of basic mechanisms of coronavirus gene functions as well as of the molecular interactions with host factors. Since the discovery of the first coronavirus (avian infectious bronchitis virus) in the 1930s[7] and the discovery of the first human coronaviruses (HCoV-229E and HCoV-OC43) in the 1960s[8,9], the coronavirus research field has made substantial progress in understanding the basic principles of coronavirus replication and pathogenesis (BOX 1). This advancement was accelerated after the emergence of SARS-CoV in 2002 and MERS-CoV in 2012 and has broadened our view on coronaviruses as zoonotic pathogens that can severely affect human health. Moreover, the unprecedented speed and technical progress of coronavirus research that has become evident in a few months after the appearance of SARS-CoV-2 at the end of 2019 has led to a rapidly growing understanding of this newly emerging pathogen and of its associated disease, COVID-19. In this Review, we discuss key aspects of coronavirus biology and their implications for SARS-CoV-2 infections as well as the treatment and prevention strategies.



Entry of coronaviruses

Coronavirus S proteins are homotrimeric class I fusion glycoproteins that are divided into two functionally distinct parts (S1 and S2) (FIG. 2). The surface-exposed S1

Box 1 | Milestones in coronavirus discovery and research

Coronaviruses (CoVs) are a large family of viruses long known to infect a wide variety of mammalian and avian species, including livestock and companion animals. In 1931, the avian infectious bronchitis virus (IBV) was the first coronavirus to be discovered[7]. Later, in 1966 and 1967, the first human coronaviruses, HCoV-229E and HCoV-OC43, were discovered[8,9]. The following period was essential in the discovery of research milestones that majorly contributed to coronavirus knowledge: polyprotein processing (1986)[62], first full-length coronavirus genome sequence (1987)[178], first recombinant coronaviruses engineered by targeted recombination (1992)[179,180], discontinuous transcription (1995)[78], full-length reverse genetic clones (2000, 2001)[181,182] and electron microscopy of double-membrane vesicles (2002)[110]. The zoonotic emergence of severe acute respiratory syndrome coronavirus (SARS-CoV) and the subsequent SARS epidemic in 2002–2003 caused 8,000 documented SARS cases, 10% of which had lethal consequences[183,184]. As human-to-human transmission mainly occurred after the onset of symptoms, drastic public health measures, including travel restrictions and isolation of infected patients, succeeded in containing the international spread to limited foyers of infections. The SARS epidemic was followed by an increased amount of virus screening and sequencing, which led to the identification of HCoV-NL63 and HCoV-HKU1 (REFS[185,186]). In contrast to SARS-CoV, HCoV-229E, HCoV-OC43, HCoV-NL63 and HCoV-HKU1 circulate annually and usually cause only mild upper respiratory tract symptoms in immunocompetent individuals[185–187]. In 2008, SARS-CoV-induced double-membrane vesicles were first shown using electron tomography[114]. The emergence of a second highly pathogenic coronavirus of zoonotic origin, MERS-CoV, resulted in more than 2,500 human MERS cases since 2012, associated with virus-induced lung injuries and severe clinical manifestations (36% case fatality rate)[188]. MERS-CoV also originated from bats and established an animal reservoir in dromedary camels[189,190]. Despite sporadic zoonotic transmissions to humans upon prolonged contact and the limited human-to-human transmission, MERS-CoV infections are still detected[190].

Recently, the pathogenic SARS-CoV-2 rapidly spread in the human population after a likely spillover from bats or from a yet unidentified intermediate host[14,191,192]. As of October 2020, more than 40 million COVID-19 cases have been declared in over 200 countries, causing more than 1 million deaths (COVID-19 Dashboard). SARS-CoV-2 targets both upper and lower respiratory tract tissues and efficient human-to-human transmission occurs even before the onset of symptoms[36,193]. Clinical manifestations range from asymptomatic or mild infections to acute lung inflammation and pneumonia, mostly in the elderly and patients with comorbidities[36,194,195].

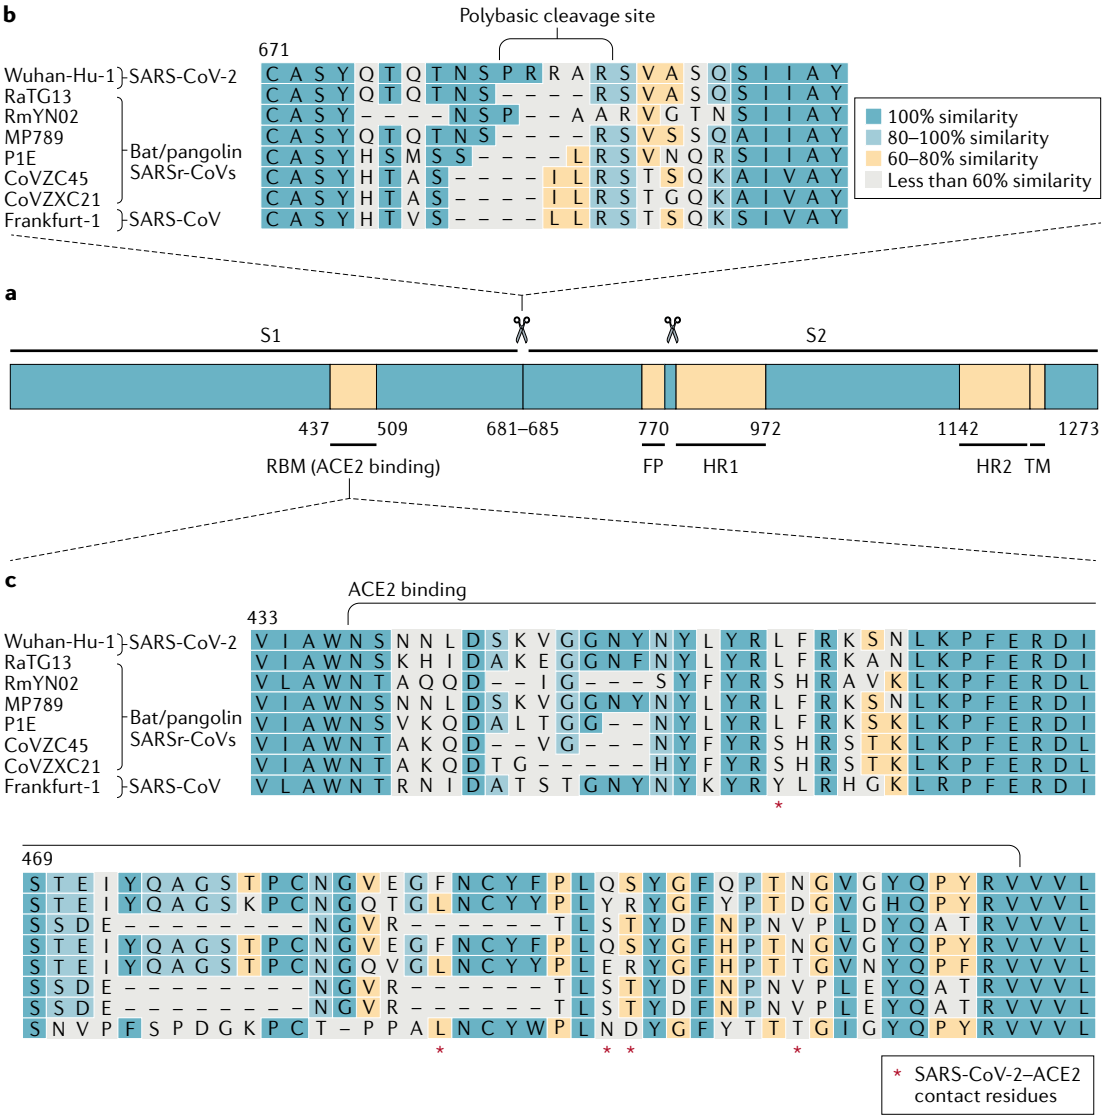

Fig. 2 | **Severe acute respiratory syndrome-related coronavirus spike sequence variation. a** | Schematic illustration of coronavirus spike, indicating domain 1 and domain 2. The receptor-binding motif (RBM) is located on S1 and the fusion peptide (FP), heptad repeat 1 (HR1), HR2 and the transmembrane (TM) domains are located on S2. The cleavage sites are indicated. The colour code designates conserved spike regions surrounding the angiotensin-converting enzyme 2 (ACE2)-binding domain among severe acute respiratory syndrome-related coronaviruses (SARSr-CoVs) and high amino acid sequence variations within the site of receptor interaction. **b** | Amino acid alignment of human SARS-CoV-2 (Wuhan-Hu-1) and SARS-CoV (Frankfurt-1), bat (RaTG13, RmYN02, CoVZC45 and CoVZXC21) and pangolin (MP789, P1E) SARSr-CoVs. The spike gene sequence alignment was performed using MUSCLE and using the default settings and codon alignment, then translated into amino acids using MEGA7, version 7.0.26. The alignment was coloured according to percentage amino acid similarity with a Blosum 62 score matrix. The colour code designates conserved spike regions surrounding the ACE2-binding domain among SARSr-CoVs and high amino acid sequence variations within the site of receptor interaction. The insertion of a polybasic cleavage site (PRRAR, amino acids 681 to 685) in Wuhan-Hu-1 is indicated, and similar insertions are depicted in bat SARSr-CoV RmYN02. **c** | Within the spike sequence, the ACE2 receptor-binding motif (amino acids 437 to 509, black line) is depicted. The spike contact residues for ACE2 interaction are marked with asterisks.

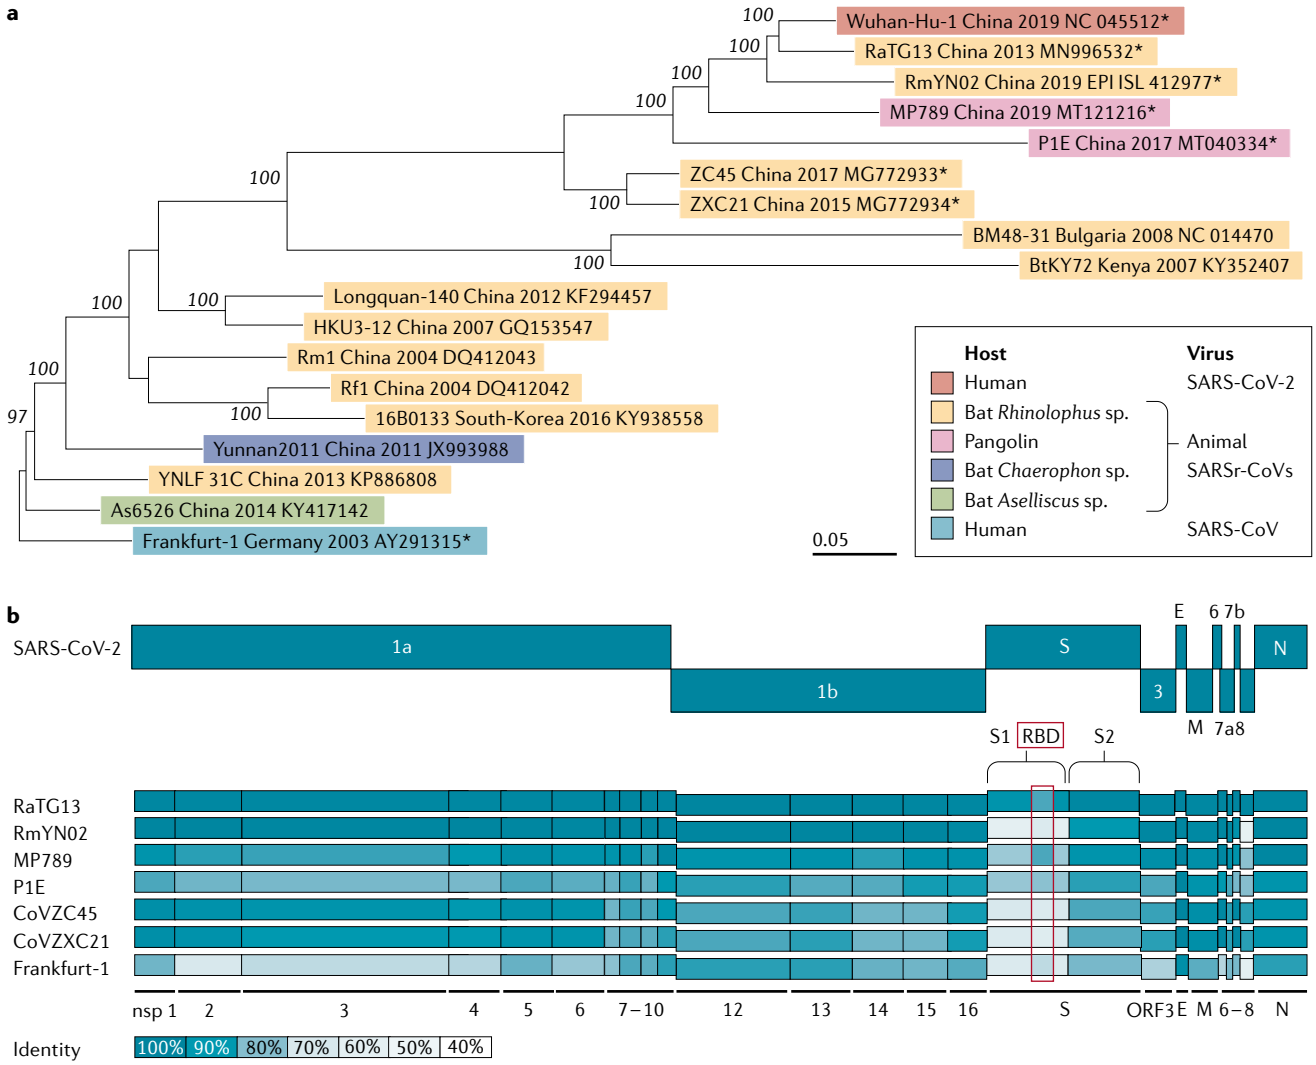
contains the receptor-binding domain (RBD) that specifically engages the host cell receptor, thereby determining virus cell tropism and pathogenicity. The transmembrane S2 domain contains heptad repeat regions and the fusion peptide, which mediate the fusion of viral and cellular membranes upon extensive conformational rearrangements[10–12]. Shortly after the 2002–2003 SARS-CoV outbreak, ACE2 was identified as the functional receptor that enables infection by SARS-CoV[13]. The high genomic and structural homology between the S proteins of SARS-CoV and SARS-CoV-2 (76% amino acid identity) supported the identification of ACE2 as the cell-surface receptor for SARS-CoV-2 (REFS[12,14–16]). Remarkably, essential SARS-CoV contact residues that interact with ACE2 were highly conserved in SARS-CoV-2 as well as in members of the species *Severe acute respiratory syndrome-related coronavirus* that use ACE2 or have similar amino acid side



FOI 26-3132 - Document 5

chain properties[14,15,17–19]. These data were corroborated by the atomic resolution of the interface between the SARS-CoV-2 S protein and ACE2 (REFS[16,19–21]). By contrast, the bat *Severe acute respiratory syndrome-related coronavirus* RaTG13 S sequence (93.1% nucleotide identity to SARS-CoV-2) shows conservation of only one out of six amino acids directly involved in ACE2 binding, even though, based on the entire genomic sequence, RaTG13 is the closest relative of SARS-CoV-2 known to date (96.2%)[14] (BOX 2).

Box 2 | **Diversity of severe acute respiratory syndrome-related coronaviruses**

SARS-CoV-2 belongs to the species *Severe acute respiratory syndrome-related coronavirus* in the subgenus *Sarbecovirus*[1,14,23]. Phylogenetic relationships of representative members of the species *Severe acute respiratory syndrome-related coronavirus* were analysed (sequences retrieved from GenBank and GISAID were analysed using MEGA7 version 7.0.26, asterisks indicate representative viruses further depicted in figure part **b**). Interestingly, SARS-CoV-2 shared 79.6% nucleotide identity with SARS-CoV and close relations to severe acute respiratory syndrome-related coronaviruses (SARSr-CoVs) ZC45 and ZXC21 from *Rhinolophus sinicus*, whereas RaTG13 from *Rhinolophus affinis* showed the highest nucleotide similarity of 96.2%[14,23] (figure part **a**).

Sequence identity differed highly upon comparison of individual genes and domains, indicating frequent recombination events in natural reservoir hosts[14,23,196]. This is exemplified by comparing the nucleotide identity of SARS-CoV-2 with bat coronavirus RaTG13, bat CoV RmYN02, pangolin CoV MP789, pangolin CoV P1E, bat CoV ZC45, bat CoV ZXC21 and human SARS-CoV (Frankfurt-1 strain). Remarkably, in all depicted SARSr-CoVs, the spike gene, a major determinant for zoonotic transmission to humans, showed lower sequence similarity with SARS-CoV-2, thus raising the question of the SARS-CoV-2 origin. Despite the detection of a wide variety of similar bat CoVs in China, SARS-CoV-2 or an immediate precursor have not been found, leaving the role of bats in the emergence of SARS-CoV-2 elusive. Moreover, the environmental separation of bats and humans might favour the existence of an intermediate host, responsible for SARS-CoV-2 adaption and transmission into the human population, just like civet cats were suggested in the SARS-CoV outbreak[197]. The example of pangolin CoV MP789, which shared five essential amino acids for ACE2 binding in the S with SARS-CoV-2 highlights the existence of a variety of unidentified betacoronaviruses in wild-life animals and their roles as possible intermediate hosts[198]. Nevertheless, the number of identified bat SARSr-CoVs represents only a fraction of the existing diversity. The recent identification of bat SARSr-CoVs that can use human ACE2 as an entry receptor (CoV WIV1, CoV bRsSHC014) indicates a possibility of direct cross-species transmission from bats to humans[20,199,200] (figure part **b**).

Received: 27 September 2017; Accepted: 22 November 2017; Published: 25 November 2017

Abstract: After the discovery of zinc deficiency in the 1960s, it soon became clear that zinc is essential for the function of the immune system. Zinc ions are involved in regulating intracellular signaling pathways in innate and adaptive immune cells. Zinc homeostasis is largely controlled via the expression and action of zinc "importers" (ZIP 1–14), zinc "exporters" (ZnT 1–10), and zinc-binding proteins. Anti-inflammatory and anti-oxidant properties of zinc have long been documented, however, underlying mechanisms are still not entirely clear. Here, we report molecular mechanisms underlying the development of a pro-inflammatory phenotype during zinc deficiency. Furthermore, we describe links between altered zinc homeostasis and disease development. Consequently, the benefits of zinc supplementation for a malfunctioning immune system become clear. This article will focus on underlying mechanisms responsible for the regulation of cellular signaling by alterations in zinc homeostasis. Effects of fast zinc flux, intermediate "zinc waves", and late homeostatic zinc signals will be discriminated. Description of zinc homeostasis-related effects on the activation of key signaling molecules, as well as on epigenetic modifications, are included to emphasize the role of zinc as a gatekeeper of immune function.

Keywords: zinc flux; zinc wave; homeostatic zinc signal; immune function; zinc deficiency; signaling pathways

1. Introduction

The transition metal zinc has long been known to be essential for the growth of fungi and development in rodents [1,2]. Symptoms arising from zinc-deficiency in animal studies were reported to be growth failure, loss of hair, testicular atrophy, as well as thickening and hyperkeratinization of the epidermis. Despite these observations, it took a century until zinc was accepted to be essential for human beings [3].

Previously, zinc deficiency was considered to be rare. Nowadays, however, zinc deficiency is known to be very common, especially in developing countries [4]. Worldwide, about two billion people are estimated to be affected by zinc deficiency. In developing countries, zinc deficiency is the 5th leading cause for the loss of healthy life years. In industrial countries, mainly the elderly population is affected by zinc deficiency [5]. Nearly 30% of the elderly population is considered to be zinc deficient. Since zinc homeostasis is known to be important in immunological reactions such as the inflammatory response, and the oxidative stress response, multiple chronic diseases observed in the elderly are probably related to zinc deficiency. Hence, diseases such as Rheumatoid Arthritis, diabetes, atherosclerosis, impaired cognitive function, as well as age-related macular degeneration (AMD) may be due to zinc deficiency, worsening chronic inflammation and triggering oxidative stress [6–9]. Besides the elderly, vegetarians or vegans and patients suffering from renal insufficiency or chronic diarrhea are affected by zinc deficiency [6,9–12]. In humans, clinical manifestations of zinc deficiency are similar to those observed in rodents and include weight loss, growth retardation, atrophy, and immune dysfunction, as well as

FOI 26-3132 - Document 5

increased oxidative stress and a boosted inflammatory immune response [3,13–16]. Dietary insufficiency and/or compromised uptake can result in perturbation of zinc homeostasis in humans [12,17,18].

Besides zinc, vitamins and other transition metals such as copper and iron, as well as calcium are essential for adequate immune function. Deficiency or exceeding levels of those nutrients can be associated with the occurrence of distinct diseases. In this regard, a multitude of diseases such as Rheumatoid Arthritis [19], multiple sclerosis [20–22] impaired cognitive function as seen in Alzheimer's disease [7,23], and AMD [24] were reported to go along with skewed concentrations of the above-mentioned nutrients.

2. Zinc Metabolism and Homeostasis

At 2–3 g in total, zinc is the second most abundant metal in humans and is distributed unequally throughout different organs and tissues. Prostate, pancreas, and bone are considerably high in zinc, containing up to 200 µg/g. In contrast, zinc concentrations in heart, brain and plasma are comparatively low at 1–23 µg/g. Although plasma has only 1 µg/g, it is probably the most important reservoir for zinc homeostasis [5].

Red meat and oysters are rich dietary sources of zinc [5]. Foods prepared from unrefined cereals, legumes, or plant parts rich in phytates decrease zinc bioavailability, by binding zinc very effectively [25]. Zinc is resorbed in the intestine by specific zinc transporting proteins and distributed in the human body. In serum, free zinc is rare since it is largely bound to proteins such as albumin, α_2-macroglobulin (A2M), and transferrin. Albumin binds zinc with a relatively low affinity, A2M with a medium affinity and transferrin with a high affinity. Subcellularly, zinc is distributed between specific zinc-storing vesicles called zincosomes (~50%), the nucleus (~30–40%), and the remainder is distributed between the cytoplasm and other organelles [26,27]. In the cytoplasm, zinc is largely bound by zinc-chelating proteins called metallothioneins (MTs) discovered in 1957 [28]. MTs play an important role in zinc homeostasis by complexing about 20% of intracellular zinc. MT-1 for example binds up to seven zinc ions, making it specifically suitable to function as a zinc buffer [29]. During evolution, cells not only evolved metal-binding proteins to maintain low cytosolic metal ion concentrations to protect themselves against high cytotoxic metal concentrations, but also mechanisms of zinc compartmentalization and zinc sequestration. Modulation of available cytosolic free zinc is facilitated by zinc storage in zincosomes or other organelles such as endoplasmic reticulum (ER) or Golgi apparatus respectively [30]. Zinc distribution between the cytosol an organelles is mediated by specific zinc transporting proteins, such as zinc importers or zinc exporters, or via membrane channels [29,31]. The cytosolic free zinc ion concentration is maintained at remarkably low picomolar to nanomolar concentrations [32]. However, through zinc release from protein and organelles zinc concentrations can increase transiently and locally, enabling zinc to affect gene expression, enzymatic activity, and cell signaling [31,33].

Zinc homeostasis is particularly controlled by 24 zinc transporting proteins, and four MTs (MT1-4), playing coordinated roles in the distribution, transport, and maintenance of intracellular zinc level. MT-1 and MT-2 are expressed ubiquitously throughout the human body, play an important role in liver and kidney function and are inducible by various stimuli such as metal ions, cytokines, glucocorticoids, and oxidative stress, respectively. In contrast, MT-3 and MT-4 are expressed cell specific. MT-3 is primarily expressed in the central nervous system, whereas MT-4 is primarily found in epithelial tissue. The expression of both MT3 and MT4 is very strictly controlled, highlighting distinct functions of MT isoforms in different organs and tissues [34–37].

Based on their membrane topology, zinc transporters are divided into two major families: (1) 14 zinc transporters of the SLC39s family (Zrt (zinc-regulated transporter)-like, Irt (iron-regulated transporter)-like proteins, ZIP 1–14) that increase cytoplasmic zinc and (2) 10 zinc transporters (ZnT 1–10) of the SLC30s family that lower cytoplasmic zinc by transporting zinc either out of the cell or into intracellular organelles [38]. Since zinc transporters are found in a myriad of different cell types in the human body, both on the outer plasma membrane, and on organelle-membranes, such as

FOI 26-3132 - Document 5

mitochondria, Golgi apparatus, lysosomes, and ER, the necessity of a proper zinc level for a specific cellular function is emphasized [38,39]. Moreover, zinc distribution was more recently mentioned in relation to receptors and ion channels other than ZIPs or ZnT, for example voltage-dependent calcium channels, transient receptor potential channels, nicotinic acetylcholine receptors, and glutamatergic receptors. Additionally, diffusion of zinc bound to amino acids is known. However, these mechanisms need to be investigated more in-depth [39].

Interestingly, zinc-dependence was found in all classes of enzymes, i.e., transferases, hydrolases, lyases, isomerases, oxidoreductases, and ligases [40,41]. The physiological importance of zinc was moreover supported by in silico studies which showed that about 10% of the overall human proteome can potentially bind zinc. Zinc binding can be facilitated by a variety of binding motifs including: (1) zinc-finger motifs; (2) Really Interesting New Gene (RING) finger domains; (3) LIM domains composed of two adjacent zinc finger domains; and (4) plant homeodomain (PHD) domains similar to RING fingers [42]. Thus, interaction of the transition metal zinc with proteins is highly complex.

The zinc proteome consists of two major groups, comprising enzymes and transcription factors respectively. Those cover 90% of the overall zinc proteome, indicating that zinc is involved in regulating catalysis and transcription [43,44]. Because zinc is required for catalysis by some enzymes, as well as for maintaining enzyme structure [26], intracellular signaling pathways can be altered due to altered zinc availability, affecting cellular maturation, differentiation, and function [45].

3. Immune Function during Zinc Deficiency

The importance of zinc for proper immune function is best observed in zinc-deficient individuals. Zinc deficiency has been known for 50 years [15] and is associated with skin abnormalities, hypogonadism, cognitive impairment, growth retardation, and imbalanced immune reactions which favor allergies and autoimmune diseases [3,5]. In the case of inherited malfunction of zinc homeostasis, as seen in Acrodermatitis Enteropathica, zinc deficiency can be lethal [17].

Zinc deficiency can be classified by severity and is divided into severe or marginal zinc deficiency, respectively. Severe zinc deficiency is often observed because of malfunction of zinc uptake in the intestine. This is reported in patients suffering from chronic diarrhea, patients being treated with penicillamine, patients receiving parenteral nutrition without zinc, or following excessive alcohol consumption [46–49]. Patients present clinical symptoms such as lymphopenia, decreased ratios of T helper (Th) cells to cytotoxic T cells, decreased natural killer (NK) cell activity, and increased monocyte cytotoxicity. The most severe form of zinc deficiency observed in Acrodermatitis Enteropathica. This zinc malabsorption syndrome is inherited as an autosomal recessive condition and is due to a mutation of the intestinal zinc uptake protein ZIP4 [17,50]. Acrodermatitis Enteropathica is characterized mainly by diarrhea, weight loss, recurrent viral and bacterial infections, dermatitis, hair loss, and neuropsychological disturbances [51]. However, all observed symptoms can be corrected by high dose (1 mg/kg) zinc supplementation [52]. Other zinc transporter-related diseases are discussed later in detail.

Marginal zinc deficiency is characterized by slight weight loss, rough skin, oligospermia, and hyperammonemia [47]. It is probably caused by nutritional zinc deficiency, often seen in vegetarians or vegans, due to the consumption of high levels of zinc-chelating agents in food originating from cereals, legumes, or plant parts. In these foods, lignin and phytates counteract zinc absorption by binding zinc and reducing its bioavailability [10,53]. Nutritionally related marginal zinc deficiency is prevalent in the elderly population. Hence, a correlation between impaired immune function and zinc status is likely in older people [6,54,55]. Within the seventh decade of life, the human immune system undergoes dramatic age-related changes, termed “immunosenescence”. Associated with this condition is an increased incidence of inflammatory disease, most notably cardiovascular diseases, whereas the immunological response to vaccines is typically impaired [56]. The underlying zinc-modulated molecular mechanisms and signaling pathways are discussed below.

FOI 26-3132 - Document 5

The overall frequency of zinc deficiency worldwide is estimated to be higher than 20% [18]. Interestingly, zinc supplementation is already widely practiced and approved for clinical treatment of multiple diseases. Zinc has proven to be very effective for the treatment of pediatric diarrhea, saving millions of children's lives in developing countries such as India [48]. The Food and Drug Administration (FDA) approved zinc supplementation for the treatment of Wilson's disease, a genetic disorder in which copper builds up in the human body [57]. In the elderly population, age-related macular degeneration (AMD) is of frequent occurrence and AMD progress, which can result in blindness, can be treated successfully by zinc supplementation [58,59]. Furthermore, not only the very young or elderly benefit from zinc supplementation, as shown by studies with patients suffering from: (1) viral infections, e.g., the common cold, diarrhea, chronic hepatitis C, or human immunodeficiency virus (HIV); (2) bacterial infections such as *shigellosis* or *Helicobacter pylori*; (3) parasitic infestations such as acute cutaneous leishmaniosis or malaria; (4) autoimmune diseases such as Type 1 Diabetes Mellitus (T1DM) and Rheumatoid Arthritis; and (5) transplant rejections [60]. This widespread variety of clinical manifestations makes zinc deficiency a serious nutritional problem. However, to date, no reliable biomarker to assess zinc status exists [61]. Thus, zinc deficiency is difficult to diagnose. Overall, zinc contributes to the overall regulation of immune cell function, influencing several signaling pathways. Hereby, zinc acts in a direct manner by binding reversibly to regulatory sites in signaling proteins, or indirectly by influencing enzymes such as phosphatases which are a component of and regulate signaling pathways [45].

Zinc homeostasis is essential for multiple aspects of the immune system including hematopoiesis, cell maturation and cell differentiation, cell cycle progression, and for the proper function of immune-cells [62]. During inflammation, adequate zinc status is essential since in acute phase responses zinc is transiently transferred from serum into organs, especially the liver, causing transient serum hypozincemia. This transient loss of serum zinc is eventually rebalanced during resolution of the inflammatory response. Here, zinc is probably released from tissue into serum. One proposed reason for this complex mechanism is to act as a danger signal for immune cells [63]. Since extracellular microorganisms are also dependent on zinc availability, zinc sequestration by the human immune system helps to combat invading pathogens. This is facilitated due to expression of pro-inflammatory acute phase proteins including interleukin (IL)-6, which upregulates expression of zinc binding peptides such as MTs and A2M [64]. In immune cells, on the one hand, increased intracellular zinc levels can intoxicate engulfed pathogens and act cytoprotectively by neutralizing reactive oxygen species (ROS) and nitrogen species (RNS). In general, zinc homeostasis and zinc signals are crucial to counteract inflammatory diseases, and the correlation of undernourishment with severe inflammatory diseases is accompanied by prolonged and severe forms of serum hypozincemia. In the literature, it has been suggested that hypozincemia goes along with elevated inflammatory mediators, e.g., ROS, and antimicrobial peptides such as calprotectin or matrix metalloproteases (MMP), causing tissue injury, especially in liver, lung, and spleen [63,65,66].

In general, cellular function, such as the intracellular killing of harmful pathogens, cytokine production as well as ROS production, are dependent on zinc and are impaired due to zinc deficiency. Zinc deficiency also adversely affects the maturation and function of T and B cells, which occurs through dysregulation of basic biological functions at the cellular level, described later in this review in more detail. For T cells, a disturbed ratio of Th1 and Th2 cells in favor of Th2-driven allergic reactions is a well-known consequence of zinc deficiency [67]. Zinc flux and homeostatic zinc signals, as defined below, are highly important for adequate T cell differentiation, and this observed malfunction can be reversed by zinc supplementation [68–71]. Moreover, the pro-tolerogenic immunoreaction is triggered by long-lasting changes in intracellular zinc levels due to induction of regulatory T cells (Treg) cells and dampening of pro-inflammatory Th17 and Th9 cells [72–75].

T cell development is strongly dependent on DC activation. Interestingly, zinc signals were recently shown to induce a tolerogenic DC phenotype in vitro and in vivo. Herein, zinc suppressed MHC-II expression and enhanced programmed cell death 1 ligand 1 (PD-L1) and PD-L2 expression

FOI 26-3132 - Document 5

resulting in the manipulation of the Treg/Th17 balance in favor of Treg cell development [76]. Moreover, on the molecular level, zinc inhibits the IL-6-induced STAT3 signaling cascade essential for Th17 development [74]. Another potential target of zinc-mediated Th17 manipulation might be found on the epigenetic level since several epigenetic enzymes as (de-)acetylases, and (de-)methylases are regulated in a zinc dependent manner [72,77].

A malfunctioning adaptive immune system has been observed in the elderly population, whereby secretion of pro-inflammatory IL-6 is pathologically elevated, while T cell activation was reduced, as were responses to stimulation or vaccination [6,56,68,70,78,79]. Interestingly, all these pathologies can be improved due to zinc supplementation, highlighting the significance of zinc for a well-balanced immunoreaction.

Regarding innate immunity, zinc deficiency leads to prioritization of maturation of innate immune cells such as monocytes. In this case, differentiation was promoted by the reduction in the concentration of intracellular free zinc [80]. This was facilitated by induced expression of the zinc-binding heterodimeric protein calprotectin [81]. In general, calprotectin was also highly expressed in neutrophils [81,82]. Recently, zinc deficiency has been shown to negatively influence critical neutrophil functions such as phagocytosis, oxidative burst, degranulation, cytokine production, chemotaxis, and neutrophil extracellular trap (NET) formation [83,84]. These observations are in line with an impaired ROS production during zinc deficiency, which is needed for NET formation, and for intracellular killing of phagocytosed pathogens by neutrophils [85,86].

Furthermore, NK cell function was weakened when zinc signals are absent. In this regard, recognition of major histocompatibility complex class I (MHC-I) on target cells, as well as lytic activity, was decreased [87–90]. In contrast, zinc supplementation increased differentiation of CD341 progenitors toward NK cells and their cytotoxic activity [91], as well as NK killing activity, and intracellular perforin concentrations [90].

Besides cellular immune responses, zinc is also indispensable for proper RNA transcription, DNA synthesis, as well as cell survival [27,92]. In relation to cell survival and apoptosis, adequate intracellular zinc levels are needed because apoptosis is triggered by zinc deficiency. Furthermore, cytokine function and secretion are adversely affected by zinc deficiency impairing the function of the basic messengers of the immune system. Thus, zinc is crucial for the appropriate development and function of the whole immune system including innate as well as adaptive immunity, and the affected signaling cascades and networks are described in detail below.

4. Types of Zinc Signals

As indicated earlier, intracellular as well as extracellular zinc is usually bound to protein. From protein, zinc can readily be made available but also made unavailable. About 10% of total human proteins bind some zinc throughout the lifetime of the protein, as it is essential for catalytic or structural functions. In these cases, zinc is not released under normal circumstances. Other proteins revealed rapid association and dissociation rates for zinc, short enough for zinc to regulate processes such as pathogen sensing, intracellular transportation and signaling. This pool of zinc is called “free”, “labile” or “mobile” zinc, describing loosely bound or unbound ions that are thermodynamically available for cellular metabolism. Coordination chemistry of those “mobile” zinc ions has been barely explored [30]. Thus, it is difficult to create artificial substances that can deliver zinc or chelate it away from protein. This explains why there is so far no clear answer to the question, which zinc compounds are best to use for zinc supplementation. In addition, it underlines why there is still no reliable method to measure zinc status of individuals and the immense discrepancies between studies even if experimental set ups seem to only differ slightly.

Zinc is released from bound protein during regular protein turnover. It is mobilized from protein by chemical processes, and can be mobilized between the extracellular and intracellular, organellar or vesicular compartments [30]. Efficient zinc buffering inside the cells, to avoid zinc-intoxication and zinc-deficiency, is regulated by coordinating expression of zinc binding proteins and zinc

FOI 26-3132 - Document 5

transporters [37]. This includes so-called muffling, where proteins transiently bind zinc and transport it to vesicles [29]. To be correct, zinc ions are never completely "free" inside the cell but always complexed with amino acids, phosphates or other low molecular weight ligands. However, "free zinc" will be used here, to distinguish the pool of zinc that is available for signaling from zinc stably bound to protein and therefore unavailable. This is the term, generally used in literature in this field, although it is not a satisfactory definition in the chemical sense [30].

After stimulation of cells, intracellular zinc fluctuation, or in short "zinc flux", has been observed, suggesting a function for zinc as a second messenger [93–95]. In myeloid cell lines, primary monocytes and granulocytes, a zinc flux can be induced by lipopolysaccharide (LPS) or phorbol-12-myristate-13-acetate (PMA), which was not detected in lymphoid cells [83,94]. Furthermore, Fc-epsilon receptor I (FcεRI) activation caused a zinc flux in mast cells [96]. Increased intracellular zinc in monocytes was also detected after stimulation with monocyte chemoattractant protein (MCP-1), tumor necrosis factor (TNF)α, insulin and Pam3CSK4 [97]. Using various ligands for toll like receptors (TLR) including Pam3CSK4 (TLR1/2), *Listeria monocytogenes* (TLR2), flagellin (TLR5), FSL-1 (TLR6/2), ssRNA40 (TLR7) and inhibitory oligonucleotides (ODN) 1826 (TLR9) all increased intracellular zinc in murine macrophages and primary human monocytes [94,97]. In these cases, zinc was mostly shown to be increased, but a decrease might occur as well. Zinc can transduce the extracellular stimulus into an intracellular signaling event. Release of zinc from the endoplasmic reticulum has been shown to be inducible by some hormones, similarly to what has been described for calcium [98]. Another source of zinc is zinc-binding-proteins as already indicated. Here, MTs play a decisive role, as they bind up to seven zinc ions, which can be released rapidly. Zinc ions can be released from their coordination environment with sulfur donors. Zinc is released from cysteine in proteins, suggesting that a redox signal can be "translated" into a zinc signal [99], which we will return to later in this review.

As the zinc flux occurs within seconds to minutes of stimulation, it is not due to changes in gene expression, but alteration of activity of existing agents. Figure 1 illustrates that not only fast zinc fluxes exist, but also a so called "zinc wave", which occurs within a few minutes. For the zinc wave, the influx of calcium is essential. This has been described after cross-linking of FcεRI in mast cells [96]. Furthermore, a delayed signal occurs a few hours after stimulation. Regarding this zinc signal, a certain stimulus activates expression of genes involved in zinc metabolism, including zinc transporters and zinc binding proteins, causing alteration of intracellular zinc levels some time after the initial stimulus. This third type of zinc signal is said to have mostly homeostatic functions and will therefore be named accordingly here. Here, intracellular zinc levels are changed long-term, i.e., permanently elevated or decreased compared to the original concentration measured inside the cell before stimulation occurred. The homeostatic zinc signal was shown to be important for major cellular changes such as the process of maturation and differentiation of myeloid and dendritic cells [80,100]. In B and T cells, stimulation induces a sustained increase in intracellular zinc due to downregulation of ZnT1, ZnT 4–7 and upregulation of ZIP6, ZIP8, and ZIP10 [60,101]. When ZIP6 and ZIP8 were silenced, cytokine production and proliferation of T cells was blocked [71,101,102]. Similarly, BCR-induced signaling was disrupted in cells from ZIP10 knockout mice [103]. Various activation signals, including mediators of diseases, change the expression of MTs, enabling regulation of zinc homeostasis in the long term as well [80,104].

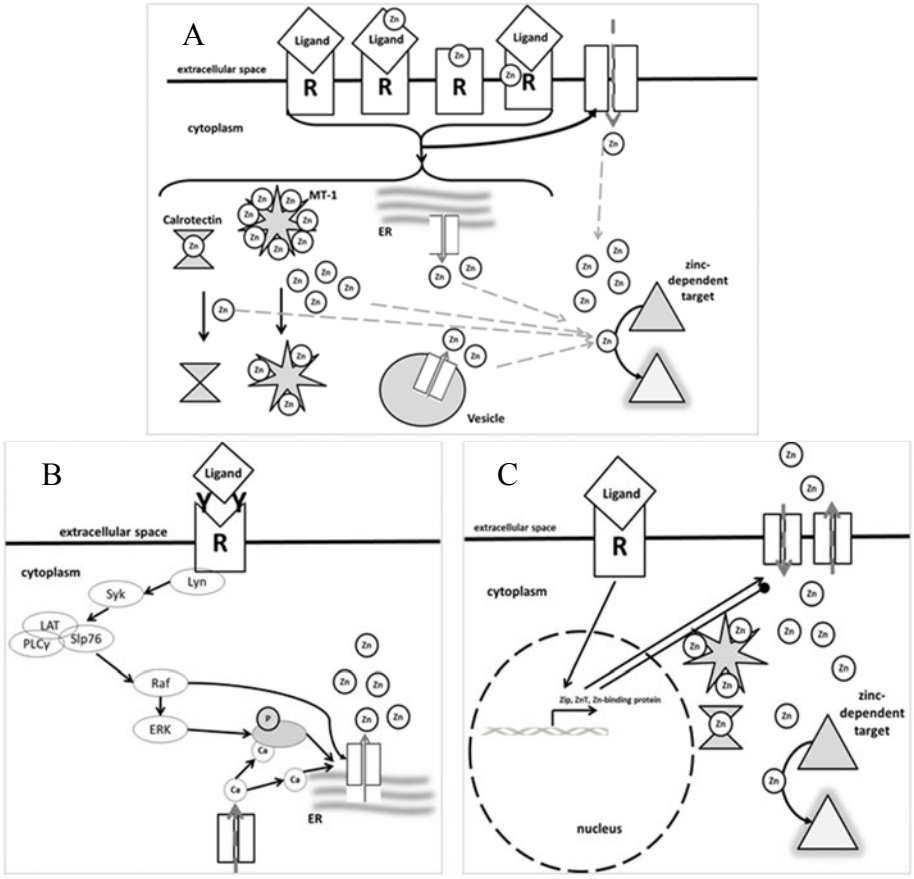

Figure 1. Different Types of Zinc Signals: (**A**) Zinc Flux, as observed after receptor triggering (e.g., binding of lipopolysaccharide (LPS) to Toll like receptor (TLR)4), is generated within seconds. (**B**) A Zinc Wave, as is induced via immunoglobulin receptors and involving calcium flux, can be observed within a few minutes. (**C**) Homeostatic Zinc Signals, for example as observed after LPS stimulation of dendritic cells, take a few hours to be established and involve the expression of zinc transport and binding proteins. For explanations see the text. Abbreviations: ER: endoplasmic reticulum; ERK: extracellular signal-regulated kinase; MT: metallothionein; PLC: phospholipase c; R: receptor; Slp76, SH2 domain-containing leukocyte protein, 76 kD. Modified after [62,96,105].

5. Effects of Zinc in Immune Cell Signaling

Changes in extracellular zinc levels, such as serum hypozincemia during acute phase reactions, have been suggested to activate immune cells, functioning as a "danger signal". In addition, cytokines, integrin binding, growth factors and other immune cell receptor ligands trigger intracellular zinc flux. In recent years more and more regulatory pathways have been demonstrated in various immune cells to directly or indirectly involve zinc signaling. The following section provides a summary of recent developments, concentrating on the major mechanisms in immune cells, and for further information the reader is referred to the extensive literature on this topic [39,62,103,106]. Exemplarily, we will describe briefly key signaling pathways for cells from the adaptive as well as the innate immune system. General concepts, such as the effect of intracellular zinc concentrations on the activities of phosphodiesterases (PDE), phospho tyrosine phosphatases (PTP) and their antagonists the tyrosine kinases (TK), or the translocation of signaling molecules and transcription factors such as NFκB to the nucleus, can probably be extrapolated to other examples of receptor-induced signaling pathways. However, cell type dependent exceptions to the paradigm might exist, underlining the importance of testing the general concepts for each individual cell type and pathway.

FOI 26-3132 - Document 5

The ideal immune response should be fast and specific against each kind of molecular pattern associated with extracellular or intracellular pathogens, and degenerate or damaged cells. Instead of assigning all the necessary functions to one single cell type, the immune response is optimized by the cooperation of various cell types, supported by soluble mediators with distinct functions, roughly separated into innate, fast responding cells and highly specific adaptive immune cells. Quiescent cells circulate in the bloodstream and enter the tissues after activation in case of an infection. Here, firstly innate immune cells, composing mainly granulocytes and monocytes, but also NK cells, mast cells and dendritic cells are recruited. These cells can recognize general pathogen-associated molecular patterns (PAMPs) via surface receptors denoted as pattern recognition receptors (PRRs). Examples of PRRs include the Toll-like receptors (TLRs), with at least 10 members in humans, nucleotide-binding oligomerization domain-like receptors (NLRs), and retinoic acid-inducible gene-I-like receptors (RLRs). Receptor triggering activates signaling pathways and subsequent anti-microbial activities such as degranulation, phagocytosis and pathogen-killing, the presentation of the antigen to other (adaptive immune) cells and cytokine production [107]. Adaptive immune cells, resembling T- and B-lymphocytes, are in contrast highly specific, but require a longer time to become fully active. Each cell has a receptor, called B cell receptor (BCR) or T cell receptor (TCR), and thereby specificity for a certain antigen [108,109]. Triggering of the naïve cell by its matching antigen activates intracellular signaling and causes the proliferation of this particular cell clone and its differentiation into an effector or memory cell. Binding of co-stimulatory molecules, for example interleukins or interferons, to their receptors is necessary for the fine-tuning of the pathogen-specific response. Adaptive immune cells carrying receptors for autoantigens, are selected and silenced.

5.1. Zinc Signals Can Regulate Phosphatase and Kinase Activities

The translation of an initial stimulus, detected by a cell surface receptor, in to gene expression in the nucleus is largely mediated by transferring phosphate residues from one signaling molecule to the next in a consecutive cascade [110]. Here, tyrosine, serine and threonine residues in signaling proteins are the acceptors of the phosphate residues in most cases. Phosphorylation is mediated by protein kinases, while protein phosphatases are responsible for removing phosphates. Combining results for tyrosine phosphorylation of multiple studies, one can assume that phosphorylation is balanced by zinc levels, as zinc affects the decision over the activity of protein tyrosine kinases (PTKs) and phosphatase (PTPs). Phosphorylation of a target protein can result in an activation or an inactivation of that protein and each case must be specifically examined [111].

Several PTKs, belonging largely to the Src family, were shown to act in a zinc–dependent manner. Here, zinc supported the phosphorylation of target molecules. Examples include p60c-Src as found in Alzheimer's patients, anaplastic lymphoma kinase, which is a member of the receptor tyrosine family, Bruton's kinase (BTK) and also mitochondrial Src tyrosine kinases, showing that kinases from various cellular compartments can be affected by zinc levels [112–116].

A group of protein kinases important for signaling in immune cells is the protein kinase C (PKC) family, reported to be zinc metallo-enzymes. These are serine/threonine kinases of several isoforms, including classic PKC, which are activated by cofactors including diacylglycerol (DAG) or calcium, novel PKCs that do not bind calcium but only DAG and atypical PKCs which bind neither of these co-factors. Zinc was reported to be important for PKC's structure. Approximately four zinc ions were found associated with each PKCα subunit and similar values have been reported for PKCβII and PKCγ. This matches well with PKC's C1 domain forming four Cys3His binding motifs, probably occupied by zinc. As this domain is conserved across all PKC isoforms, zinc might be structurally important for all PKCs [117]. Whether more zinc ions can be bound is questionable, but a release of zinc from PKC after incubation with lipid second messengers or due to thiol oxidation has been noted [118]. Activation of PKC, especially by homeostatic zinc signals, has been shown. Thus, amongst others, binding of phorbol esters to the cytoskeleton and the plasma membrane has been found to require zinc [119]. IKK and NFκB activity was decreased in macrophages negative for PKCε. LPS stimulation

FOI 26-3132 - Document 5

of such PKCε knockout macrophages, showed lower ERK and p38 phosphorylation compared to wildtype controls, suggesting that here, the zinc signal alters signal transduction via PKC [120].

In this context, the tight interrelation of zinc homeostasis with redox metabolism should be mentioned. PKC, activated through PMA, subsequently causes the production of reactive oxygen species by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Induction of a zinc flux by PMA was mentioned earlier [93]. When NADPH oxidase was inhibited, no increase in intracellular zinc was observed after PMA stimulation [66]. Incubation of cells with H_2O_2 on the other hand, elicited elevated intracellular zinc concentrations, suggesting an association of ROS production with the occurrence of a zinc signal. In this case, the source of zinc might be PKC itself, or zinc-binding proteins such as MT, both known to release zinc when oxidized. Alternatively, zinc might be released from cellular compartments in an oxidant-sensitive way [71,94,101,121,122]. Maybe as a feedback mechanism, zinc affects ROS production as well. Incubation of cells with a high concentration (100 μM) of the zinc chelator TPEN caused altered mobilization of PKC between plasma membrane and the cytoskeleton and inhibition of PKC activity [93,123,124]. When myeloid cells were depleted of zinc by incubation in zinc-deficient medium, basal and stimulation-induced ROS levels were increased [66]. Increased ROS production in zinc deficient neutrophils was also observed [66,84,125–127]. ROS as well as zinc are essential second messengers for the activation of various functions in neutrophils and other immune cells [83].

Activity of PKA and PKG (both serin/threonine kinases) are mainly affected by levels of the second messengers cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), respectively. Increased cGMP additionally cross-activates PKA. PDEs are zinc dependent and hydrolysis of both cAMP and cGMP has been shown to be affected by zinc. Zinc is tightly bound to the catalytic center of PDE, but PDE also has an inhibitory site, where available zinc binds if present in elevated concentrations [128,129]. Furthermore, it was shown that zinc affects LPS-induced expression of certain PDEs, including PDE4B [130]. Therefore, cAMP and cGMP levels increased if high zinc concentrations were available because hydrolysis by PDE was inhibited. This was shown for PDE 4, 3, and 1, which were all inhibited by zinc in monocytes. Zinc flux activated adenylate cyclase (AC) while the enzyme was inhibited by homeostatic zinc signals, probably as a feedback mechanism to resolve stimulation-mediated effects. Alterations in guanylate cyclase (GC) activity were only affected by the zinc flux [131,132]. Downstream targets of PKA include Raf-1, responsible for NFκB activation, while PKG targets members of the MAPK family, offering another mechanism of zinc's effect on signaling, which remains to be investigated in more detail [133].

As suggested earlier, zinc seems to balance phosphorylation of signaling molecules in direct and indirect ways, altering the activities of kinases and their antagonists, the phosphatases. PTPs are largely regulated by proteolysis, dimerization, the redox state of the cell and phosphorylation and dephosphorylation. Zinc is one more regulator to add to the list, as was shown amongst others for PTP1B (IC_{50} (zinc) = 3–17 nM), SHP-1 (IC_{50} (zinc) = 93 nM, SHP-2 (IC_{50} (zinc) = 1–2 μM), PTPRB (IC_{50} (zinc) = 98 pM), PTEN (IC_{50} (zinc) = 0.6 nM) [134,135] and the same might be true for several others from the list of 107 PTPs in humans. IC_{50} values all fit well with the physiological concentration of zinc within cells, so that regulation of their activity by zinc signals is plausible. Suggested mechanism underlying the regulation of PTP activity by zinc include the displacement of co-factors by zinc and the direct interaction of zinc with the catalytic center of PTPs [136]. Prolonged protein tyrosine phosphorylation was described in many signaling pathways of immune cells [94,97,137]. An effect of zinc has thus not been investigated in all of them, but its involvement in regulating those signaling pathways is likely. Similar inhibitory effects of zinc were found for MAPK phosphatases (MKP), which are closely related to PTPs, but largely affected the phosphorylation of threonine residues [138] and for calcineurin (CN), a threonine/serine phosphatase (IC_{50} (zinc) = 10 nM–10 μM). Because the range of zinc IC_{50} for this enzyme is large, the effect of an intracellular zinc signal might be questionable. However, in vitro investigations in T cells revealed

FOI 26-3132 - Document 5

that CN's activity was indeed decreased by zinc. In this case, replacement of catalytically active nickel by zinc was found as one underlying mechanism [101,139,140].

Regarding intracellular signaling, the major targets of protein kinases and protein phosphatases are members of the mitogen activated protein kinase (MAPK) family. Here, phosphorylation of extracellular Signal-regulated Kinase (ERK), MAPK/Erk kinase (MEK), p38 has been shown to vary depending on the zinc status of a cell [134,136,141–143]. Long-term zinc deficiency was associated with increased p38 activity in myeloid cells [66]. In contrast, zinc activated ERK in fibroblasts [144]. Differences in effect are most probably due to divergent experimental conditions and cell types, such as duration and intensity of zinc supplementation or deficiency. Another group of signaling molecules whose phosphorylation status and activity is altered by zinc are STAT molecules, as was demonstrated for STAT1, STAT3, and STAT6 [145,146]. Investigations of the role of zinc signals in the regulation of STAT5 activity showed varying results and may depend on the signaling pathway [71,135,147].

5.2. Effects of Zinc Finger Proteins on Signal Transduction

When it comes to homeostatic zinc signals, the zinc-finger protein A20 is of interest, being significantly involved in the resolution of infections. Induction of A20 expression by zinc signals, which resulted in increased intracellular A20 protein levels, was observed in pre-monocytic and endothelial cells as well as in other immune cells. In TLR- and TNFR-triggered signaling pathways, A20 was shown to down-regulate signaling, thereby ameliorating inflammation. TNF receptor associated factor (TRAF) 6 is de-ubiquinated by A20, abrogating TLR-induced signaling. A20 can remove ubiquitin from receptor interacting protein (RIP)-1. RIP-1 binding to IKKγ is thereby disturbed and NFκB is retained in the cytoplasm, also inhibiting TNFR-induced signaling [45,148,149]. Additionally, decreased signaling, induced via other receptors, was found to involve the inhibition of NFκB by A20. In line with the anti-inflammatory role of A20, expression of IL-1β, TNFα, C-reactive protein (CRP), and other inflammatory mediators, as well as lipid peroxidation, were downregulated as found in humans, mice and chicken due to altered zinc homeostasis [148,150–153].

Another zinc-finger protein which plays a role in homeostatic zinc signaling is peroxisome proliferator-activated receptor (PPAR)α. Similar to A20, PPARα expression was induced by zinc. PPARα alters the binding of NFκB to DNA and thereby abrogates the induction of pro-inflammatory cytokines and adhesion molecules [150].

5.3. Zinc Alters Hematopoiesis by Altering Intracellular Signaling

In mice, acute phase reaction was paralleled by transient serum hypozincemia and an increase in the leukocyte count in the blood [63]. Moreover, long-term dietary-induced zinc deficiency affected hematopoiesis in mice, causing a shift in the ratio of leukocyte subsets towards innate myeloid immune cells [154]. In humans, T cells were clearly diminished during zinc deficiency. A prioritizing of cells from the myeloid lineage (monocytes and granulocytes), at the cost of lymphoid cells (especially the T cell compartment), if zinc supply is limited, has been hypothesized in humans as well, however this remains to be proven.

Decreased intracellular zinc levels were shown to be necessary for the differentiation of monocytes and dendritic cells and were suggested to play a role in granulopoiesis [80,100]. In dendritic cells, LPS stimulation caused expression of ZIP6 and ZIP10 as well as of ZnT-1, ZnT-4, and ZnT-6 via pathways involving TRIF, resulting in an altered cellular zinc homeostasis [100]. Alteration in TRIF signaling by the zinc status of a cell has also been described for LPS stimulated macrophages [97].

One centrally important molecule regulating differentiation in various cell types is STAT3. Recent studies revealed that phosphorylation, and thereby activation of this signaling molecule, was altered depending on the zinc status of a cell, while total protein concentration remained unaltered [155]. In myeloid cells, TLR3 and NLPR3 inflammasome-triggering activated the janus kinase (JAK)-STAT3 as well as the MAPK pathway. Pre-existing zinc deficiency augmented the effect of IL-6-or IL-1-induced JAK-STAT3 signaling. When zinc deficient cells were reconstituted with zinc prior

FOI 26-3132 - Document 5

to stimulation, signaling was normalized [142]. STAT3 is phosphorylated by SHP1/2, known to be zinc-dependent PTP [156]. Zinc chloride increased transient STAT3 Tyr705 phosphorylation in murine hematopoietic stem cells, maintaining pluripotency and self-renewal of the stem cells, even replacing leukemia inhibitory factor (LIF), which is normally essential for this process. After zinc incubation, expression of pluripotency genes was increased and expression of differentiation-associated genes was inhibited. Zinc was able to prevent retinoic acid-induced differentiation, at least for a restricted time-frame [143].

Zinc deficiency caused B cell proliferation via increased STAT3 phosphorylation [145]. However, increased STAT3 phosphorylation was noted when murine embryonic stem cells were incubated with zinc chloride, suggesting that cell type specific effects exist [157]. In addition, the timing was different between the studies, which might help to explain the differences. In a very recent study, zinc was shown to alter STAT3 phosphorylation in neuronal cells via redox-mediated mechanisms. Interestingly, phosphorylation patterns of STAT3 residues were different when nuclear and cytoplasmic fractions were compared [155]. Whether this effect can be extrapolated from neuronal cells to immune cells remains to be tested. However, redox status and zinc metabolism are highly intertwined, so that a similar mechanism is highly likely. Finally, STAT3 was also suggested to be decisive for the switch from regular to demand-adapted emergency myelopoiesis during inflammatory diseases such as sepsis [158]. However, the association between disease-related serum hypozincemia, STAT3 activity and emergency differentiation needs to be proven.

Maturation and differentiation of T cells in the thymus is affected greatly by zinc availability. It has long been shown that the activity of thymulin, an essential factor for T cell development, is severely disturbed during zinc deficiency. This results in disturbed suppressor function, allogenic cytotoxicity and IL-2 production [159]. In addition, zinc deficiency seems to decrease the expression of anti-apoptotic factors such as B cell lymphoma (Bcl)-2 and Bcl-xL by T cells. In connection with the increased levels of pro-apoptotic factors detected in serum during zinc deficiency, this explains the severe reduction of T cell numbers [160]. Furthermore, zinc was shown to affect caspase activity. The cell cycle regulator p21 was cleaved by caspase 3 during zinc deficiency, activating cyclin-dependent kinase 2 (CDK2). Consequently, cells entered prematurely into S-phase and were subjected to apoptosis [92,161]. In addition to its intra-thymic activity, thymulin affects proliferation and activation of T cells in blood and tissue [162]. As zinc supplementation was able to restore thymulin activity in the thymus as well as in blood and tissue in humans and mice suffering from mild zinc deficiency, the reversibility of defects arising from zinc deficiency is probable and therapeutic zinc application should therefore be beneficial [163–165]. Interestingly, expression of MT-1 and calprotectin is increased in various cell types during differentiation. As both are important intracellular zinc binding proteins, this could increase the amount of zinc immediately available for signaling processes [80,166]. The latter might explain the manifold stronger reaction of mature cells to stimulation compared to immature cells, as the magnitude of the fast zinc signal is most probably much higher due to high MT levels.

5.4. Zinc, Smad Signaling and the Development of Regulatory T Cells

The natural importance and therapeutic benefits of regulatory T cells (Tregs) in preventing auto-immune diseases and transplant rejection is becoming more and more accepted [167]. One important trigger for Treg development is TGF-β-induced Smad 2/3 signaling, which induces expression of the transcription factor forkhead-box-protein p3 (FoxP3), which is essential for lineage commitment. Zinc supplementation augmented TGF-β-induced Smad 2/3 signaling and thereby FoxP3 expression [168]. Proteasomal degradation of FoxP3 involves the histone deacetylase Sirtuin-1 (Sirt1), which is inhibited by zinc as was shown for other histone deacetylases as well [72,169]. Another important, zinc dependent molecule in Treg cell development is interferon regulatory factor (IRF)-1, as it is able to repress FoxP3 activity [170]. Zinc supplementation dampened IRF-1 activity, increasing tolerance.

FOI 26-3132 - Document 5

In addition to its role in Treg development, zinc also affected Treg function. Here, CK2-mediated activation of ZIP7 was of central importance [171]. The transporter ZIP7 is located in the endoplasmic reticulum and responsible for the release of zinc into the cytosol. Phosphorylation of ZIP7 by casein kinase II (CK2) activated it, causing a zinc flux, which was suggested to cause activation of signaling pathways, resulting in cell proliferation and migration [171]. Thus, zinc was able to induce and stabilize Treg cells in this study, underlining its therapeutic importance.

Rice et al. investigated MT expression and efficiency of signal transduction in Type 1 regulatory T cells (Tr1), another recently described member of the family of Treg cells. Intracellular zinc and MT expression were increased during differentiation of naïve T cells into Tr1 cells after six days [172]. When IL-27 was also added, zinc increases and MT-1 expression was augmented. In addition, cells with higher MT levels more efficiently transduced a ROS signal into a zinc signal, as monitored via p38 MAPK signaling. MT overexpression was observed during chronic inflammatory diseases and cancer. The correlation of MT expression with efficiency of signal transductions might explain the high reactivity of cells during chronic zinc deficiency [172]. Whether this explains hyperinflammation, observed during sepsis-induced augmented serum hypozincemia, needs to be explored. Calprotectin is another zinc binding protein that is elevated during severe inflammatory disease and serum hypozincemia [63]. In contrast to MT, expression of calprotectin was recently shown to be induced by zinc deficiency, similarly to what has been described for pro-inflammatory cytokines [66,173].

5.5. PMA-Induced NET Formation in Granulocytes

A representative example illustrating nicely the importance of zinc in regulating cell signaling is the formation of NETs by granulocytes. ROS production in neutrophils via NADPH oxidase is an important prerequisite for NET formation. Both zinc deficiency as well as excess have been shown to inhibit superoxide anion production [174] and thereby the formation of NETs. When zinc was chelated in granulocytic cells, the PMA-induced increase in intracellular zinc was abolished, as well as NET formation [83], showing that the assumption of a tight zinc and redox metabolism interrelationship holds true for granulocytes and their functions. Whether other pathways are involved in NET induction remains to be investigated.

5.6. TLR4-Induced Signaling: A Great Example of Fine-Tuning of Signaling Pathways by Zinc

Triggering of TLR4 at the surface of myeloid cells by LPS or other ligands activates several signaling pathways as illustrated in Figure 2. This is a great example to illustrate how zinc flux and homeostatic zinc signals are able to fine tune cell signaling. This example also shows how long-term changes in extracellular zinc resulted in different effects to those from acute alterations.

LPS binding to TLR4 caused a zinc flux, which subsequently inhibited dephosphorylation of MAPK and supported phosphorylation of IKKα/β so that NFκB translocated into the nucleus and activated expression of pro-inflammatory cytokines [94]. When zinc signals were prevented using chelators such as TPEN (*N*,*N*,*N*′,*N*′-Tetrakis(2-pyridylmethyl)ethylenediamine), activation of kinases ERK1/2, IKKβ, MKK3/6 and IκB was abrogated, as shown for murine macrophages. Zinc chelation blocked the destruction of IRAK1 causing its accumulation in the cytosol. In contrast, IRAK1 phosphorylation and ubiquitination were not affected shortly after LPS-triggering. This might be due to the inhibition of zinc-dependent MMPs, which are probably responsible for IRAK1 destruction during adequate zinc conditions. IRAK1 is responsible for the degradation of NFκB inhibitors by IKK. Therefore, NFκB did not translocate to the nucleus. Furthermore, ERK signaling was disturbed when zinc was chelated, which might be associated to the effect of zinc on PTP and PTK activities as described earlier [175,176].

The MAPK and NFκB pathways described above are all induced by TLR4 ligation via myeloid differentiation marker (MyD)88. In addition, MyD88-independent/Toll-interleukin-1 receptor (TIR) domain-containing adaptor-inducing interferon (TRIF)-dependent pathways involving TRIF-related

FOI 26-3132 - Document 5

adaptor molecule (TRAM), TRIF and interferon regulatory factor (IRF)-3, are also activated. In contrast to pro-inflammatory mediators, activated via MAPK and NFκB, IFNβ expression is triggered here, which functions in an autocrine fashion and activates the JAK-STAT pathway as well as a delayed translocation of NFκB to the nucleus after binding to the IFNR on the cell surface. This upregulates CD40, CD80, and CD86 expression enabling the cell to interact with T cells [97,177].

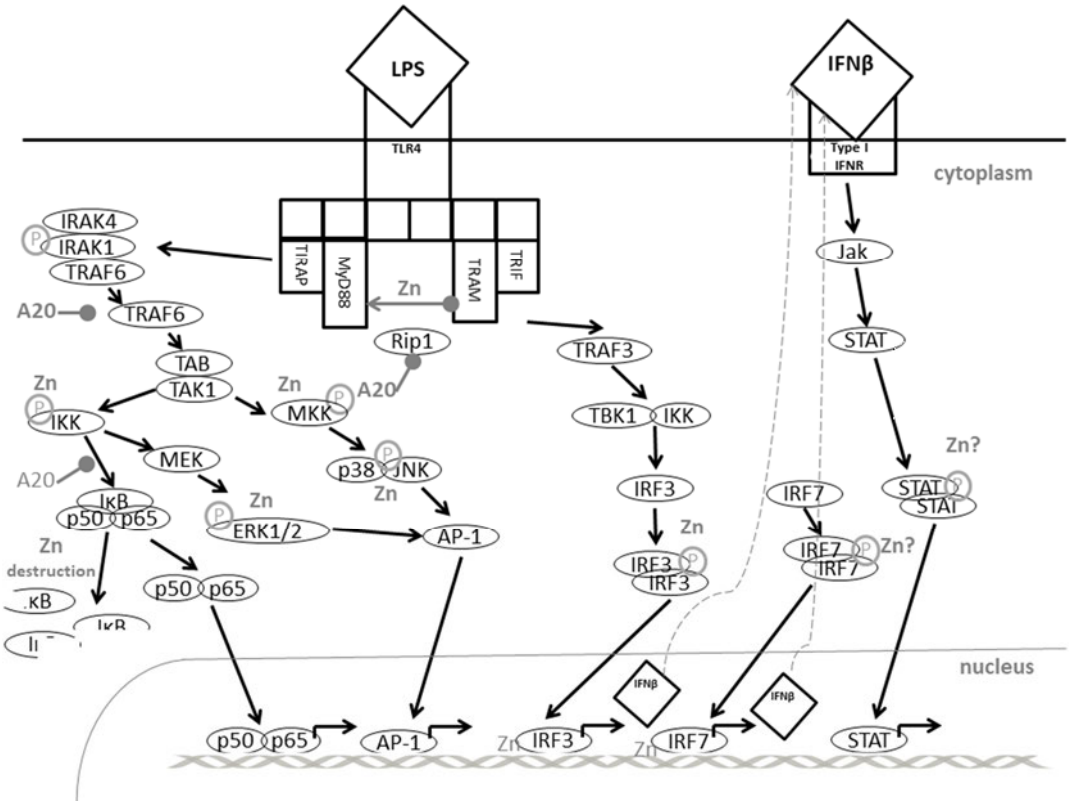

Figure 2. Zinc in Toll like receptor 4-induced signaling. For explanation, see text. Abbreviations: A20: zinc finger protein; AP-1: Activator protein 1; ERK: extracellular Signal-regulated Kinase; IFN: interferon; IRAK: Interleukin-1 receptor-associated kinase; IκB: Inhibitor of NFκB; IKK: IκB kinase; IRF: interferon related factor; JAK: JNK janus kinase; JNK: c-Jun *N*-terminal Kinase; LPS: Lipopolysaccharide; MAPK: mitogen activated protein kinases MEK: MAPK/Erk kinase; MKK: MAPK kinase; MKP: MAPK phosphatase; MyD88: Myeloid differentiation primary response gene; NFkB: nuclear factor (NF)κB; PI3K: phosphatidyl-inositol-3-phosphate; RIP: receptor interacting protein; STAT: Signal transducers and activators of transcription; TAB: TAK-binding protein; TAK: TGF β-activated kinase; TBK: Tank-binding kinase 1; TIRAP: toll-interleukin 1 receptor (TIR) domain containing adaptor protein; TLR: Toll like receptor; TRAF: TNF receptor-associated factor; TRAM: TRIF-related adaptor molecule; TRIF: Toll-interleukin-1 receptor (TIR) domain-containing adaptor-inducing interferon. Altered from [97,176,178].

Furthermore, the inducible nitric oxide synthases (iNOS) is induced via the JAK-STAT pathway, resulting in NO production to support the anti-microbial reaction. During zinc deficiency, murine macrophages were shown to produce more NO after LPS stimulation than controls. Zinc deficiency also augmented LPS-induced expression of IFNγ, CD80 and CD86 in murine macrophages either bone marrow-derived, or from cell culture, while expression of IL-1β, IL-6 and IL-10 was decreased. All effects were normalized when zinc deficient cells were reconstituted with zinc prior to stimulation. Here, analyses were performed a few hours after LPS stimulation, representing homeostatic zinc signals. As incubation of cells with a zinc chelator after LPS-stimulation still had the

FOI 26-3132 - Document 5

same effects, one can conclude that effects on MyD88-independent pathways are not associated with the zinc flux, but rather by the homeostatic zinc signal [97].

The delayed favoring of the MyD88-independent pathways is paralleled by inhibition of parts of the MyD88-dependent pathways as well. Here, ubiquitinated TRAF6 activates IKK and MKK via the kinase TAK1. However, as mentioned earlier, ubiquitin residues are removed from TRAF6 by A20, highly expressed due to the homeostatic zinc signal, resulting in suppression of gene expression [148,179,180]. In addition to zinc, pro-inflammatory cytokines are known inducers for A20 in macrophages, possibly representing a feedback-mechanism to prevent hyperinflammatory reactions [181]. This fits well with the deregulated inflammatory response seen during chronic and severe serum hypozincemia, as observed during sepsis [63,65]. Finally, a role of zinc in TLR4-triggered signaling via zinc's effect on cyclic nucleotides was suggested. In this connection, elevated cGMP could be responsible for increased Raf-1 phosphorylation, which inactivates this MAPK and also prevents NFκB activation and translocation. Signaling induced via other TLR might be regulated in a similar manner. Zinc-dependent regulation of TRIF/IRF/IFNβ signaling was observed as well when cells were stimulated with TLR3- or TLR7-specific agents [97].

Recently, a first approach to analyzing the zinc-dependents of the proteome was published. Here, macrophages were incubated with either zinc oxide nanoparticles or zinc acetate in equivalent doses. After at least one day, the proteome of the cells was analyzed using a 2D gel electrophoresis technique. The amount of several signaling molecules was altered by zinc incubation. Most interestingly, MyD88 protein levels were altered due to incubation with the nanoparticles or the zinc acetate [182]. Unfortunately, there is so far no information as to whether this is due to increased expression or decreased degradation of the protein and tests of MyD88 function were also not included, thus more analyses are needed. However, the results of this study suggest new targets that are probably affected by zinc signals and cellular zinc homeostasis.

Altogether, this is not only a great example of fine-tuning of signaling by zinc but also underlines the complexity of zinc's role in intracellular signal transduction.

5.7. Zinc Levels Regulate Fc Receptor-Induced Signaling

Instead of recognizing PAMPs, some immune cells are equipped with receptors for immunoglobulins (Ig) to detect immune complexes or opsonized pathogens. One example is the Fcε receptor (FcεR) on mast cells, whereby ligand binding causes degranulation and thereby the release of anti-microbial agents. Those granules are also known to contain high amounts of zinc, released during degranulation, probably causing zinc intoxication of pathogens in close proximity to the immune cell. The role of zinc in mast cells and their signaling has been poorly investigated, but some data indicate that triggering the FcεR causes a zinc wave via release of zinc from the perinuclear area, such as from the endoplasmic reticulum (ER) [96,183]. Thereby, PKC was transported to the plasma membrane, ERK1/2 and JNK1/2 were phosphorylated and NFκB was activated and translocated to the nucleus, inducing expression of pro-inflammatory cytokines [96,184]. When the zinc wave was prevented by incubation of the cells with TPEN, signaling and gene induction were blocked. In line with this, signaling was prolonged when zinc was added to the cells. In addition, zinc seems to be important for fusion of the granules with the plasma membrane, thus enabling degranulation [184]. Zinc chelation inhibited degranulation. Within these studies, two pools of zinc were identified by using different zinc probes: the larger pool of granular zinc and the smaller, variable pool of cytoplasmic zinc. This emphasizes that individual probes can vary in their intracellular location, also depending on the cell type and its activation state [71,185,186].

5.8. Killing Activity of NK Cells Varies with Zinc Availability

NK cells are able to destroy transformed or infected cells, largely due to recognition of changes in major histocompatibility complex MHC-I composition that are caused by the degeneration or the pathogen. In contrast, regular cells are protected from killing by NK cells as long as they carry

FOI 26-3132 - Document 5

surface MHC-I, which is bound by the killer cell inhibitory receptor (KIR) on NK cells [187]. To form the so-called NK cell synapse, KIR multimerization is essential, and was shown to be zinc-dependent [87,89]. Unfortunately, there are no data on complex formation during zinc deficiency, but a disturbance in zinc homeostasis would explain why killing is reduced if zinc supply is limited and increased if additional zinc is supplied [88]. Some recent data suggest a zinc signal after NK cell activation with IL-1β [188]. IL-1R signaling is known to be affected by zinc as will be described later. Because NK cells carry a variety of surface receptors containing tyrosine phosphorylation sites, including immunoreceptor tyrosine-based inhibitory motif (ITIM) and immunoreceptor tyrosine-based activation motif (ITAM), a role for zinc in signal transduction is likely, and this possibility should be tested.

5.9. The Role of Zinc in IL-2-Induced Signaling in T Cells

When IL-2 binds to its receptor, signal transduction via Jak1 and Jak3 is initiated and the adaptor Shc is recruited. Oligomerization of the receptor is essential for its function, thus the IL-2R subunits are found in lipid rafts. Subsequent to IL-2 stimulation, three different pathways can be activated, centering around PI3K/Akt, STAT5 and MEK1/2-ERK1/2. IL-2 is known to induce proliferation and development of effector functions in T cells, inducing anti-apoptotic and cell-cycle related genes as well as certain cytokines and lineage decisive factors [189].

Similar to the effects of other growth-promoting factors, binding of IL-2 to its receptor induces a zinc flux. Here, zinc is released from lysosomes and zincosomes, which was linked to ERK1/2 and Akt activation, but did not affect STAT5. In this context, Phosphatase and tensin homologue deleted on chromosome 10 (PTEN) is of importance, as it degrades PI3K-produced PI(3, 4, 5)P3, which subsequently activates Akt. The zinc IC_{50} of PTEN was found to be 0.59 nM, which would allow its blockade by zinc flux, explaining activation of Akt [71,135].

5.10. Zinc in T Cell Receptor Signaling

The major function of the T cell receptor (TCR) is the specific recognition of a certain antigen, presented by an MHC molecule. As the TCR lacks intrinsic kinase activity, the CD3-complex, responsible for signal transduction, needs to be recruited and non-covalently bound to form the functional receptor. PTKs, involved in the subsequent highly organized signaling cascade include members from Src, Syk, Csk (C-terminal Src kinase) and Tec families. In addition, certain adapter proteins and effector enzymes are involved, as illustrated in Figure 3. Activation of the signaling molecules via phosphorylation by PTKs can be rapidly reversed, as PTPs have a higher capacity than the PTKs. Genes expressed after TCR triggering are dependent upon the stimulus and co-stimuli characteristic of a certain T cell subsets, causing proliferation and differentiation [109].

The importance of zinc as an ionic signaling molecule after TCR triggering has been investigated in various studies. A zinc flux was measured within less than one minute after ligand binding to the TCR. As silencing of ZIP6, located in the plasma membrane, prevented this fast zinc signal, the origin of the zinc seems to be extracellular [190]. When extracellular zinc was depleted from the media, no fast zinc signal occurred after TCR triggering, supporting this hypothesis. Subsequent to its fast increase, zinc is compartmentalized into a subsynaptic region, which is quite different from the calcium wave, which originates from intracellular stores and spreads rapidly throughout the cell [191]. However, in addition to extracellular zinc, the fast zinc signal might also be caused by ZIP8-mediated release of zinc from lysosomes, recruited to the TCR complex after stimulation [101]. In response to certain environmental conditions, basal expression of MTs was increased. This rendered more releasable zinc available for subsequent stimulation. Consequently, lower levels of MTs observed during prolonged zinc deficiency could explain the lower response of T cells to antigen, as less zinc for a zinc flux would be immediately available.

FOI 26-3132 - Document 5

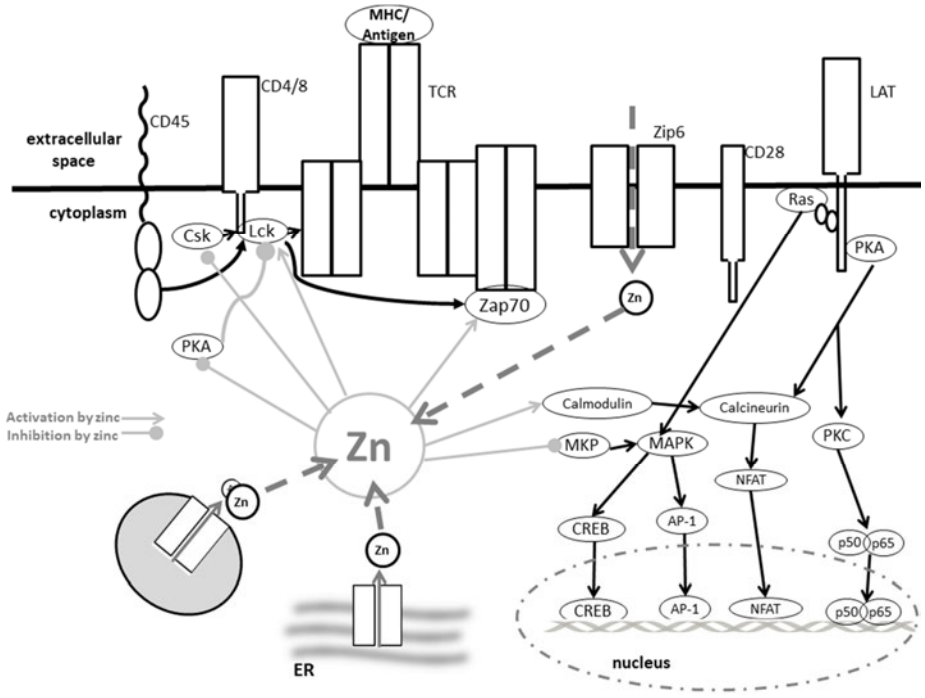

Figure 3. Zinc in TCR-induced signaling. For explanation, see text. Abbreviations: AP-1: Activator protein 1; CREB: cAMP response element-binding protein; Csk: C-terminal Src kinase; ER: endoplasmic reticulum; Lck: lymphocyte-specific protein tyrosine kinase; LAT: linker for activation of T cells; MAPK: mitogen activated protein kinases; MHC: major histocompatibility complex; MKP: MAP kinase phosphatase; NFAT: Nuclear factor of activated T cells; p50/p56: nuclear factor NF-kappa-B subunit p50/p65; PKA: protein kinase A; PKC: protein kinase C; Ras: Rat sarcoma; TCR: T cell receptor; ZAP: z-chain-associated protein kinase; Zip: Zrt-like, Irt-like proteins. Modified after [109,170].

Targets of this zinc flux have been found within several stages of signal transduction after receptor triggering. As has been described above, the TCR alone is not able to activate a signaling cascade. Therefore, CD4 brings the Src kinase Lck (lymphocyte-specific protein tyrosine kinase) into proximity with the TCR, thus enabling tyrosine phosphorylation of signaling molecules, including ZAP70 and CD3ζ. Zinc facilitated the binding of Lck to CD4, as it did to CD8, wherefore it is of central importance for complex assembly and the initiation of the signaling process [192].

Not only recruitment, but also activity of Lck, were affected by zinc, as it enabled Lck homodimerization by stabilizing the SH3 domain [193]. Lck activity can additionally be inhibited by phosphorylation of tyrosine Y505, regulated by the PTP CD45 and the kinase Csk [194], or activated by phosphorylation of Y394, which is dephosphorylated by PTPN22. A direct effect of zinc on the activity of phosphatases and kinases was described [195]. Zinc supplementation of T cell lysates did indeed result in dose-dependent decrease of total phosphatase activity [71]. In support of this, Csk is inhibited by zinc [196], as probably is PTPN22. Moreover, recruitment of PTPN22 is regulated by Csk [102]. A direct effect of zinc on CD45 activity has been found in vitro, when zinc was supplemented in high doses, and this remains to be investigated in more detail [103]. As Lck is responsible for the phosphorylation of ZAP70, which then further activates signaling molecules such as MAPK, abrogation of the initial zinc flux can have far reaching consequences [71,197,198].

Further downstream, zinc might also affect transcription factor binding. One important target is NFAT, responsible for IL-2 expression, but retained in the cytoplasm of resting T cells due to constitutive phosphorylation. After TCR triggering, it is dephosphorylated by CN, serine/threonine phosphatase [199]. As physiological concentrations of zinc between 10 nM and 10 µM were able to

FOI 26-3132 - Document 5

inhibit CN activity, NFAT translocation might also be affected by the zinc flux. However, no direct evidence is available and, as the zinc signal seems to stay local, i.e., close to the receptor, this needs to be further investigated. In addition, regulation of CN activity is rather complex. CN itself is constitutively inactivated by phosphorylation. Here, phosphatidyl-inositol-3-kinase (PI3K) is responsible. PI3K activity is also zinc sensitive. Zinc supported enzymatic activity via effects on Akt and PTEN explored in detail for IL-2-induced pathways [135]. If effects are similar for TCR-induced signaling, needs to be explored.

In this regard, consequences of homeostatic zinc signals will be described, as they also affect CN activity. TCR triggering causes upregulation of ZIP8 expression. Therefore, zinc is released from the lysosomes causing an increase in intracellular zinc, when the zinc flux has probably already vanished. This homeostatic zinc signal has been connected to a blockade of CN activity which results is transcription of IFNγ [101]. Another consequence of the homeostatic zinc signal is augmented PKC activity due to facilitated binding of phorbol esters and higher affinity to cytoskeleton and plasma membrane [119]. As a final note on the importance of zinc for TCR-triggered T cell response, the activation threshold for stimulation was lowered when additional zinc was supplemented to the cells. Thus, even suboptimal antigen conditions caused T cell proliferation [102], which might be interesting for optimizing vaccination. As a note, calcium influx was unaltered, when zinc conditions were changed.

When T cells are activated, MT expression increases, which was associated to decreased intracellular zinc and ROS levels and a sustained proliferation of the T cells [101]. Thus, also for TCR-induced signaling, effects of zinc further downstream are likely. As the zinc flux increased MT expression in the T cells, not only immediate signaling pathways were affected, but T cell proliferation and survival were supported in the long term [200]. In addition, TCR ligation was also followed by ROS generation, known to provide zinc from protein for signaling regulation [201]. Triggering of TCR led not only to increased activity, but also to an increased expression of ZIP6 [202]. The influx of extracellular zinc inhibited the recruitment of SHP-1. As SHP-1 is a negative regulator of TCR-signaling, this might function as a feedback mechanism to end TCR-mediated signaling [102]. The lower recruitment of SHP-1 might either be due to changes in its conformation or the serine phosphorylation of Lck, which prevents SHP-1 binding.

5.11. The Role of Zinc in IL-1 Receptor Signaling in T Cells

IL-2 functions as a majorly proliferative agent for T cells, whereas other cytokines, such as IL-1 also induce the expression of inflammation-related genes such as IFN-γ, in addition to supporting proliferation. After IL-1R triggering, IL-1 receptor-associated kinase (IRAK) is activated, causing NFκB translocation to the nucleus, culminating in gene activation. Here, zinc supplementation of T cells was shown to decrease IRAK activity, similarly to its decreasing TLR4-induced signaling pathways, resulting in repression of the memory Th17 response [97,203]. It has been reported that IL-1 binding causes a zinc signal [204]. MyD88 is another central signaling molecule of IL-1-induced signaling, and a role for zinc in this pathway has been described [97]. Effects have not been explored for the IL-1R, yet.

The last paragraphs underline the complexity of zinc's effect on T cell development, lineage decision and activity. As effects were described for each pathway individually, this is an oversimplification of the in vivo situation. In addition, effects of for example zinc supplementation and zinc deficiency on the outcome of the investigated T cells will also depend on other environmental factors and the cellular environment, rendering prediction of an overall effect impossible.

5.12. The Role of Zinc Signaling in B Cells

When B cells are mentioned, antigen recognition and antibody production come to mind. Antigen recognition, and thereby choice and activation of a certain B cell clone, is mediated via the B cell receptor (BCR). BCR activates almost the identical intracellular pathways to TCR. These pathways focus, amongst others, on the same kinases (PKC, MAPK) and transcription factors (NFAT, NFκB) [108].

FOI 26-3132 - Document 5

Surprisingly, the correlation between zinc status and the proliferation and overall functions of B cells was much weaker than for T cells, as was shown by investigations in mice [205,206]. A considerable difference was found between the effects of acute and chronic zinc deficiency: While acute zinc deficiency caused a reduction in overall B cell numbers, this was far less pronounced during chronic zinc deficiency [207]. Recently, the regulation of ZIP10 expression by STAT3 and STAT5 was revealed and associated with suppression of apoptosis in human B cell lymphoma, suggesting some effects of homeostatic zinc signals on the development and survival of B cells.

Generally, binding of antigen alone is not sufficient to activate the complete maturation of a B cell into an antibody-producing plasma cell. Recent studies indicate that ligation of the B cell-activating factor receptor (BAFFR), TLRs and CD40, synergize with the BCR to define the repertoire of the mature B cell [208]. Additionally, co-stimulation by T cells is required. As T cell numbers and activation are strongly compromised during zinc deficiency, zinc was first suggested to play an indirect role. This was in line with the observation that especially T cell-dependent antibody production was affected [209]. However, antibody production per cell was largely constant under zinc deficient conditions [210]. To circumscribe effects due to alteration of T cell numbers and functions, Hojyo et al., in an elegant study, blocked the zinc signal in B cells, while not affecting the T cell compartment [211]. The group identified ZIP10 as being responsible for zinc signals in antigen-presenting cells, including B cells. To specifically knock out ZIP10 in antigen-presenting cells (APC), the ZIP10 gene was conditionally ablated by being put under the control of the invariant chain promotor. The invariant chain gene is constitutively activated in APC, but not in other cells including T cells. Interestingly, BCR-induced signaling was severely disturbed in cells from ZIP10 knockout mice and production of specific immunoglobulin (Ig)M and IgG was strongly decreased, which suggest that zinc indeed plays an important role in BCR-induced signaling. Interaction with T cells usually induces the germinal center (GC) reaction necessary for Ig class switch in B cells. Formation of GC B cells was also reduced in cells from ZIP10 knockout mice. BCR-crosslinking-induced proliferation was diminished, although hyperactivation of ERK, AKT and NFκB was observed and activity of SYK and LYN was increased. Only CD45 activity was less than half in cells from ZIP10 knockout mice compared to ZIP10 expressing controls [211]. In general, those observations are in line with what has been observed in zinc-deficient animals, suggesting that not only indirect effects via the disturbed T cell compartment are responsible for the defect in B cell response. Of note is that TLR-induced signaling was not affected by ZIP10 knockout. As the origin of zinc for TLR-triggered zinc signals is largely protein and organelle-based, this is also in line with previous findings [94,98,212].

In addition to BCR-induced signaling, pathways in B cells affected by zinc included those centered on STAT3 and STAT6, activated for example by IL-6 or IL4, respectively. Here, in vitro studies revealed that IL-4-induced STAT6 and IL-6-induced STAT3 phosphorylation were decreased during zinc deficiency [145]. As the IL-4-induced pathway is essential for the immunoglobulin class switch to IgE, this might explain why susceptibility towards especially parasite infections is increased under low zinc conditions [145]. IL-6 is essential for the induction of terminal B cell development into plasma cells [213], providing an additional reason for the decrease in antibodies during zinc deficiency. On the other hand, IL-6 is known to induce the production of autoantibodies if plasma levels are highly elevated. Thus, the association of IL-6, STAT3 phosphorylation, and (auto-) antibody production needs to be investigated more closely.

Furthermore, zinc deficiency was shown to increase apoptosis in B cells during early developmental stages, similar to what was described for T cells [214]. Fewer naïve B cells were found during zinc deficiency, while numbers for precursor B cells and cycling pro-B cells were not largely affected. While the response to known antigens was still efficient, reaction to neoantigens by B cells declined during zinc deficiency. This might be one reason for the decreased efficiency of vaccination in the elderly, who are known to be at least marginally zinc deficient in most cases [215,216]. Along with this, zinc uptake into cells through the zinc transporter ZIP10 was essential for early B cell development, increasing cell survival [217]. Others found that the effect of zinc on apoptosis via

FOI 26-3132 - Document 5

caspase activity depends on the dosage: treatment of Burkitt Lymphoma cells with up to 50 μM of zinc inhibited caspase 3 activation and apoptosis, whereas higher concentrations up to 100 μM rather induced programmed cell death via caspase 3 [218].

Homeostatic zinc signals affected various stages in apoptotic signaling cascades, including production and activity of members of the Bcl/Bax family [214]. In addition, DNA fragmentation was decreased when sufficient zinc was available, as the endonuclease responsible for this process is calcium dependent but inhibited by zinc. Furthermore, caspases 3, 6 and 8 were inhibited by zinc in a dose-dependent manner. IC_{50} for caspase 3 was for example 10 nM zinc, which is within the physiological intracellular range [137,219]. These three caspases are known mediators within the apoptotic pathway [220].

6. Zinc and Transcription Factors

In the early 1980s, zinc binding sites were found in *Xenopus laevis* transcription factor IIIA (TFIIIA) 24. This discovery offered new approaches to discover structural zinc binding sites in other species similar to those uncovered in *Xenopus laevis*. Thus, for the first time the typical zinc-finger structure was defined in TFIIIA and consisted of nine repetitive sequences containing cysteine (C) and histidine (H) residues. Since then, the discovery of zinc-binding sites dramatically increased within a short period, based on homology searches in sequence databases for the characteristic ligands in TFIIIA. Today, nearly 3000 proteins with zinc-binding motifs have been identified by bioinformatic approaches, making up ~10% of the proteins encoded within the human genome potentially regulated by zinc [43].

Regarding the human immune system, the innate and adaptive immune system are both regulated by zinc-finger-bearing transcription factors. Hence, a direct as well as an indirect role of zinc in altering intracellular signaling can be anticipated. During the development of innate immune cells, essential transcription factors such as GATA-4/-5/-6 and KLF-4/-5 are potentially zinc-regulated targets since they contain a zinc-finger domain [221,222]. Moreover, the promyelocytic leukemia zinc-finger is a critical transcription factor for iNKT cell development. In myelopoiesis, expression of the transcription factor PU.1 is decisive for lineage commitment [223]. With respect to the adaptive immune system, a multitude of zinc-finger-containing transcription factors have been identified. In T cell development, various transcription factors are important for the adequate differentiation into $CD4^+$ T cells, such as the zinc-finger transcription factors GATA-3 and Zbtb7b (Thpok, cKrox) [224,225]. Moreover, GATA-3 is essential for Th1 and Th2 subpopulation differentiation [226,227]. Generally, the zinc-finger-containing KLF family has an important function in immune cell differentiation, for example KLF-2/-3 in B cells, KLF-2/-13 in NKT cells, and KLF-2/-4/-10 in T cells [228]. Consequently, it is not surprising that Treg differentiation is driven, amongst other things, by zinc-dependent KLF-10 modulation [170].

Concerning the overall regulation of zinc homeostasis, numerous genes exhibiting metal response elements in their promotors are involved. These can be induced by binding of the metal-response element-binding transcription factor (MTF)-1 that itself is regulated by the surrounding available free zinc concentration. Thus, MTF-1 acts as an intracellular zinc sensor, leading to the suggestion that feedback mechanisms may exist [229]. The field of zinc-regulated transcription factors is still under investigation and offers great opportunities for further research to better understand modulation of the immune function due to zinc supplementation or zinc deficiency, respectively. Regulation of transcription factors by zinc homeostasis is a good example of how a single element such as zinc can balance the immune response and therefore acts as a "gatekeeper".

7. Zinc, Epigenetics, and Immunity

Over 75 years ago, Waddington chose the term "epigenetics" to describe changes to DNA other than in its sequence that were able to alter gene expression [230]. Those non-DNA-encoded changes include mainly DNA methylation (methylation of cytosine bases) and modification of histone tails by adding chemical groups such as one or more acetyl, methyl, or sumoyl residues. Alterations cause

FOI 26-3132 - Document 5

nucleosome re-positioning and expose or block binding sites for transcription factors or suppressors, thereby promoting or inhibiting the expression of adjacent genes [231]. Non-coding RNAs and transcription factor regulatory networks also count as epigenetic mechanisms. During recent years, the field of nutritional epigenetics emerged, covering the effects, amongst others, of nutritional elements such as zinc, but also barium, calcium, chromium, manganese, magnesium, iron, selenium, sodium, molybdenum, phosphorus, potassium and sulfur on the epigenome [232,233].

The finding that the establishment of the epigenome starts as early as during oocyte development, clearly underlines the importance of a well-balanced nutritional and mineral supply during pregnancy and breast-feeding. Zinc supply influences health and development from early in life, into old age [234]. In addition, lifestyle-dependent changes in the epigenome can occur throughout life. Dysregulations within the epigenome have been observed to accumulate in the elderly [235]. Epigenetic changes can even be carried over to the next generation, as has been shown by experiments with rats [236]. Various environmental factors, including: (1) individual characteristics such as age, gender and genetic predisposition; (2) lifestyle-related factors including the amount of exercise, smoking, and stress; and (3) nutrient-related factors such as dose, route, duration of the exposure as well as the presence and variety of elements, affect the epigenome and are summed up as "interactome". However, the interactome is difficult to estimate, as already drinking water and soil might contain different amounts of each trace element depending on the region [233]. Dysplasia and disease originating from all developmental stages, including diabetes, multiple sclerosis and other mainly auto-immune and neurological diseases have so far been connected to epigenetic abnormalities, caused by nutritional dysbalance, as will be exemplified later regarding zinc [233,237,238].

As indicated earlier, zinc is an important co-factor for enzymes from all classes of enzymes. This includes epigenetically-active enzymes such as class I, II, and IV histone deacetylases (HDACs) [239] and acetylases (HATs), DNA methyltransferases (DNMTs), histone methylases and methyl-binding proteins. Zinc deficiency has been associated with global DNA hypermethylation [240]. One explanation is the effect of zinc on activity of methionine synthase. This enzyme is responsible for the regeneration of methionine from homocysteine, providing substrates for DNA and histone methylation [241].

Disturbance of bone development during zinc deficiency has been shown to be epigenetically determined. Indirect effects of zinc on the epigenome include the multi-zinc-finger enzyme Trps1, named after the "Tricho-Rhino-Phalangeal syndrome", where it is deregulated. During mitosis Trps1 regulates histone deacetylation in a zinc-dependent manner. In addition, it increases the activity of HDAC1 and HDAC2, leading to histone H3 hyperacetylation if *Trps1* is non-functional. As a consequence, prometaphase cells accumulate due to impaired HP1 binding and chromatin condensation in Trps1-deficient chondrocytes [242]. Trps1 might be involved in regulation of mitosis in T cells, which needs to be explored in more detail and would offer another explanation for the dependents of hematopoiesis on zinc homeostasis.

As is true for most trace elements, zinc deficiency during pregnancy was associated with abnormalities in development of the embryo and poor health of the newborns, amongst others due to disturbances in immune cell development [243,244]. Here, various studies revealed that effect on development depends on the stage at which zinc deficiency was present. Regular development of the oocytes was paralleled by increasing methylation of their chromatin. Moreover, zinc was required to complete meiosis, as was shown for oocyte development in vitro and in vivo [236]. If the oocyte was zinc deficient after fertilization, meiosis failed due to disorganized chromatin, which should also be investigated in immune cell development. Various pathologies, such as chronic inflammatory diseases that appear later in life, have been associated with zinc deficiency during pregnancy. In addition to hypertension, autism and impaired learning, persistent immunodeficiency was observed for three subsequent generations in rats [245–248]. Interestingly, the regulation of genes, involved in zinc homeostasis was also affected by epigenetic mechanisms. Zinc-dependent epigenetic changes in the MT-2 gene in utero caused significantly higher MT-2 expression in the liver later in life as

FOI 26-3132 - Document 5

observed in mice [249]. Similarly, not only the function, but also the expression of zinc-finger proteins, including ZNF804A and ZNF326, was affected by the zinc status via epigenetic mechanisms [250,251]. As found during investigations in autistic patients, zinc deficiency during pregnancy caused epigenetic abnormalities in genes encoding MTF1, ZnT5, COMMD1 (COMM domain-containing protein 1), ERK1, TrkB (tyrosine-related kinase B), and ProSAP/Shank (proline-rich synapse-associated protein/SH3 and multiple ankyrin repeat domains) [252–255]. As those are important players regulating immune cell development and function, investigations on similar effects in immune cells are warranted.

Chronic inflammation, but increased susceptibility to infections are a typical symptom of aging. Amongst others, the accumulation of unusual epigenetic changes during aging was suggested to be responsible for altered activation of immune cells, causing those symptoms. Basal expression of inflammatory mediators such as IL-1β, IL-6 and TNFα was increased in vitro, largely due to changes in chromatin structure of the corresponding genes [66,185]. As the expression of zinc transporters was also altered via epigenetic modifications, this creates a self-reinforcing positive feed-back loop [256,257]. In particular, ZnT5, ZnT1, and ZIP6 expression was affected, causing a decline of zinc in the elderly [241]. The reversibility of epigenetic changes if zinc is supplemented needs to be explored.

8. Zinc Deficiency in the Context of Disease

Zinc status is strictly regulated by the zinc transporting proteins ZIP and ZnT. Malfunction of either ZIP or ZnT causes tremendous immunological impairment. Altered zinc homeostasis in the context of clinical manifestation of disease is summarized in Figure 4.

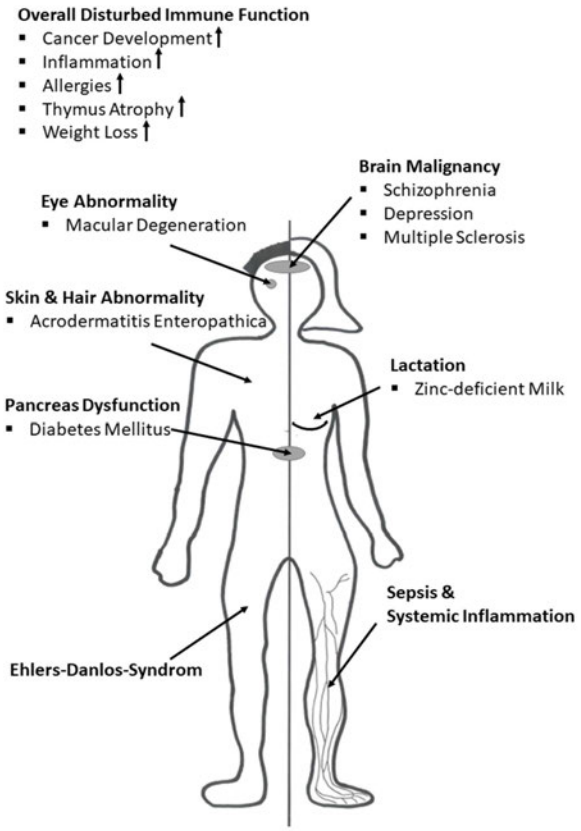

Figure 4. Influence of zinc and zinc deficiency on various organ systems as well as on the immune system. Zinc deficiency is causally associated with multiple immunological dysfunctions that lead to the manifestation of various diseases indicated in this figure. For a detailed explanation see the text. Modified after [5]. ↑ = upregulted/enhanced.

FOI 26-3132 - Document 5

8.1. Zinc and Acrodermatitis Enteropathica

Disruption of the ZIP4 gene was reported to impair early embryonic development in mice. This was due to malfunction of appropriate zinc transport into the developing embryo via the visceral yolk sac and to insufficient zinc uptake in the intestine, resulting in severe zinc deficiency. Similar effects of a non-functioning ZIP4 transporter and subsequent zinc deficiency were observed in humans suffering from Acrodermatitis Enteropathica (AE), as discussed above [47,258]. Patients suffering from AE showed several immunological alterations, such as thymus atrophy as well as decreased lymphocyte counts and lymphocyte function. This was not surprising, since the function of virtually all immune cells strictly depends on zinc homeostasis. Especially T cell function and maturation are highly zinc dependent, as described later in detail. Hence, AE patients have an increased susceptibility to infection, especially intercurrent bacterial, fungal, and other opportunistic infections are prevalent. Moreover, chronic diarrhea and lactose intolerance are also known, and without therapy AE is in general lethal. However, dietary zinc supplementation reversed the symptoms in both mice and humans [17,47,259]. T cell restricted malfunctions as well as abnormal chemotaxis were completely corrected by zinc supplementation.

8.2. Zinc in Cancer Development

The zinc transporter ZIP4 was shown to have an important role in cancer development. Microarray analysis identified steady state levels of ZIP4 mRNA to be highly upregulated in pancreatic cancer [260]. Biopsy analysis uncovered elevated ZIP4 mRNA expression in tumor samples as well as overaccumulation of ZIP4 protein [261]. Cell culture analysis determined that ZIP4 overexpression in human pancreatic cells increased zinc accumulation and cell proliferation respectively showing a connection between zinc status and cancer progression. Comparable results were obtained in experiments with mice. ZIP4 overexpression increased tumor weight as well as pathological fluid accumulation (ascites incidence). Additionally, increased zinc accumulation was apparent, as was a higher rate of cellular proliferation [262]. Knockdown of ZIP4 gene expression by siRNA inhibited tumor growth significantly and increased the survival rate of the mice [263]. Interestingly, increased ZIP4 expression was additionally found in hepatocellular carcinomas [264], emphasizing a potential role for ZIP4 in tumor development in general. At the molecular level, it was supposed that zinc transport via ZIP4 influenced cAMP response element-binding protein (CREB) activity, controlling numerous factors important in cellular proliferation [263,265,266]. Moreover, ZIP4 probably suppresses apoptosis and increases in vitro tumor cell migration [264].

In regard to breast cancer, the zinc transporters ZIP6, ZIP7 and ZIP10 were shown to be mainly involved in growth and invasive behavior. ZIP6, a member of the LIV-1 subfamily of ZIP proteins, was found to be estrogen-responsive and can therefore be used as biomarker for estrogen-receptor-positive cancers [267,268]. Additionally, luminal A-type breast cancer can be identified by ZIP6 expression [137]. Besides ZIP6, ZIP7 were highly abundant in breast cancer and were required for increasing the intracellular free zinc level [269,270]. ZIP10 expression was associated with breast cancer metastasis in lymph nodes and was strongly linked to invasive behavior [271]. Thus, ZIP6, ZIP7, and ZIP10 expression contributed to cancer cell survival and cancer progression [272,273]. At the molecular level, E-cadherin expression was modulated by ZIP6 as well as epidermal growth factor receptor (EGFR), Src, and insulin-like growth factor 1 receptor (IGF-1R) signaling molecules by ZIP7. Hence, cancer growth and invasive behavior is supported [274]. More recently, studies indicated a direct connection of phosphorylation of ZIP7 to be important for zinc efflux from intracellular zinc stores into the cytosol, leading to an elevated cytoplasmic free zinc level [98,275]. Consequently, signaling pathways such as mitogen-activated protein kinase (MAPK) signaling and tyrosine kinase activity were altered, leading to modulation of kinases and promoting aggressive breast cancer behavior. Amongst others, GFR, Src and IGF-1R signaling molecules were affected by zinc [269,276,277]. Cancer cells were highly apoptosis resistant due to an elevated intracellular zinc level, since caspase activity was found to be zinc-regulated [214]. Thus, killing of

FOI 26-3132 - Document 5

cancer cells by NK cells and cytotoxic T lymphocytes (CTL), respectively, was compromised. Moreover, a zinc-rich milieu induced Treg, impairing the anti-tumor response by inducing tolerance. Treg secreted high amounts of anti-inflammatory cytokines such as IL-10 and transforming growth factor (TGF)-β1 [278], constraining immunological anti-tumor defense.

8.3. Zinc and Schizophrenia

It was reported recently that nonsynonymous variants in both ZIP8 [279] and ZIP12 expression [280] were associated with schizophrenia. The brains of patients suffering from schizophrenia showed lower zinc concentration than healthy controls [281]. In general, ZIP12 has a conserved function in vertebrate nervous systems, being responsible for proper development. A correlation between a homozygous missense mutation in the *ZIP12* gene and the frequency of schizophrenia was detected and claimed as a possible explanation [37,282]. Altered expression of ZIP12 was linked to congenital malformations caused by zinc deficiency [280]. Since T cell maturation, proliferation, differentiation, and function are highly zinc-dependent, and zinc deficiency impairs Th cell function [45,71,72,283,284], schizophrenia might be triggered due to malfunction of Th differentiation and function.

8.4. Zinc and Depression

Depression is a psychiatric disorder associated with high morbidity and mortality, being the cause of about 50–70% of all suicides [285]. The World Health Organization has predicted that depression will be the second leading contributor to the global burden of disease by 2020 [286]. Common symptoms for depression are sadness, exhaustion, and lack of interest in the daily activities of living [287].

In patients suffering from depression, increased pro-inflammatory cytokine concentrations, such as IL-1β, IL-6, and IFNγ, were found [288]. Furthermore, serum hypozincemia was observed, which was normalized by effective anti-depressant treatment. Interestingly, high amounts of zinc are present in the brain, particularly in the hippocampus and cerebral cortex [26,289]. It was shown that zinc deficiency negatively influenced brain zinc homeostasis and resulted in impaired mental function, altered behavior, learning, and susceptibility to epileptic convulsions [287,290]. Interestingly, zinc administration exhibited antidepressant-like effects when tested for antidepressant activity. Zinc administration produced antidepressant-like effects in the "forced swim test", in both mice and rats, and in the tail suspension test [287]. During anti-depressant therapy in humans, Treg cells were induced while IL-1β level decreased concurrently [291]. Zinc administration induced Treg cells [72,170], leading to a dampened pro-inflammatory immune reaction. Thus, zinc deficiency can favor the development of depression, whereas zinc administration can exhibit antidepressant-like activity.

8.5. Zinc and Multiple Sclerosis

Worldwide there are about two million patients diagnosed with Multiple Sclerosis (MS), making it the most common chronic-inflammatory disease of the central nervous system (CNS) [22]. MS is characterized by: (1) inflammation of the CNS; (2) destruction of the myelin sheath, which surrounds the neuronal axon and forms an electrically insulating layer that is essential for proper signal transmission and thus for the function of the nervous system; and (3) paralysis, mediated by myelin-specific $CD4^+$ Th cells.

One possible hypothesis for MS progression is believed to be due to T cell infiltration into the CNS boosting inflammation. Interestingly, T cell function is strictly regulated by zinc concentration, and zinc deficiency caused malfunctions and altered T cell differentiation, leading to an imbalanced immune response. Indeed, failures in zinc homeostasis were associated with the development of MS. In this regard, dietary zinc deficiency, as well as increased zinc uptake, were shown to be link with increased risk of MS and the development of pathogenic pro-inflammatory T cells in experimental autoimmune encephalomyelitis (EAE) [20,292,293]. Patients suffering from MS displayed lower plasma zinc levels and lower zinc concentrations in chronic MS lesions [21,22,294]. Zinc administration in EAE

FOI 26-3132 - Document 5

diminished EAE symptoms by inducing Treg cells and diminishing Th17 cells. Thus, the pro-tolerogenic immunoreaction was favored while the pro-inflammatory was dampened. In line with that, zinc signals are well known to be of central importance in keeping unwanted T cell-mediated immunoreactions in check, by suppressing apoptosis, immune cell proliferation, and pro-inflammatory cytokine production as well as IL-2, IL-10 and IL-17 production [214,295–298]. Therefore, adding zinc supplementation to current therapeutic standard treatments can be considered as potentially effective for patients suffering from MS.

8.6. Zinc and Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome (EDS) is a human disorder characterized by joint hypermobility, hyperelasticity of the skin, progressive kyphoscoliosis, and severe hypotonia of skeletal muscles [299]. The zinc transporter ZIP13 plays crucial roles in bone, tooth, and connective tissue development. Disturbed zinc homeostasis due to ZIP13 malfunction appeared to contribute to EDS pathogenesis, whereby the mutant ZIP13 protein was quickly degraded [300,301].

In addition to the identification of the EDS/ZIP13 relationship in humans, ZIP13 knockout mice were investigated. Those showed an abnormal systemic growth, bone growth, abnormal cartilage development, reduced dentin and alveolar bone, abnormal craniofacial and decreased dermal and corneal stromal collagen. At the molecular level, the absence of ZIP13 provoked a dysregulation of bone morphogenetic protein (BMP)-mediated gene expression [302]. Since BMP signaling covers a high variety of target genes, bone, tooth, and craniofacial development was impaired. Both BMP and transforming growth factor (TGF)-β signal via the TGF-β receptor and activate Smad signaling molecules containing a zinc-binding motif in the DNA binding domain, thus making Smad signaling a potential target of zinc signaling [303]. Therefore, ZIP13 might influence zinc availability for that motif.

Another zinc-conditioned target in BMP signaling is Smad protein phosphorylation. Smad proteins need to be phosphorylated for translocation to the nucleus. Altered intracellular free zinc concentrations led to inhibition of phosphatase activity, subsequently increasing Smad phosphorylation, as demonstrated recently [168]. Smad signaling is highly important for adequate development of Treg and for tolerance induction. If this mechanism is not working accurately, inflammation is triggered. Elevated levels of inflammatory markers, ROS and MMPs are well known to cause tissue injury in numerous tissues. Since EDS is accompanied by disturbed collagen synthesis, and MMPs are one key factor in collagenolysis, MMP malfunction can be considered as a possible explanation for EDS. In this context, zinc signals are crucial because inflammation, as well as MMP hyperfunction, accompanies serum hypozincemia [5,63,66].

Hence, altered intracellular zinc level in EDS might be due to ZIP13 malfunction. For this reason, a possible therapeutic approach could be based on the regulation of the mutant ZIP13 protein stability [300].

8.7. Zinc in Inflammatory Disease and Sepsis

ZIP8 influences the innate as well as adaptive immune function during bacterial infection and inflammation and a multitude of other diseases are at least related to ZIP8 malfunction [304,305]. In lung epithelia, ZIP8 is crucial for cyto-protection upon inflammation, mediated by zinc signals [306,307]. Moreover, ZIP8 controls the expression of the pro-inflammatory cytokine IFNγ and its immunological function through the regulation of zinc release from lysosomes [101]. Besides adaptive immunity, ZIP8 also regulates innate immunity through zinc-mediated inhibition of nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) function in macrophages and monocytes [202].

Besides local inflammation, as described above, systemic inflammation, as observed in sepsis, is frequently observed in the population. In this regard, altered zinc transport mechanisms seem to contribute to the inflammatory effects of sepsis. Most likely, ZIP14, which is inducible by pro-inflammatory stimuli, influences zinc metabolism during sepsis and serves as a target for therapy [63]. Zinc signals act in an anti-inflammatory manner during sepsis by attenuating the

FOI 26-3132 - Document 5

pro-inflammatory response, due to cellular zinc uptake by ZIP14. Hence, zinc signals and proper ZIP14 function are essential in pro-inflammatory responses, and zinc deficiency is strongly associated with an elevated risk for exaggerated inflammation and mortality due to sepsis [63,65].

8.8. Zinc in Lactation

Some breast-fed full-term infants show apparent clinical showing symptoms similar to Acrodermatitis Enteropathica, such as growth retardation, dermatitis, diarrhea, and alopecia. Studies showed this was the result of zinc deficiency caused by low zinc concentrations in the breast milk [308–310]. Zinc in breast milk is essential for the growth and health of neonates, since infantile zinc deficiency is associated with autism spectrum disorders [247]. Genetic analyses indicated that malfunction of ZnT2 was responsible for this condition [309,311,312]. Symptoms can be alleviated by zinc supplementation to the infant, but not to the mother. Interestingly, similar observations were described for mice bearing malfunctioning ZnT4 [313], whereby decreased zinc content in milk was detectable [314]. With time, low zinc-concentrations were lethal for suckling pups. ZnT4 has profound consequences on mammary epithelial cell function and negatively influences nutrition secretion into the milk, and additionally promotes tissue remodeling in the mammary gland during early lactation [315]. Animal studies in mice bearing a malfunction of ZnT4, showed these defects to be associated with decreased Akt expression, and Signal transducer and activator of transcription 5 (STAT5) activation. Moreover, in humans a significantly decreased ZnT5 and ZnT6 mRNA expression was found in fibroblasts and lymphoblasts of mothers secreting zinc-deficient milk [316]. Thus, other ZnT proteins are probably involved in the etiology of this disease. Therefore, future studies are needed to elucidate the entire molecular mechanism of the regulation of ZnT2 expression in mammary epithelial cells to protect breast-fed infants against zinc deficiency and to guarantee proper growth and health of neonates.

8.9. Zinc and Diabetes

Diabetes is a chronic disease which damages blood vessels, heart, eyes, kidneys, and nerves. About 340 million people are affected worldwide making diabetes a major cause of morbidity and mortality [317]. Up to ninety percent of patients suffering of diabetes are diagnosed as having type 2 diabetes mellitus (T2DM) and 10–15% type 1 diabetes (T1DM). Whereas T2DM is mainly related on lifestyle, T1DM is an autoimmune disease with an early onset [318]. DM is characterized by loss of glycemic control, disturbed metabolic homeostasis through deterioration of pancreatic β-cell function, and insulin resistance. Besides behavioral factors, hereditary factors also play an important role in determining T2DM risk. The latter include a malfunctioning ZnT8 gene [105]. Thus, ZnT8 transporter is associated with both T1DM and T2DM, respectively [319,320]. Mice that are deficient in ZnT8 have impaired insulin secretion, impaired crystal formation and clear insulin rapidly from the liver [321,322]. Regarding T1DM, ZnT8 autoantibodies are present in 60–80% of patients at the onset of clinical disease [319,323,324]. However, ZnT8 was the last autoantigen uncovered in T1DM, whereas insulin, 65kDa glutamic acid decarboxylase (GAD65) and insulinoma-associated protein 2 (IA-2) where already established long before [318]. Since the prevalence of autoantibodies against ZnT8 has a similar frequency to standard T1DM autoantigens, ZnT8 can be used additionally to detect diabetes-related autoimmunity [325,326].

In diabetes, zinc plays a critical role in the formation of insulin crystals in β-cells. Moreover, both insulin and zinc released from β-cells are considered to have crucial paracrine and/or autocrine effects, leading to modulation of various molecular mechanisms [327,328]. In these processes, ZnT8 is essential to guarantee the transport of zinc into secretory vesicles that contain insulin. Those are referred to as insulin granules. The importance of ZnT8 was highlighted by studies investigating ZnT8 knockout mice [322,329,330]. These had significantly decreased zinc contents in β-cells and show only fragmented immature zinc/insulin crystals. Additionally, studies using β-cell-specific, as well as

FOI 26-3132 - Document 5

α-cell-specific ZnT8, knockout mice revealed that ZnT8 deficiency contributed to a higher incidence of T2DM through β-cell- and non-β-cell-specific effects, respectively [330,331].

Dietary zinc supplementation in mice in vivo was able to attenuate hyperglycemia and hyperinsulinemia, and induced elevated pancreatic zinc concentrations [117], and improved glucose clearance in diabetic rats and mice was observed [123,146]. In line with that, it is well known that zinc-deficient animals are less sensitive to insulin [147]. Oral zinc administration in both mice and humans improves glycemic control in T1DM and T2DM patients, respectively [3]. Since plasma zinc levels in T1DM and T2DM patients were reduced compared to healthy individuals, oral zinc supplementation might be useful as an adjunct therapy to promoting insulin signaling [332,333]. Autoantibody production observed in T1DM might be dampened by zinc supplementation, since especially T cell-dependent antibody production is affected by zinc deficiency [209]. Furthermore, zinc intake may stabilize regulatory T cells as discussed above [72]. This is important in relation to environmental factors such as zinc in drinking water and soils. Although T1DM is clearly related to genetic factors such as HLA-DR3-DQ2 and HLA-DR4-DQ8 [318], the risk of onset of T1DM is associated with low levels of zinc in drinking water and soils [233,334]. Moreover, zinc deficiency triggers the IL-6-induced phosphorylation of STAT3 [145], thereby pathologically enhancing B cell differentiation into antibody-producing plasma cells and autoantibody production. This is due to IL-6 overproduction that is associated with autoantibody production [335].

However, further molecular research needs to be done in this field. ZnT8 may be engaged in the pathogenesis of T2DM in multiple ways and further molecular research is needed to reveal the complete molecular mechanisms responsible for the increased risk to develop DM.

8.10. Zinc and Alzheimer's Disease

Alzheimer's disease (AD) was first described in 1906 and accounts nowadays for 60–80% of all dementia cases reported [336]. AD is a chronic neurodegenerative disorder representing the most prevalent form of dementia in modern society. Patients suffering of AD show a progressive cognitive decline. Post-mortem examinations uncovered extracellular deposits, referred as plaques, intracellular deposits, referred as neurofibrillary tangles (NFTs), as well as a significant thinning of cortical grey matter, enlargement of the ventricular spaces, and an overall atrophy of the brain [5].

It is well known that a zinc dyshomeostasis is present in AD that might trigger AD-related pathology and symptoms. While the ultimate cause of this zinc imbalance remains to be fully elucidated yet, a dysregulation in various metal storage and transport proteins is likely [337].

An imbalanced zinc homeostasis in the hippocampal/parahippocampal gyrus brain area is related to preclinical stage of AD. This is probable due to an increased expression of the zinc transport proteins ZnT4, and ZnT6, and decreased expression of ZnT10 altering zinc concentration and zinc signals in the hippocampal/parahippocampal gyrus [105,338,339]. In addition to that, ZnT1 expression was observed to be reduced in the same brain region individual's mild cognitive impairment. However, ZnT1 expression was increased in early and late stage AD compared to healthy controls [340]. In accordance to that, zinc-associated activation of tyrosine kinases has been uncovered in patients suffering from AD, leading to misdirection of signaling cascades in neuronal cells of affected patients [112]. Moreover, zinc buffering by MT or calcineurin seems to be altered in AD. Some reports claim changes in MT expression, especially in MT-III [341,342]. However, this is still controversy discussed [343]. Additionally, more recent studies uncovered calcineurin activation to be linked to beta-amyloid (Aβ)-mediated neurodegeneration in AD [344,345]. Analysis of brain tissue uncovered a significant decrease in zinc levels found in AD patients' neocortex, hippocampus, medial temporal gyrus and thalamus, and superior frontal and parietal gyri [346]. However, these findings are still under discussion [347,348]. Interestingly, high zinc concentrations seem to trigger AD progression, however low zinc concentrations at ratios of 1:0.1 (Aβ/Zn ratio) and 1:0.01 have a protective effect against Aβ toxicity [349,350]. This is in line with findings of Lee et al., showing that ZnT3 KO mice having less vesicular zinc, simultaneously have less cortical and hippocampal plaques [351].

FOI 26-3132 - Document 5

Another explanation of the zinc-driven protective effect against Aβ toxicity is due to zinc binding to Aβ peptide instead of copper. When copper is bound to the Aβ peptide ROS production and cellular damage is triggered [352]. Hence, cellular damage can be reduced by zinc binding to the Aβ peptide.

In summary, all studies uncover that a disturbed zinc homeostasis may play a role in the pathogenesis of AD. Nevertheless, more research is necessary to uncover potential therapeutic targets to improve patients' lives.

9. Conclusions

Zinc flux, zinc wave, and homeostatic zinc signals control the adequate function of innate as well as adaptive immunity. On the one hand, zinc deficiency causes severe impairment of immune function, comprising the adaptive as well as the innate immune system. On the other hand, high zinc excess provokes an impairment of the immune system comparable to zinc deficiency (see Figure 5). This is why a balanced zinc homeostasis is crucial for either defending against invading pathogens or protecting the human body against an overreactive immune system causing autoimmune diseases, chronic inflammation or allergies. In this regard, zinc can be considered as a gatekeeper of the immune system, since the adequate function of virtually all immune cells is highly zinc-dependent. Knowledge about the molecular mechanisms in zinc-regulated immune reactions is growing and inherited disorders such as Acrodermatitis Enteropathica, as well as nutrition-related immunological malfunctions observed in the elderly, can be treated by appropriate zinc administration. Thus, zinc can be seen as potential therapeutic for clinical use to influence beneficially the well-being of patient's suffering from immune diseases. However, to completely understand the complex-regulated zinc-triggered immunoreactions, more research will be necessary.

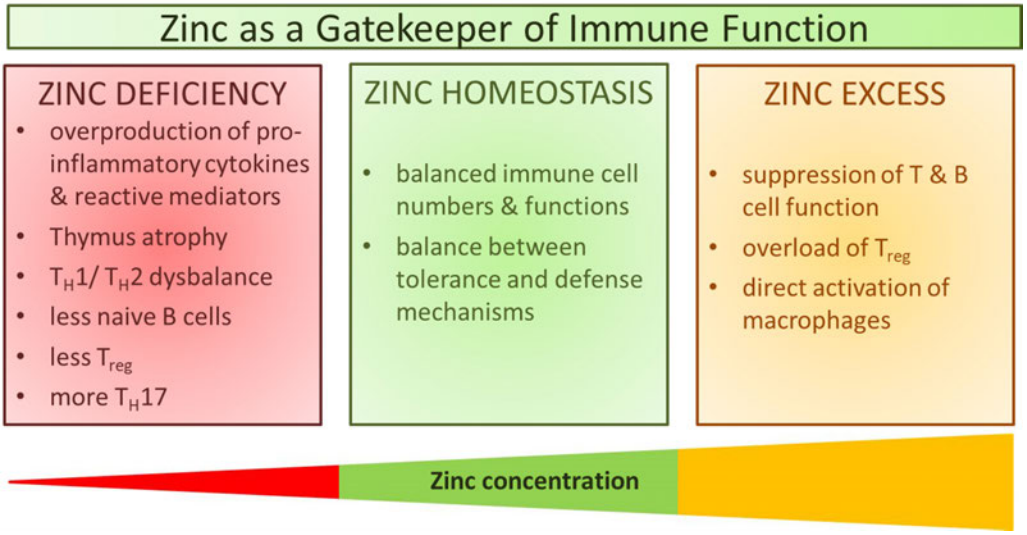

Figure 5. Influence of zinc status on the overall immune function. Adequate zinc homeostasis is essential for a well-functioning immune system. Zinc deficiency as well as zinc excess lead to malfunction of the adaptive and innate immune system, eventually resulting in the development of numerous immune diseases.

The Potential Impact of Zinc Supplementation on COVID-19 Pathogenesis

Inga Wessels[1†], *Benjamin Rolles*[2†] *and Lothar Rink*[1*]

[1] *Institute of Immunology, Faculty of Medicine, RWTH Aachen University, Aachen, Germany,* [2] *Department of Hematology, Oncology, Hemostaseology and Stem Cell Transplantation, Faculty of Medicine, RWTH Aachen University, Aachen, Germany*

During the current corona pandemic, new therapeutic options against this viral disease are urgently desired. Due to the rapid spread and immense number of affected individuals worldwide, cost-effective, globally available, and safe options with minimal side effects and simple application are extremely warranted. This review will therefore discuss the potential of zinc as preventive and therapeutic agent alone or in combination with other strategies, as zinc meets all the above described criteria. While a variety of data on the association of the individual zinc status with viral and respiratory tract infections are available, study evidence regarding COVID-19 is so far missing but can be assumed as was indicated by others and is detailed in this perspective, focusing on re-balancing of the immune response by zinc supplementation. Especially, the role of zinc in viral-induced vascular complications has barely been discussed, so far. Interestingly, most of the risk groups described for COVID-19 are at the same time groups that were associated with zinc deficiency. As zinc is essential to preserve natural tissue barriers such as the respiratory epithelium, preventing pathogen entry, for a balanced function of the immune system and the redox system, zinc deficiency can probably be added to the factors predisposing individuals to infection and detrimental progression of COVID-19. Finally, due to its direct antiviral properties, it can be assumed that zinc administration is beneficial for most of the population, especially those with suboptimal zinc status.

INTRODUCTION

The importance of the trace element zinc for the development and function of the immune system across all kinds of species has been proven in numerous studies (1–3). As zinc deficiency results in altered numbers and dysfunction of all immune cells, subjects with suboptimal zinc state have an increased risk for infectious diseases, autoimmune disorders, and cancer (3–6). In addition to malnutrition, risk groups for zinc deficiency include the elderly and patients with various inflammatory and autoimmune diseases, which will be discussed in detail later in the article (7, 8). As mild zinc deficiency is largely sub-clinical, it is unnoticed in most people. However, the World Health Organization (WHO) assumes that at least one third of the world population is affected by zinc deficiency (9). The fact that zinc deficiency is responsible for 16% of all deep respiratory infections world-wide (9) provides a first strong hint on a link of zinc deficiency with the risk of infection and severe progression of COVID-19 and suggests potential benefits of zinc supplementation.

The most common symptoms of COVID-19 are impaired smell and taste, fever, cough, sore throat, general weakness, pain as aching limbs, runny nose, and in some cases diarrhea (10). In the subsequent chapters, we will associate most of those symptoms with altered zinc homeostasis and explain how zinc might prevent or attenuate those symptoms, as summarized in **Figure 1**, and thus should be regarded as promising cost-effective, globally available therapeutic approach for COVID-19 patients, for which minimal to no side effects are known.

ZINC PROTECTS THE HUMAN BODY FROM ENTERING OF THE VIRUS

The entry of infectious agents into the human body is prevented by tissue barriers equipped with cilia and mucus, anti-microbial peptides like lysozymes and interferons. Regarding SARS-CoV2, the angiotensin-converting enzyme 2 (ACE2) and the cellular protease TMPRSS2 are the major mechanism for entering the cells (11).

a) Mucociliar clearance of viruses is affected by zinc
   Infections with coronaviruses go along with damage of the ciliated epithelium and ciliary dyskinesia consecutively impairing the mucociliar clearance (12). It was shown that physiological concentrations of zinc increase ciliary beat frequency (13). Moreover, zinc supplementation in zinc deficient rats had a positive effect on the number and the length of bronchial cilia (14) (**Figure 1.4**). Improved ciliary clearance does not only improve the removal of virus particle, it also reduces the risk of secondary bacterial infections, as discussed later. Alterations of the extracellular matrix, as monitored by increased epidermal growth factor and proliferating cell nuclear antigen (PCNA) immunostaining of rat lungs during zinc deficiency have also been described (15).
b) Zinc is essential for preserving tissue barriers
   Disturbances in the integrity of the respiratory epithelia facilitate the entry of the virus as well as co-infecting pathogens and can lead to pathogens entering the blood stream. An *ex-vivo* model of the chronic obstructive pulmonary disease (COPD) showed that decreasing zinc levels raised the leakage of the epithelium of the respiratory tract (16), while zinc supplementation improved lung integrity in a murine model of acute lung injury *in vivo* (17). Increased apoptosis and E-cadherin/beta-catenin proteolysis were amongst the underlying mechanisms (17–19). The expression of tight junction proteins like Claudin-1 and ZO-1 was found to be zinc-dependent, offering another explanation for zinc's positive effects on lung integrity (16). In addition, an inhibitory effect of zinc on LFA-1/ICAM-1 interaction weakened inflammation in the respiratory tract via reduction of leukocyte recruitment (20). Furthermore, high zinc levels improved the tolerance of the lung towards damage induced by mechanical ventilation (21) (**Figure 1.4**).
c) Zinc-dependent alterations in gene expression by pneumocytes could affect viral entering
   ACE-2, mainly expressed on pneumocytes type 2, is a zinc-metalloenzyme. Zinc binds to its active center and is thus essential for its enzymatic activity. If zinc binding also affects the molecular structure of ACE-2 and thereby its binding affinity to the virus, remains to be tested (22, 23). However, this is likely as zinc is important for stabilizing protein structures and altering substrate affinity of various metalloproteins (24, 25). Finally, zinc homeostasis might affect ACE-2 expression, as zinc-dependent expression was reported for other zinc-metalloenzyme such as metallothionein and matrix metalloproteinases (26). This suggestion is strengthened by the finding that ACE-2 expression is regulated by Sirt-1 (27, 28). As zinc decreases Sirt-1 activity (27), it might decrease ACE-2 expression and thus viral entry into the cell (**Figure 1.2**).

A lack of adequate secretion of type I and type II interferons was reported for COVID-19 patients (29). For human interferon alpha (IFN-α) it was shown that zinc supplementation can reconstitute its expression by leukocytes and potentiates its anti-viral effect via JAK/STAT1 signaling as observed for rhinovirus-infected cells (30, 31). However, as it was suggested that SARS-CoV2 might take advantage of the interferon-dependent expression of ACE2, which was recently addressed by Ziegler et al. (32), the overall effects of zinc need to be carefully evaluated in future studies.

ZINC DIRECTLY INHIBITS VIRAL REPLICATION

As a virus, SARS-CoV2 is highly dependent on the metabolism of the host cell. Direct antiviral effects of zinc have been demonstrated in various cases, which was reviewed in great detail (33–37). Examples include coronaviridae, picornavirus, papilloma virus, metapneumovirus, rhinovirus, herpes simplex virus, varicella-zoster virus, respiratory syncytial virus, human immunodeficiency virus (HIV), and the hepatitis C virus (34, 35, 37–39). It was suggested that zinc can prevent fusion with the host membrane, decreases the viral polymerase function, impairs protein translation and processing, blocks viral particle release, and destabilizes the viral envelope (35, 37, 40). Low-dose zinc supplementation together with small concentrations of the zinc ionophores pyrithione or hinokitol decreased RNA synthesis in influenza, poliovirus, picornavirus, the equine arteritis virus, and SARS-CoV by directly inhibiting the RNA-dependent RNA polymerase of the virus (34, 41). There is evidence that zinc can enhance the effect of chloroquine, another known zinc ionophore, while zinc ionophores like epigallocatechin-gallate or quercetin remain to be tested (42–45). There are close similarities of SARS-CoV2 and other coronaviridae like SARS-CoV and Middle East respiratory syndrome-related coronavirus (MERS-CoV) (46). Also, the alcohol-aversive drug disulfiram can bind the papain-like proteases of SARS-CoV and MERS-CoV resulting in release of cysteine-bound zinc that results in protein destabilization (47). Detailed studies on zinc's effect specifically on SARS-CoV2 are highly required (**Figure 1.3**).

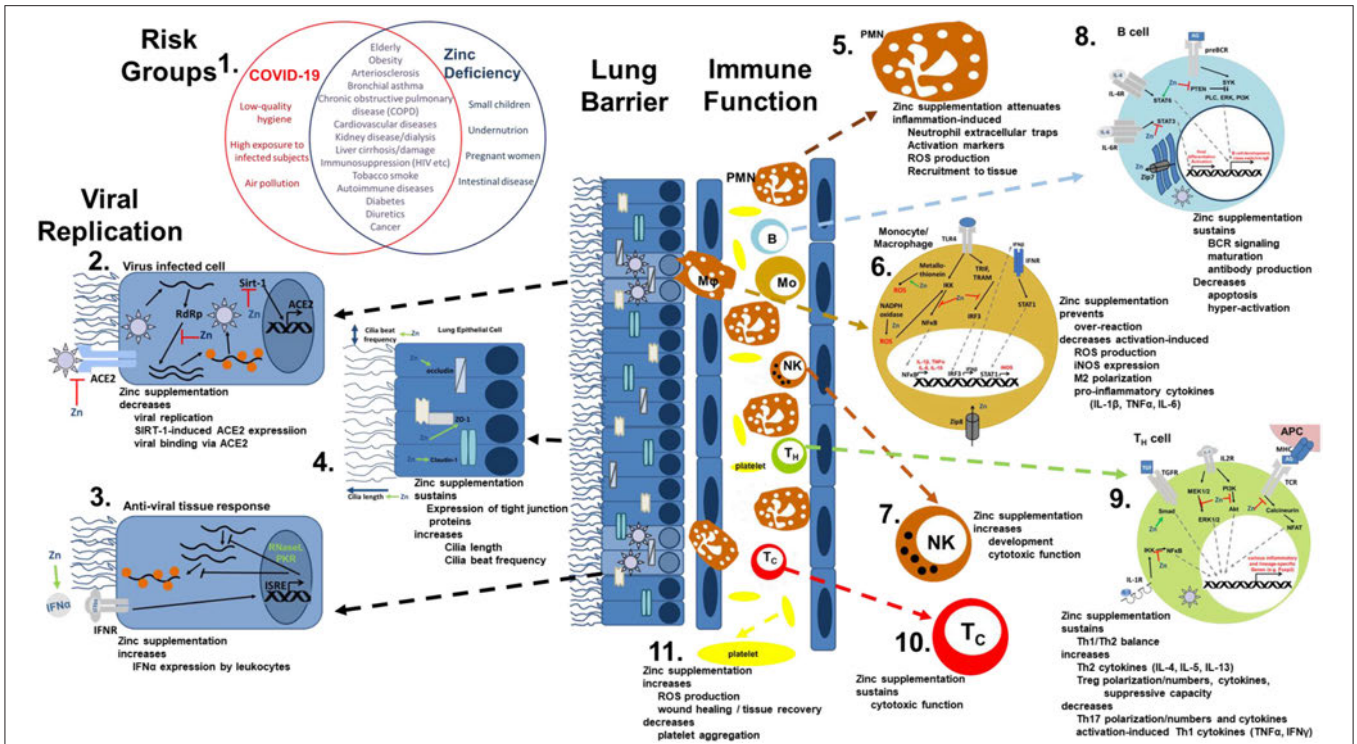

FIGURE 1 | Viral mechanism of COVID-19 and how they might be opposed by zinc data. **(1)** There is an impressive intersection of known risk factors for zinc deficiency (blue circle) and the predisposition for a severe COVID-19 infection (red circle). **(2,3)** Zinc (Zn) supplementation might already prevent the viral entry and also suppresses its replication, while it supports the anti-viral response of the host cells. **(4)** As zinc is known to increase ciliary length and movements and also sustains tissue integrity, entrance of the virus is impeded. **(5–10)** The importance of zinc on the development and function of the immune cells is manifold. It should be underlined, that zinc's effects should not generally be described as activating or inhibiting, as zinc in various cases normalizes overshooting immune reactions and balances the ratios of the various immune cell types. Zinc thus prevents for example that high levels of inflammatory mediators including reactive oxygen and nitrogen species destroy the host tissue. **(11)** On first view it appears contradicting, that zinc increases activation induced production of reactive oxygen species in platelets, while it is generally considered as anti-oxidative. However, in case of platelets, up to a certain threshold, ROS production is essential, as it can prevent the formation of platelet aggregates. In summary, zinc therefore might be able to prevent vascular complications observed in COVID-19 patients. Details for each point can be found in the text. ACE2, angiotensin converting enzyme 2; AG, antigen; IFN, interferon; IFNR, interferon receptor; ISRE, interferon-sensitive response element; APC, antigen presenting cell; IKK, IκB kinase; IL, interleukin; iNOS, inducible nitric oxide synthase; IRF3, IFN regulatory factor 3; MHC, major histocompatibility complex; MEK1/2, mitogen-activated protein kinase kinase 1/2; NADPH oxidase, nicotinamide adenine dinucleotide phosphate oxidase; NFAT, nuclear factor of activated T-cells; NF-κB, nuclear factor kappa B; PKR, protein kinase R; Akt, protein kinase B; PI3K, phosphatidylinositol-3 kinases; ROS, reactive oxygen species; RdRP, RNA-dependent RNA polymerase; RNase L, ribonuclease L; Sirt-, Sirtuin 1; STAT, signal transducer and activators of transcription; TCR, T cell receptor; Tc, cytotoxic T cell; TH, helper T cell; TGF, transforming growth factor; TRAM, TRIF-related adaptor molecule; TRIF, TIR-domain-containing adapter-inducing interferon-β; TLR, toll-like receptor; TNF, tumor necrosis factor; Zip, Zrt- and Irt-like protein; ZO-1, zona occludens.

ZINC BALANCES THE IMMUNE RESPONSE DURING INFECTIOUS DISEASES

One of the hallmarks of COVID-19 is an imbalanced immune response (48). Due to hyper-inflammation, immune products including pro-inflammatory cytokines like interleukin (IL)-6, C-reactive protein (CRP), tumor necrosis factor (TNF)α and IL-1β (summarized as cytokine storm or cytokine release syndrome), reactive oxygen, and nitrogen species in connection with the recruitment of high numbers of strongly activated immune cells to the lungs, the destruction of the tissue, permanent lung damage and death due to systemic inflammation, and organ failure are expected, while the anti-inflammatory response is insufficient (48–52). A high number of patients develop an acute respiratory distress syndrome (ARDS) accompanied by high alveolar leakage leading to alveolar and interstitial edema with severely limited oxygen exchange (53). Advanced SARS-CoV2 infections are characterized by a systemic involvement with organ complications and accompanying cytokine storm (52, 54).

There is no doubt on the anti-inflammatory and anti-oxidative properties of zinc and underlying mechanisms have been the focus of numerous studies (1–3, 6, 55–60). A detailed description of zinc metabolism in airway epithelium and during inflammation of the airways has been published by Zalewski et al. (61). On the other hand, zinc deficiency was associated with elevated levels of pro-inflammatory mediators, increased reactive oxygen species (ROS) levels and pre-disposing for severe progression of inflammatory diseases, especially those affecting the lung, often reversible by zinc supplementation (6, 17, 56, 62–66) (**Figures 1.5,1.6**). As one example, exposure to organic dust increased lung damage, inflammation and

FOI 26-3132 - Document 5

macrophage hyper-activation in animals with zinc deficiency, predisposing these animals to pulmonary fibrosis, while zinc supplementation 24 h before induction of acute lung injury significantly attenuated the inflammatory reaction and tissue damage (17, 67). Regarding systemic inflammatory diseases the number of studies showing benefits of especially preventive zinc supplementation is constantly increasing (17, 18, 58, 65, 68). Amongst the underlying mechanism, zinc's role as second messenger and importance in regulating intracellular signaling as detailed in **Figure 1** were described as well as zinc's effects on the epigenome (56, 57, 69–74).

Furthermore, leukocytosis with neutrophilia and lymphopenia, especially affecting $CD8^+$ T cells, were associated with poor prognosis of COVID-19 and the recovery of lymphocyte counts lead to clinical recovery (75, 76). Similar changes in lymphopoiesis and myelopoiesis have been described in zinc deficient rodents, which were normalized when zinc was supplemented (17, 19). Circulating and lung-resident T cells from COVID-19 patients showed increased expression of markers for T cell exhaustion like Tim-3 and PD-1 (77). The extent of these changes had an impact on the patient's prognosis (50). During the past decades, an immense literature was generated on the need of zinc for lymphocyte development and function and that zinc supplementation (6, 19, 63, 64, 78, 79) can reverse lymphopenia. Enumerating all findings and underlying mechanisms is beyond the scope of this article, and a lot of aspects have been discussed in related publications (36) but as one of the many key roles of zinc in the context of T cell function, zinc is indispensable in the signal cascade of the T cell receptor and IL-2 as a second messenger (78, 80) (**Figure 1.9**). The B cell compartment also strongly benefits from a balanced zinc homeostasis, as zinc is required for B cell maturation and function (72, 81) (**Figure 1.8**). Also important to mention, but neglected by previous related articles, is that there is evidence (82, 83) that SARS-CoV2 can directly infect T cells as well as B cells and impair their cell specific function. This could explain the impact of SARS-CoV2 infection on lymphoid tissues like the human spleen and lymph nodes (84). However, as data are limited to *in vitro* experiments, this needs to be verified *in vivo* as well as if zinc affects the virus-induced changes in T and B cells.

Additionally, granulocytes play a vital role during the inflammation-induced destruction of the lung (85). Recent evidence suggests that lipopolysaccharide-induced hyper-activation, recruitment and formation of neutrophil extracellular traps are attenuated by zinc supplementation *in vivo* and that cytokine expression, phagocytosis and burst, chemotaxis and degranulation, and intracellular signaling are zinc regulated (17, 86, 87) (**Figure 1.5**). Important defense mechanisms of the innate immunity include the toll like receptors. For instance, *in silico* data suggest that toll-like receptor (TLR)-4 can potentially recognize outer components of SARS-CoV2's like the viral spikes (88), while intracellular receptors including TLR3, TLR7/8, and TLR9 can recognize viral dsRNA, ssRNA, and unmethylated CpG DNA respectively (89–92). Intranasal pretreatment with a TLR3 agonist and, to a lesser extent, with TLR9, TLR7/8, or TLR4 agonists, provided a high level of protection against infections by SARS coronavirus and influence virus in mice, suggesting that TLR signaling can induce protective antiviral immunity (93). This might be a completely novel approach to consider regarding COVID-19 as well. Zinc is an essential regulator in TLR-4- and TLR-3-induced signaling in innate immune cells (94). Thus, zinc deficiency potentially disturbs the innate immune response toward SARS-CoV2, enabling the virus to easily spread throughout the host without an adequate immune response (**Figure 1.6**).

Clinical improvement of COVID-19 patients was correlated to an increase of $CD14^+$ monocytes and NK cells in the recovery phase (48). For a physiological inflammatory response and phagocytic activity macrophages need sufficient intracellular zinc levels (1). In addition, for NK cells and cytotoxic T cells it was shown that zinc supplementation increased their cytotoxicity toward target cells (1, 2, 95) (**Figures 1.7,1.10**).

In summary zinc's (re-)balancing power regarding immune cell numbers and functions might be highly beneficial in regard to therapy of COVID-19.

ZINC SUPPLEMENTATION IN RESPIRATORY INFECTIONS

Our suggested benefits of zinc supplementation to prevent and treat COVID-19 are supported by a row of successful supplementation studies focusing on respiratory tract infection, of which we listed some selected publications in **Table 1**. In most cases, prophylactic zinc supplementation was more effective than therapeutic proceedings (106–108, 111). Up to 30% of the everyday respiratory infections, briefly named "common cold," are due to infections with coronaviruses (112). Studies showed reduced symptom severity, reduced frequency, and duration of the common cold after zinc administration (99, 100, 113, 114) depending on dosage, zinc compound and the start time after initial symptoms (115). Most importantly, zinc supplementation of children revealed significant benefits in various studies (96, 106) and reduced 15% pneumonia-specific morality and 19% of pneumonia morbidity in developing countries (116).

RISK GROUPS AND SYMPTOMS OF COVID-19 AND ZINC DEFICIENCY REVEAL A LARGE OVERLAP

As illustrated in **Figure 1.1**, the intersection between risk groups of COVID-19 and zinc deficiency is impressive. In patients with chronic obstructive pulmonary disease (COPD), bronchial asthma, cardiovascular diseases, autoimmune diseases, kidney diseases, dialysis, obesity, diabetes, cancer, atherosclerosis, liver cirrhosis, immunosuppression, and known liver damage low serum zinc levels are regularly observed (4, 117). At the same time, these groups are particular at risk for COVID-19 (10, 51, 118, 119). For example 57.5% elderly and nursing home residents in the U.S., for which high incidence of respiratory tract infections is described, showed significantly decreased zinc intake levels and are considered subjects with high risk regarding COVID-19 (120). Moreover, other studies showed that serum zinc levels were inversely correlated with pneumonia and cystic

TABLE 1 | Selected zinc supplementation studies in respiratory infections.

Compound	Conc. [mg/d]	Duration	Disease	Effect	References
Treatment					
Zinc bis-glycinate	30 (elemental)	Max 7 days/dis-charge from the hospital	Lower RTI (Children)	Reduction of days of ALRI and shorter hospital stay	(96)
Zinc acetate	20	5d	Lower RTI (children)	Increased recovery rates (boys)	(97)
Zinc gluconate	10	6 mo	Lower RTI (children)	Decreased episodes of infection, more infection free days	(98)
Zinc gluconate Zinc actetate Gluconate nasal gel SULFITE nasal spray	60–313 76.8–102.4 2.1 0.044	Until symptoms are gone	Common cold	Variable results but generally reduced duration if supplementation started within first 24 h	Meta-study of 16 studies (99)
Zinc acetate vs. zinc gluconate	80–92 192–207	Until symptoms are gone	Common cold	<75 mg/day: reduced duration; zinc acetate better than gluconate	Meta-study of 7 studies (100)
Zinc gluconate	30 (elemental)	12 mo	Cystic fibrosis (children)	Reduced duration of antibiotics	(101)
Prophylactic					
Zinc sulfate	20 (elemental)	2 wk/6 mo follow-up	Lower RTI (children)	Reduced morbidity	(102)
Zinc sulfate	20 to ZD children	14d, 6 mo follow-up	Upper and lower RTI (children)	Decreased incidence and duration of upper and lower RTI	(103)
Zinc oxide	5	12 mo	Upper RTI (children)	Decreased incidence	(104)
Zinc gluconate	10	6 mo	Lower RTI	Decreased incidence	(105)
Zinc acetate, gluconate, methionine, sulfate	Min 70 mg/wk	>3 mo	Lower RTI	Decreased incidence (depending on criteria)	Meta-study of 10 studies (106)
Zinc in mineral mix	6 (f)−7.5 (m)	12 mo	Naturally occurring pneumonia	Decreased incidence and duration, decreased duration of antimicrobial therapy	(107)
Zinc sulfate	60–90	12 mo	Ventilation associated pneumonia	Decreased incidence	(108)
Zinc gluconate	Up to 12x 23 mg/d	Until symptoms are gone	Common cold	Decreased clinical score	(109)
Zinc sulfate	15	7 mo	Common cold	Decreased incidence	(110)
Murine models					
Zinc-enriched rodent diet	ZD: 50 ppm–ZS: 100 ppm	18d ZD followed by 3d ZS	Sepsis-induced ALI	Decrease in inflammation, lung damage, and mortality (vs. ZD mice)	(68)
Zinc aspartate	30 μg/ mouse	24 h	Acute lung injury (LPS inhalation), mice	Decreased hyper-inflammation, tissue damage	(17)

Conc, concentration; d, day; mo, months; ref, reference; RTI, respiratory tract infection; ZD, zinc deficiency; ZS, zinc supplementation; wk, week.
Single studies are not included in the meta-studies.

fibrosis (121, 122). On the other hand, zinc supplementation was able to reconstitute immune function in elderly and zinc deficient individuals (107, 123), which remains to be addressed for SARS-CoV2 infections (36). In this regard, the low response of older patients with low serum zinc to a 23-valent pneumococcal polysaccharide vaccination compared to those with higher zinc level (124), should be mentioned. However, zinc's role in the response to vaccination is generally discussed controversially and no data are available for vaccination against any corona virus.

Several studies indicate that there is an association between chemosensory dysfunctions and COVID-19 (125–133). Smell or taste is largely decreased, which might be a good disease biomarker (133). It was suggested that this might either be due to direct destruction of sensory cells by the virus, as ACE-2 is highly

expressed by the oral mucosa, or by viral entry into the brain and neuronal pathologies as was described for other SARS-CoV (133, 134). Zinc deficiency was related to significantly reduced taste sensitivity and impaired saliva secretion in humans and animals, which might involve zinc's importance for the action of carbonic anhydrase (135–140). Results from supplementation studies largely describe improvements in chemosensory functions (140, 141), but some studies did not find any effects (142) or even more severe disturbances when very high zinc concentrations were used (143). This is possibly due to investigating olfactory diseases of various origins, the lack of controlled trials and inclusion of observable studies. Thus, the benefits of zinc supplementation alone or in combination with common medical strategies should be tested for taste and smell diseases according to the available guidelines (144).

About 50% of patients that died of COVID-19 had bacterial or fungal co-infections (145), underlining the importance of sustaining the immune function by a sufficient zinc supply (1, 2, 36). In animal experiments it was shown that zinc restriction made mice highly susceptible to bacterial infection with *streptococcus pneumoniae* (146). As mentioned earlier, marginal zinc deficiency affects one third of the worldwide population and most subjects with COVID-19 are at risk of zinc deficiency (**Figure 1**). During physiological inflammatory responses, zinc is additionally redistributed to the tissues, resulting in serum hypozincemia (1, 65). In combination with the pre-existing suboptimal zinc supply, this will decrease serum zinc levels to critically low values and thereby significantly increase the susceptibility for co-infections with detrimental progression. In critically ill patients persistent low serum zinc was associated with recurrent sepsis and serum zinc levels were inversely correlated with mortality from sepsis (62), underlining the potential benefits of monitoring the zinc status of the patients and implementing zinc supplementation into therapy of COVID-19.

Vascular complications resulting from atherosclerosis development, microangiopathic organ failure, and venous thromboembolism were found as a major cause of death in COVID-19 patients (147–149), suggesting an important role of disease-induced coagulopathy, which, however, needs further investigation. Zinc influences thrombocyte aggregation and coagulation (150). Recently, a functional association between zinc and ROS production in platelets was described, indicating that zinc could decrease thrombus formation in a clinical context (151). Complications of SARS-CoV2 infections also include tissue damage affecting the gastrointestinal system (152), the liver (153), heart (154), nervous system (155), kidneys (156), blood vessels (149), and the skin (157). In this regard it should be mentioned that a balanced zinc homeostasis is essential for wound healing and tissue recovery after mechanical and inflammation-mediated damage (158, 159), adding more potential benefits of zinc supplementation of COVID-19 patients (**Figure 1.11**).

CONCLUSION

In this perspective, we reviewed the most important literature on the role of zinc homeostasis during viral infections, focusing on the potential benefits of zinc supplementation to prevent and treat SARS-CoV2 infections. Although data specifically on SARS-CoV2 are unfortunately still pending and randomized controlled studies have not been conducted, the enumerated evidence from the literature strongly suggests great benefits of zinc supplementation. Zinc supplementation improves the mucociliary clearance, strengthens the integrity of the epithelium, decreases viral replication, preserves antiviral immunity, attenuates the risk of hyper-inflammation, supports anti-oxidative effects and thus reduces lung damage and minimized secondary infections. Especially older subjects, patients with chronic diseases and most of the remaining COVID-19 risk groups would most likely benefit. Although studies are needed testing the effect of zinc as therapeutic option for established disease, preventive supplementation of subjects from risk groups should begin now, as zinc is a cost-efficient, globally available and simple to use option with little to no side effects. The first clinical trials on zinc supplementation alone and in combination with other drugs such as chloroquine have been registered (124, 160–162). Thus, first results and treatment regimens regarding zinc supplementation for COVID-19 risk groups and patients can be anticipated soon.

Doxycycline treatment of high-risk COVID-19-positive patients with comorbid pulmonary disease

Paul A. Yates, Steven A. Newman, Lauren J. Oshry, Robert H. Glassman, Ashton M. Leone and Elias Reichel

***Abstract*:** Infection with novel SARS-CoV-2 carries significant morbidity and mortality in patients with pulmonary compromise, such as lung cancer, autoimmune disease, and pneumonia. For early stages of mild to moderate disease, care is entirely supportive. Antiviral drugs such as remdesivir may be of some benefit but are reserved for severe cases given limited availability and potential toxicity. Repurposing of safer, established medications that may have antiviral activity is a possible approach for treatment of earlier-stage disease. Tetracycline and its derivatives (e.g. doxycycline and minocycline) are nontraditional antibiotics with a well-established safety profile, potential efficacy against viral pathogens such as dengue fever and chikungunya, and may regulate pathways important in initial infection, replication, and systemic response to SARS-CoV-2. We present a series of four high-risk, symptomatic, COVID-19$^+$ patients, with known pulmonary disease, treated with doxycycline with subsequent rapid clinical improvement. No safety issues were noted with use of doxycycline. Doxycycline is an attractive candidate as a repurposed drug in the treatment of COVID-19 infection, with an established safety profile, strong preclinical rationale, and compelling initial clinical experience described here.

The reviews of this paper are available via the supplemental material section.

Keywords: COVID-19, doxycycline, pulmonary disease, SARS-CoV-2, therapeutic

Received: 24 June 2020; revised manuscript accepted: 7 July 2020.

Introduction

SARS-CoV-2 is a newly emerged coronavirus for which there are limited therapeutic options and no available vaccine.[1] Patients who test positive are advised to self-quarantine, with supportive care including rest and fluid intake.[1] Hospitalization is indicated for severe disease and may be considered for patients with moderate disease with high-risk features, including immunocompromised states (e.g. cancer treatment, chronic lung disease, diabetes, severe obesity).[1] Mortality in patients with lung cancer and COVID-19 infection is high; 33% in a recently reported international series.[2]

There is significant interest in repurposing existing, approved medications for treatment of COVID-19. Tetracycline and its derivatives (e.g. doxycycline) may offer a rational and safe treatment for COVID-19$^+$ patients. Doxycycline is commonly dosed at 100 mg twice daily to treat bacterial infections and dermatologic conditions (e.g. acne vulgaris and rosacea).[3] Tetracyclines have both antiviral and anti-inflammatory properties that may ameliorate the response to viral infection.[3–6] Clinical studies indicate efficacy of doxycycline against dengue and chikungunya viral infections.[4,5] In addition, doxycycline may affect several pathways regulating viral replication.[7–9] These pleiotropic features of tetracyclines likely result from actions on nontraditional, antibiotic molecular pathways.[3]

Doxycycline has several potential mechanisms of action through which it may prevent or ameliorate

FOI 26-3132 - Document 5

the effects of COVID-19 infection. Doxycycline is well known to inhibit metalloproteinases (MMPs), in particular MMP-9, which is likely required for initial viral entry into the cell.[3] Doxycycline inhibits interleukin (IL)-6, with both IL-6 and MMPs key regulators of the 'cytokine storm' often associated with severe viral pneumonitis.[10–12] Doxycycline is an established ionophore, helping transport zinc intracellularly, with increased cellular concentrations of zinc shown *in vitro* to inhibit coronavirus replication.[3,13] Doxycycline inhibits nuclear factor (NF)-κB[3,14], which may lower risk of viral entry due to direct inhibition of DPP4 cell surface receptor[15] and diminish a hyperactive immune response following infection. Nonantimicrobial, low-dose doxycycline has been found *in vivo* to inhibit expression of CD147/EMMPRIN,[16] which may be necessary for SARS-CoV-2 entry into T lymphocytes.[16,17] Structural analysis demonstrates that doxycycline has the potential to inhibit papain-like proteinase (PLpro) and 3C-like main protease (3CLpro), viral proteins both essential to viral replication and lifecycle.[9]

In view of the above considerations, we report a series of four patients with COVID-19 infection and known high-risk pulmonary disease who were placed on standard doses of doxycycline for a course between 5 and 14 days. Patients were initiated on therapy with doxycycline after discussion of potential risks and benefits and after informed consent was obtained. There was no concomitant use of any other antibiotics, antiviral agents, antimalarial drugs, zinc, or any supplements postulated to be beneficial in therapy for SARS-CoV-2 in these four patients.

Case 1

A 48-year-old black woman, never smoker, with stage IV epidermal growth factor receptor (EGFR) mutated adenocarcinoma of lung, diagnosed in August 2018, was treated with osimertinib since November 2018 with response in all sites of disease. Other medications included loperamide and doxycycline, as needed for EGFR inhibitor-related diarrhea and rash, respectively. She worked as a nursing assistant. On 6 April 2020 she reported fever of 101° F, headache, anorexia and anosmia. On examination: temperature 101° F, pulse 102, blood pressure 115/71, O_2 sat 98% on room air. She was noted to have mild cough with normal respiratory effort. Laboratory tests revealed white blood cell count of 2.7, with lymphopenia, similar to prior recent determinations; C-reactive protein (CRP) 10.6 (0–5 mg/l), creatine kinase (CK) 2996 (46–179 U/l), troponin <0.006 (negative), aspartate aminotransferase 105 (13–39 U/l), creatinine 1.3 (05–1.1) mg/dl. Chest X-ray showed chronic stable right retrocardiac midlung opacities with no new focal consolidation or effusion. The following day her swab returned positive for SARS-CoV-2. As she had declined hospitalization, she was instructed to discontinue osimertinib but to start doxycycline initially 200 mg followed by 100 mg daily for 5 days. She noted improvement in all symptoms within 5 days.

Case 2

A 71-year-old white male physician with a 9 year history of pulmonary sarcoidosis, treated with intermittent steroids, noted new intermittent cough and one episode of diarrhea in early April 2020. Nasopharyngeal swab was positive for SARS-CoV-2. No additional evaluation was performed. The patient was started on doxycycline 100 mg orally twice a day and self-monitored pulse oximetry at home. Revisit to the emergency department was prompted by transient drop in oxygen saturation to 88% on day six. His temperature was 100.4° F, chest X-ray showed evidence of his chronic lower lung changes attributed to sarcoidosis, O_2 sat was 96%. The patient returned home without supplemental oxygen and remained on doxycycline for 10 days. Fever resolved and he remained asymptomatic. After 3 weeks retesting was negative for SARS-CoV-2 and he returned to work.

Case 3

A 40-year-old Asian woman, never smoker, with stage IV EGFR mutated lung adenocarcinoma, on osimertinib since 13 June 2018, also treated with stereotactic radiation to right lower lobe primary lesion in July 2019, presented to an urgent care clinic with 4 days of anosmia, mild cough, and mild dyspnea. She worked as a personal care assistant for elderly patients at home. Nasopharyngeal swab testing was positive for SARS-CoV-2 RNA. The patient continued to take osimertinib and doxycycline 100 mg twice daily (previously prescribed for EGFR-I related

rash). Symptoms improved within 1 week. Repeat nasopharyngeal swab testing on 9 May 2020 was negative for SARS-CoV-2 RNA.

Case 4

An 88-year-old white man, with several comorbidities including sick sinus syndrome, cardiovascular disease, lacunar strokes, mild obstructive lung disease, and chronic indwelling bladder catheter, was admitted from a Veterans Nursing Home with fever to 102°F, severe dry cough, weakness, and dyspnea. Chest X-ray showed bilateral diffuse infiltrates. Laboratory tests were notable for nasopharyngeal swab positive for SARS-CoV-2 RNA, CRP 11, mild hypoxia with O_2 sat 89–92%. Ceftriaxone, azithromycin and 2 liters of nasal prong O_2 were begun. His initial hospital course showed progression of his pulmonary symptomatology with decreasing O_2 saturation requiring 4 liters of nasal prong O_2 by day 3, with CRP increase to 13. On day 4 ceftriaxone was discontinued and azithromycin was replaced with doxycycline 100 mg twice daily. His pulmonary course quickly improved alongside decreasing CRP. By day 8, he no longer required oxygen and his CRP was 1.0. He never received any antiviral, IL-6 antibody, nor convalescent plasma. He was discharged on day 28 after his lung infiltrates resolved on chest X-ray after 14 days of doxycycline therapy.

Discussion

These reported cases are the first to provide a correlative relationship between doxycycline and potential reduction of severity of symptoms in COVID-19$^+$ patients. It is difficult to establish a definitive causal link between use of doxycycline and accelerated recovery or decreased morbidity from SARS-CoV-2 infection in a small case series. We believe this study provides a rationale for initiating larger controlled trials evaluating the use of doxycycline in COVID-19$^+$ patients.

The patients we report had a number of high-risk features, predictive of severe disease and increased risk of mortality. Patients one and four had advanced lung cancer on treatment, a group for whom mortality rates with COVID-19 infection is in excess of 33%.[2] Elevated inflammatory markers, including CRP, transaminases, and CK (as in cases 1 and 4) are also associated with worse outcomes.[18] Advanced age and diffuse bilateral infiltrates (case 4), are also predictors of high morbidity and mortality.[19] Case 4 demonstrated a temporal relationship between administration of doxycycline and clinical improvement, after several days of worsening on azithromycin. Patients with active pulmonary sarcoidosis, as in case 2, are also at greater risk of complications from COVID-19 due to immunologic dysfunction and dysregulation.[20] The described patients were at a significant increased risk from COVID-19 morbidity and mortality. All improved, with one showing resolution of bilateral pulmonary infiltrates. None progressed to severe disease.

A standard antimicrobial dose of doxycycline (100 mg twice daily or daily) was administered to the four patients in this case series. Doxycycline is unique among the many tetracycline derivatives, in that it has a clear dosing split between its cellular cytotoxic/antimicrobial effects (>100 mg) and its potential anti-inflammatory/antiviral/pro-ionophoric effects (40 mg).[3,4,7,8,12] This may be an important consideration for low-dose doxycycline (20 mg twice daily) as a potential prophylactic treatment against COVID-19 infection.

Potential efficacy of doxycycline against COVID-19 may be due to pleiotropic effects against the general pathways involved in viral infection, replication, and associated over-exuberant inflammatory response, with associated angiogenic effects.[3] Doxycycline has no known direct specificity for inhibition of SARS-CoV-2. Doxycycline likely has activity against known coreceptors DPP4/CD26, through demonstrated inhibition of NF-κB,[14,15] and coreceptor CD147/EMMPRIN, necessary for entry of SARS-CoV into T lymphocytes, even at submicrobial doses.[16,17] DPP4 appears to have a binding site for NF-κB and inhibition of NF-κB decreases DPP4 expression.[15] DPP4 demonstrates increased expression in older patients and those with diabetes or pulmonary disease, and may account in part for increased morbidity and mortality to COVID-19.[8] Finally, MMP-9 also appears to be required for the virus to traverse the cell wall for infection.[10,11]

Once COVID-19 has infected the cell, structural analysis indicates doxycycline may be able to bind to PLpro, which is responsible for proteolytic cleavage of the replicase polyprotein that releases nonstructural proteins 1, 2 and 3 (Nsp1, Nsp2 and Nsp3), essential for viral replication.[9] It is similarly predicted to bind to 3CLpro or

FOI 26-3132 - Document 5

Nsp5, which is cleaved from the polyproteins, causing further cleavage of Nsp4-16, mediating maturation of Nsps essential in the virus lifecycle.[9] Doxycycline is an ionophore that binds divalent cations (including zinc) to facilitate cell membrane transport, and thereby increase zinc concentration in the cell.[3,13] Elevated zinc has an inhibitory effect on the replication of SARS-CoV-2.[13] The presumed mechanisms are through inhibition of proper processing of replicase proteins and RNA-dependent RNA polymerase (RdRp) activity.[13]

Lastly, doxycycline may help prevent the 'cytokine storm' following COVID-19 infection presumed to be due to hyperactivity of the immune response to SARS-CoV-2. A primary driver of the anti-inflammatory activity of doxycycline is secondary to its direct inhibition of NF-κB.[14] NF-κB directly regulates IL-6 expression, which is a key driver of the cytokine storm.[21] Doxycycline may also precipitate apoptosis of senescent epithelial cells,[8] which have known increased expression of DPP4/CD26, likely exhibiting increased viral replication in these cells which leads to induction of the cytokine storm.

Conclusion

In summary, we present reports of four patients at high risk for morbidity and mortality from SARS-CoV-2 infection who experienced improvement and/or mild clinical course in association with doxycycline. Despite the safety of doxycycline, we would not recommend general use of this medication for treatment of COVID-19^{+} patients, except under direct physician guidance and monitoring. A larger randomized controlled trial should be considered.

ABSTRACT

OBJECTIVE

To study the clinical characteristics of patients in Zhejiang province, China, infected with the 2019 severe acute respiratory syndrome coronavirus 2 (SARS-Cov-2) responsible for coronavirus disease 2019 (covid-2019).

DESIGN

Retrospective case series.

SETTING

Seven hospitals in Zhejiang province, China.

PARTICIPANTS

62 patients admitted to hospital with laboratory confirmed SARS-Cov-2 infection. Data were collected from 10 January 2020 to 26 January 2020.

MAIN OUTCOME MEASURES

Clinical data, collected using a standardised case report form, such as temperature, history of exposure, incubation period. If information was not clear, the working group in Hangzhou contacted the doctor responsible for treating the patient for clarification.

RESULTS

Of the 62 patients studied (median age 41 years), only one was admitted to an intensive care unit, and no patients died during the study. According to research, none of the infected patients in Zhejiang province were ever exposed to the Huanan seafood market, the original source of the virus; all studied cases were infected by human to human transmission. The most common symptoms at onset of illness were fever in 48 (77%) patients, cough in 50 (81%), expectoration in 35 (56%), headache in 21 (34%), myalgia or fatigue in 32 (52%), diarrhoea in 3 (8%), and haemoptysis in 2 (3%). Only two patients (3%) developed shortness of breath on admission. The median time from exposure to onset of illness was 4 days (interquartile range 3-5 days), and from onset of symptoms to first hospital admission was 2 (1-4) days.

CONCLUSION

As of early February 2020, compared with patients initially infected with SARS-Cov-2 in Wuhan, the symptoms of patients in Zhejiang province are relatively mild.

WHAT IS ALREADY KNOWN ON THIS TOPIC

As of 8 February 2020, coronavirus disease 2019 (covid-19) caused by the 2019 severe acute respiratory syndrome coronavirus 2 (SARS-Cov-2) has been responsible for more than 30 000 infections and 700 deaths globally, and the numbers are still increasing rapidly

The reported mortality from infection with SARS-Cov-2 in Wuhan, China reached 11-15%, which was inconsistent with what was observed outside of Hubei province

The epidemiological and clinical characteristics of patients outside of Wuhan have not been described, especially in Zhejiang province, where by 8 February 2020 more than 1000 people were diagnosed as having covid-19

WHAT THIS STUDY ADDS

In patients infected with SARS-Cov-2 in Zhejiang province, the median time from exposure to onset of illness was 4 days (interquartile range 3-5 days) and from onset of symptoms to first hospital admission was 2 (1-4) days

The most common symptoms were fever, cough, expectoration, headache, myalgia or fatigue, diarrhoea, and haemoptysis, and only two patients developed shortness of breath on admission

At present, compared with the initial patients infected in Wuhan, the symptoms of patients in Zhejiang province are relatively mild

Introduction

In December 2019 a group of patients with pneumonia of unknown cause were confirmed to be infected with a novel coronavirus, known as 2019-nCoV, in Wuhan, Hubei province, China, which had previously not been detected in humans or animals.[1] Epidemiological evidence suggested that most of these patients had visited a local seafood market in Wuhan[2] and that the gene sequence of the virus obtained from these patients was highly similar to that identified in bats.[3] The virus was subsequently renamed SARS-Cov-2 as it is similar to the coronavirus responsible for severe acute respiratory syndrome (SARS-CoV), a member of the subgenus Sarbecovirus (Beta-CoV lineage B), with which it shares more than 79% of its sequence, but it is more distant to the coronavirus responsible for Middle East respiratory syndrome (MERS-CoV), a member of the Merbecovirus subgenus (only 50% homology with SARS-Cov-2). All these viruses are categorised within the same genus of the subfamily Orthocoronavirinae within the family Coronaviridae.[4-7] Some researchers have found that SARS-Cov-2 has strong affinity to human respiratory receptors,[8] suggesting a potential threat to global public health.

Initially, the first confirmed cases were nearly all related to the Huanan seafood market (closed on 1 January 2020) and were concentrated in Wuhan.[9] Coronavirus disease 2019 (covid-19) soon drew global attention because of the rapidly increasing numbers of new cases.[2] The new type of coronavirus infection was believed to have been transmitted from animals, and by January 2020 it was suspected that the initially

FOI 26-3132 - Document 5

affected patients had been infected with the virus through human to human transmission.[10] Since January 2020 the spread of covid-19 has escalated and the virus has extended rapidly to most parts of China as well as to other countries. As of 8 February 2020 a confirmed 37 589 people have been infected with SARS-Cov-2 globally, including 302 people across 24 other countries.[11] These figures are updated daily and are expected to increase further.

Despite the increasing number of confirmed cases, the clinical investigation of patients was insufficient. A previous study reported the clinical characteristics of the first 41 infected patients in the greater Wuhan area, contributing to an understanding of the epidemiological, clinical, laboratory, and radiological characteristics and treatment and clinical outcomes of those patients.[9] A second study found a familial cluster of SARS-Cov-2, clearly suggesting human to human transmission in family homes and hospitals and showing that spread of the virus between cities is possible.[10] In late January 2020 large numbers of people across China were returning to their home towns after visiting Wuhan for the Chinese lunar new year. This weeklong holiday accounts for the largest mass movement of people worldwide each year. Consequently, over time more patients are expected to emerge across China and perhaps the world. We found that the characteristics of patients outside of Wuhan differed from those initially reported in patients in Wuhan.[10]

We describe the clinical characteristics and laboratory findings of patients in Zhejiang province infected with SARS-Cov-2 to provide an insight into the prevention and treatment of covid-19 across China and elsewhere.

Methods

Data sources

We conducted a retrospective study focusing on the clinical characteristics of confirmed cases of covid-19 in Zhejiang province from 10 January 2020 to 26 January 2020. Since the outbreak of covid-19, strict precautionary measures have been implemented in Zhejiang province, including the creation of fever clinics that exclusively receive patients with suspected SARS-Cov-2 infection, defined as presenting with a fever or any respiratory symptoms, including dry cough, and especially in those with a history of travel to Wuhan or exposure to infected people within two weeks before the onset of illness since January 2020. Case definitions of confirmed human infection with SARS-Cov-2 are in accordance with the interim guidance from the World Health Organization.[1] Only patients with a laboratory confirmed infection were enrolled in this study. We collected data on 62 patients admitted to hospital with laboratory confirmed SARS-Cov-2 infection in seven designated tertiary hospitals in Zhejiang province (see supplementary file for further details). Information was collected on dates of illness onset, visits to clinical facilities, and hospital admissions. Epidemiological data were collected through brief interviews with each patient. Several investigators interviewed each patient to collect exposure histories during the two weeks before illness onset, including the dates and times of close contact (gathering, living, or working together) with individuals from Wuhan with confirmed or suspected SARS-Cov-2 infection. The incubation period was defined as the time from exposure to the onset of illness, which was estimated among patients who could provide the exact date of close contact with individuals from Wuhan with confirmed or suspected SARS-Cov-2 infection. We also investigated the possibility of familial clusters—that is, index patients who travelled to Wuhan and then infected others in their families.

We extracted the medical records of patients and sent these to the data collection centre in Hangzhou. A team of doctors who had been treating patients with covid-19 collected and reviewed the data. Because of the urgent need to collect data on this emerging pathogen, the requirement for informed consent was waived. We used a standardised case report form to collect clinical data. If information was not clear, the working group in Hangzhou contacted the doctor responsible for the treatment of the patient for clarification.

Laboratory confirmation and treatment

Sputum and throat swab specimens collected from all patients at admission were tested by real time polymerase chain reaction for SARS-Cov-2 RNA within three hours. Laboratory confirmation of the virus was performed using real time reverse transcription polymerase chain reaction.[9] Virus detection was repeated twice every 24 hours.

Laboratory tests were conducted at admission, including a complete blood count, serum biochemistry, and identification of other respiratory pathogens such as influenza A virus (H1N1, H3N2, H7N9), influenza B virus, respiratory syncytial virus, parainfluenza virus, and adenovirus. Most patients received antiviral treatment with interferon alpha inhalation (50 µg twice daily), lopinavir and ritonavir (400 mg twice daily and 100 mg twice daily, respectively), and arbidol (200 mg three times daily). Patients received treatment with corticosteroid (40-80 mg/day) and gamma globulin (15-20 g/day) for 3-5 days when their resting respiratory rate was more than 30 per minute, or oxygen saturation was below 93% without oxygen, or multiple pulmonary lobes showed more than 50% progression of disease in 48 hours on imaging. Patients also received treatment with probiotics in most cases. Quinolones and second generation beta lactams (oral and intravenous) were administered if fever lasted for more than seven days or C reactive protein levels were 30 mg/L or more (normal range 0-8 mg/L). Patients suspected of being infected with SARS-Cov-2 were discharged from hospital once the results of two real time reverse transcription polymerase chain reaction tests taken 24 hours apart were negative for SARS-Cov-2 antigens.

Statistical analysis

As a previous study[9] has shown that patients' condition worsens on the 10th day after illness onset, we divided the cohort into patients with symptoms for more than

BMJ: first published as 10.1136/bmj.m606 on 19 February 2020. Downloaded from http://www.bmj.com/ on 15 March 2023 by guest. Protected by copyright.

doi: 10.1136/bmj.m606 | *BMJ* 2020;368:m606 | the bmj

10 days and those with symptoms for less than 10 days. We summarised continuous variables as either means and standard deviations or medians with interquartile ranges. For categorical variables, we calculated the percentages of patients in each category. All analyses were done with SPSS software, version 22.0.

Patient and public involvement

This was a retrospective case series study and no patients were involved in the study design, setting the research questions, or the outcome measures directly. No patients were asked to advise on interpretation or writing up of results.

Results

Epidemiological characteristics

By 26 January 2020, clinical data were collected on 62 patients in Zhejiang province with laboratory confirmed SARS-Cov-2 infection. Twenty five (40%) of the patients were aged 19-40 years, 33 (53%) were aged 41-65 years, 2 (3%) were aged 10 and 11 years, and 2 (3%) were aged 65 years and older. The median age was 41 years (interquartile range 32-52 years; table 1). As of 26 January 2020, more than half of the 62 patients (35, 56%) were men. No patients had a history of exposure to the Huanan seafood market and all 62 patients had been exposed to individuals with confirmed SARS-Cov-2 infection. Among the 62 patients, 23 (37%) resided in Wuhan and the remaining 39 (63%) had made short term trips to Wuhan before illness onset. Fifty six (90%) patients could provide the exact date of close contact with someone with confirmed or suspected SARS-Cov-2 infection.

Of the 33 patients with symptoms for more than 10 days after illness onset, 10 (30%) were aged 19-40 years, 22 (67%) were aged 41-65 years, and 1 (3%) was older than 65 years. The median age of patients was 45 years (interquartile range 37-54 years; table 1).

Clinical features

Twenty of the 62 patients (32%) had underlying diseases—seven (11%) had liver disease, five (8%)

Percentages do not total 100% owing to missing data.

had hypertension, and one (2%) each had chronic obstructive pulmonary disease, diabetes, renal disease, and cerebrovascular disease. Twenty one of the 62 patients (34%) were associated with familial clusters.

Of the 33 patients with symptoms for more than 10 days after illness onset, 13 (39%) had underlying diseases: four (12%) patients had liver disease, four (12%) had hypertension, and one each had chronic obstructive pulmonary disease (3%), diabetes (3%), and cerebrovascular disease (3%). Among 56 patients who could provide the exact date of close contact with someone with confirmed or suspected SARS-Cov-2 infection, the median incubation period from exposure to symptoms was 4 days (interquartile range 3-5 days). The median time from onset of symptoms to first hospital admission was 2.0 (1.0-4.3) days. The most common symptoms at illness onset were fever (48, 77%), cough (50, 81%), expectoration (35, 56%), headache (21, 34%), myalgia or fatigue (32, 52%), diarrhoea (3, 8%), and haemoptysis (2, 3%). Only two (3%) patients developed shortness of breath. Among the 33 patients who had symptoms for more than 10 days after illness onset, the median incubation period from exposure to symptoms was 3 days (interquartile range 3-4 days). The median time from onset of symptoms to first hospital admission was 6.5 (5.0-9.0) days. The most common symptoms at onset of illness were cough (27, 82%), fever (24, 73%), expectoration (19, 58%), myalgia or fatigue (19, 58%), headache (15, 45%), diarrhoea (3, 9%), and haemoptysis (2, 6%). Only one (3%) patient developed shortness of breath.

On admission, the blood counts of 19 of the 62 (31%) patients showed leucopenia (white blood cell count <4×10^9/L) and 26 (42%) showed lymphopenia (lymphocyte count <1.0×10^9/L; table 2). The D-dimer levels were within normal range (median 0.2 mg/L (interquartile range 0.2-0.5 mg/L). Levels of aspartate aminotransferase increased in 10 (16%) patients.

BMJ: first published as 10.1136/bmj.m606 on 19 February 2020. Downloaded from http://www.bmj.com/ on 15 March 2023 by guest. Protected by copyright.

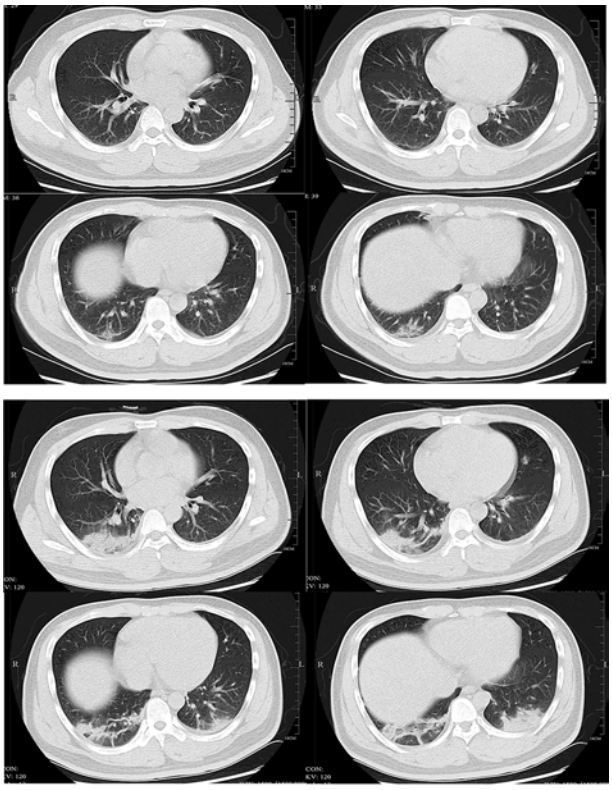

Fig 1 | Transverse chest computed tomograms from a 32 year old man, showing ground glass opacity and consolidation of lower lobe of right lung near the pleura on day 1 after symptom onset (top panel), and bilateral ground glass opacity and consolidation on day 7 after symptom onset (bottom panel)

Fifty five (89%) patients had normal serum levels of procalcitonin (<0.1 ng/mL). Abnormalities on chest computed tomograms or radiographs were detected among all of the patients except for one. Fifty two (84%) patients showed bilateral involvement on chest radiographs (table 2). Typical chest computed tomography findings of infected patients on admission were bilateral or multiple lobular or subsegmental areas of consolidation or bilateral ground glass opacity (fig 1). Only one patient did not have pneumonia. Of the 62 patients, only one was transferred to an intensive care unit for acute respiratory distress syndrome and received mechanical ventilation (table 3). Fifty five (89%) patients received antiviral treatment, 28 (45%) were given empirical antibiotic treatment, and 16 (26%) were given systematic corticosteroid and gamma globulin treatment. At this point, one (2%) patient had been discharged and no patients had died. Fitness for discharge was based on abatement of fever for at least three days, with improved evidence on chest radiography and viral clearance in samples from the lower respiratory tract.

Discussion

As of 8 February 2020, more than 30 000 laboratory confirmed cases of infection with the novel coronavirus (SARS-Cov-19) were reported in China.[12] The number of infections is increasing rapidly. It is possible that an even greater number of infected patients exist without a diagnosis because their symptoms were less severe and because of the incubation period. Thousands of patients with suspected SARS-Cov-2 infection could eventually receive a diagnosis. The clinical features of early cases of covid-19 in Wuhan were not the same as those in other areas of China. According to our data, none of the infected patients in Zhejiang province had been exposed to the Huanan seafood market, and as the number of familial clusters in infected patients in our study is large, this might suggest human to human transmission. This finding is also consistent with a published article.[10] Further detailed investigations should aim to ascertain the exact mode of transmission.

Most of the infected individuals in Zhejiang province were male patients, but the age range of patients is large as SARS-Cov-2 also infected children and those older than 65 years.[9 13] No major differences were found between the initial clinical symptoms of patients in Zhejiang province and those in Wuhan. Most of

FOI 26-3132 - Document 5

the patients in Zhejiang province, however, had mild to moderate symptoms, and only a small portion of them had dyspnoea. Only one patient developed acute respiratory distress syndrome and was admitted to an intensive care unit. The laboratory test results showed that the patients also experienced mild illness. There were fewer patients with abnormal renal function and lactate dehydrogenase and procalcitonin levels. Through media and national advocacy, patients with fever, cough, expectoration, and other upper respiratory tract symptoms were asked to go to hospital at an early stage. Even those who had contact with other patients, or patients with suspected infection were asked to go to hospital. We also analysed patients with symptoms for more than 10 days after illness onset. We found that the clinical features of patients with symptoms for longer than 10 days in Zhejiang province were less severe than those of the primary infected patients from Wuhan.[9 13] This phenomenon was also apparent during the transmission of MERS-CoV. The global case mortality of MERS-CoV was about 40%, whereas the mortality from second generation MERS-CoV was about 20%.[14 15]

Patients in the two cohorts received antiviral treatment, but the types of drugs used varied between patients. Treatment with lopinavir and ritonavir were reported to have the potential to treat SARS infections,[16] and we suppose this treatment might be a beneficial part of the treatment for covid-19. The rate of antibiotic and corticosteroid use was different. Less than half the patients in Zhejiang province received antibiotics. Whether the use of antivirals, antibiotics, or steroids affects the prognosis of patients remains unknown.

Given that most infections in Zhejiang province were in patients who had no direct contact with the original site of outbreak, our findings provide valuable information in the understanding of the clinical features of covid-19, as the number of people with confirmed disease continues to increase rapidly. Our study population might represent most of the clinical characteristics of infected patients since January 2020. Further containment proposals should be implemented by the Chinese government, such as preventing people from Wuhan having contact with those elsewhere, banning gatherings of more than 100 people, conducting daily public-wide educational campaigns on precautionary measures against exposure to SARS-Cov-2, encouraging people to cancel traditional family gatherings such as during the Chinese lunar new year, and extending the Chinese lunar new year holiday to prevent large scale spread.

Limitations of this study

Our study has several limitations. Firstly, only 62 patients were included. A large number of patients were continually being admitted to hospital as data were being collected, and thus we obtained data on most but not all of the patients with laboratory confirmed infection in Zhejiang province during the study period. Secondly, as the patients were only from Zhejiang province, it might be that more clinical features related to covid-19 will be identified. Thirdly, at the time of study submission, most patients had not been discharged, so we are unable to estimate either the case fatality rate or the predictors of fatality. Moreover, the time since illness onset in some of our patients might be shorter than the observation period of 10 days, which could result in biases of clinical observation characteristics.

Conclusion

Compared with the symptoms of the initial patients with SARS-Cov-2 infection in Wuhan, those of patients from Zhejiang province in our study were relatively mild. Currently, no effective drug treatment or vaccine exists. It is necessary for monitoring of the virus to be strengthened and drugs and vaccines to be developed against SARS-Cov-2 infection as soon as possible.

REVIEW ARTICLE

The mechanisms of action of Ivermectin against SARS-CoV-2: An evidence-based clinical review article

Asiya Kamber Zaidi[1,2] · Puya Dehgani-Mobaraki[3]

Abstract

Considering the urgency of the ongoing COVID-19 pandemic, detection of various new mutant strains and future potential re-emergence of novel coronaviruses, repurposing of approved drugs such as Ivermectin could be worthy of attention. This evidence-based review article aims to discuss the mechanism of action of ivermectin against SARS-CoV-2 and summarizing the available literature over the years. A schematic of the key cellular and biomolecular interactions between Ivermectin, host cell, and SARS-CoV-2 in COVID-19 pathogenesis and prevention of complications have been proposed.

Introduction

A relatively recent surge in zoonotic diseases has been noted over the past few decades. Several reasons could be responsible for this "spill-over" of disease-causing agents from animals to humans. These include an exponential rise in the global population causing man to encroach new ecological habitats in search of space, food, and resources as well as improved opportunities for rampant wildlife trade causing inter-species pathogen jumps. The 1980s was known for HIV/AIDS crisis that originated from the great apes, while the Avian flu pandemic in 2004-07 came from the birds. The pigs lead to the Swine flu pandemic in 2009 and bats were the original hosts of Ebola, Severe Acute Respiratory Syndrome (SARS), Middle Eastern respiratory syndrome (MERS), and probably Severe Acute Respiratory Syndrome coronavirus 2 (SARS-CoV-2) outbreak as well.

COVID-19 has already caused millions of deaths worldwide and has paralyzed not only the world's health-care system but also the political and economic relations between countries [1]. The fact that the SARS-CoV-2 virus has been thought to have originated from wildlife and may have "jumped" into humans, not only highlights future risks from animal-borne diseases but also provides an important clue to its resolution. In such a scenario, where this "jump" has been made from animal to human, it seems only logical to review a drug that has worked efficiently against a disease-causing agent and is available in a form that is safe for human consumption since the early 1980 s.

Ivermectin belongs to a group of avermectins (AVM), which is a group of 16 membered macrocyclic lactone compounds discovered at the Japanese Kitasato institute in 1967 during actinomycetes cultures with the fungus *Streptomyces avermitilis* [2]. This drug radically lowered the incidence of river blindness and lymphatic filariasis and was discovered and developed by William C. Campbell and Satoshi Ōmura for which they received the Nobel Prize in Physiology or Medicine in 2015 [3, 4]. Ivermectin is enlisted in the World Health Organization's Model List of Essential Medicines [5].

Drug repurposing, drug redirecting, or drug reprofiling is defined as the identification of novel usages for existing drugs. The development risks, costs as well as safety-related failure, are reduced with this approach since these drugs have a well-established formulation development, in vitro and in vivo screening, as well as pharmacokinetic and pharmacodynamic profiles. Moreover, the first clinical trial phases of many such drugs have been completed and can be bypassed to reduce several years of development. Therefore, drug repurposing has the potential to reduce the time frame for the whole process by up to 3–12 years and carries great potential [6].

Table 1 All 55 ivermectin COVID-19 trials (As per data available on 16 May 2021) divided based on stage of treatment (Early Vs Late) and the type of study

Study	Study Type
EARLY TREATMENT	
Random effects meta-analysis with pooled effects showed 79% improvement for early treatment RR 0.21 and CI [0.11-0.37]	
Double-Blind Randomized controlled trial	Mahmud et al.*, Ahmed et al.*, Chaccour et al.*, Babalola et al.*, Kirti et al., Mohan et al., Schwartz et al., Lopez- Medina et al.*, Chahla et al.
Single-blind Randomized controlled trial	Raad et al.
Randomized controlled trial	Bukhari et al., Chowdhury et al.*, Faisal et al.*
Retrospective quasi-randomized study	Loue et al*, Merino et al
Other studies	Espitia-Hernandez et al.*, Carvallo et al., Cadegiani et al., Afsar et al., Elalfy et al.*, Roy et al., Mourya et al.*
LATE TREATMENT	
Random effects meta-analysis with pooled effects showed 46% improvement for late treatment RR 0.54 and CI [0.40-0.72]	
Randomized controlled trial	Kishoria et al.*, Podder et al.*, Chachar et al.*, Elgazzar et al.. Pott-Junior et al.*
Double-Blind Randomized controlled trial	Niaee et al.,Okumus et al.*, Shahbazn et al.*, Gonzalez et al.*. Huvemek et al.
Single-Blind Randomized controlled trial	Hashim et al.
Other studies	Gorial et al., Khan et al., Soto-Becerra et al, Rajter et al.*, Camprubi et al.*, Spoorthi et al*, Budhiraja et al., Lima Morales et al.*

The 29 peer-reviewed trials have been marked with an asterisk as a superscript. (*) (source: https://ivmmeta.com/)

Although several drugs received Emergency Use Authorization for COVID-19 treatment with unsatisfactory supportive data, Ivermectin, on the other hand, has been sidelined irrespective of sufficient convincing data supporting its use. Nevertheless, many countries adopted ivermectin as one of the first-line treatment options for COVID-19.

With the ongoing vaccine roll-out programs in full swing across the globe, the longevity of the immunity offered by these vaccines or their role in offering protection against new mutant strains is still a matter of debate. The adoption of Ivermectin as a "safety bridge" by some sections of the population that are still waiting for their turn for vaccination could be considered as a "logical" option.

Several doctor-initiated clinical trial protocols that aimed to evaluate outcomes, such as reduction in mortality figures, shortened length of intensive care unit stay and/or hospital stay and elimination of the virus with ivermectin use have been registered at the US ClinicalTrials.gov [7]. Real-time data is also available with a meta-analysis of 55 studies to date. As per data available on 16 May 2021, 100% of 36 early treatment and prophylaxis studies report positive effects (96% of all 55 studies). Of these, 26 studies show statistically significant improvements in isolation. Random effects meta-analysis with pooled effects using the most serious outcome reported 79% and 85% improvement for early treatment and prophylaxis respectively (RR 0.21 [0.11–0.37] and 0.15 [0.09–0.25]). The results were similar after exclusion based sensitivity analysis: 81% and 87% (RR 0.19 [0.14–0.26] and 0.13 [0.07–0.25]), and after restriction to 29 peer-reviewed studies: 82% and 88% (RR 0.18 [0.11–0.31] and 0.12 [0.05–0.30]). Statistically significant improvements were seen for mortality, ventilation, hospitalization, cases, and viral clearance. 100% of the 17 Randomized Controlled Trials (RCTs) for early treatment and prophylaxis report positive effects, with an estimated improvement of 73% and 83% respectively (RR 0.27 [0.18–0.41] and 0.17 [0.05–0.61]), and 93% of all 28 RCTs. These studies are tabulated in Table 1. The probability that an ineffective treatment generated results as positive for the 55 studies to date is estimated to be 1 in 23 trillion ($p = 0.000000000000043$). The consistency of positive results across a wide variety of cases has been remarkable. It is extremely unlikely that the observed results could have occurred by chance [8].

However, a controlled outpatient trial by López-Medina et al. demonstrated that, in mild COVID-19, Ivermectin showed no improvement [9]. Misinterpretation of results were noted due to possible gaps in regards to the study quality (study design, the methodology adopted, statistical analysis, and hence the conclusion).

Ivermectin has rapid oral absorption, high liposolubility, is widely distributed in the body, metabolized in the liver (cytochrome P450 system) and excreted almost exclusively in feces [4]. Following a standard oral dose in healthy humans, it reaches peak plasma levels at 3.4 to 5 h; and plasma half-life has been reported to be 12 to 66 h [10]. Despite its widespread use, there are relatively few studies

Table 2 A list of studies demonstrating the role of Ivermectin (IVM) on SARS-CoV-2

MAIN ROLE OF IVERMECTIN AGAINST SARS-COV-2	STUDY AUTHORS	STUDY YEAR	REFERENCES
A. DIRECT ACTION ON SARS-COV-2			
Level 1: Action on SARS-CoV-2 cell entry			
IVM docks in the region of leucine 91 of the spike protein and histidine 378 of the ACE2 receptor	Leher et al.	2020	[22]
IVM has the highest binding affinity to the predicted active site of the S glycoprotein; Considerable binding affinity to the predicted active site of the SARS-CoV-2 RdRp protein; Highest binding affinity to the predicted active site of nsp14; highest binding affinity to the active site of the TMPRSS2 protein	Eweas et al.	2021	[23]
IVM utilizes viral spike protein, main protease, replicase, and human TMPRSS2 receptors as the most possible targets for executing its antiviral efficiency by disrupting binding	Choudhury et al.	2021	[24]
Level 2: Action on Importin (IMP) superfamily			
in presence of a viral infection, IVM targets the IMPα component of the IMP α/β1 heterodimer and binds to it, preventing interaction with IMP β1, subsequently blocking the nuclear transport of viral proteins.	Yang, S.N.Y et al.	2020	[26]
Level 3: Action as an Ionophore			
Two ivermectin molecules, reacting with each other in a "head-tail" mode, can create a complex suitable to be considered as ionophore. These ionophores allow neutralizing the virus at an early stage of the infection before it can adhere to the host cells and enter it.	Rizzo E et al.	2020	[28]
B. ACTION ON HOST TARGETS FOR VIRAL REPLICATION			
Level 4: Action as an antiviral			
IVM has antiviral properties against other viruses including the RNA viruses such as Zika Virus (ZKV), Dengue virus, yellow fever virus (YFV), and West Nile virus (WNV), Hendra virus (HEV), Newcastle virus, Venezuelan equine encephalitis virus (VEEV), Chikungunya virus (CHIKV), Semliki Forest virus (SFV), and Sindbis virus (SINV), Avian influenza A virus, Porcine Reproductive and Respiratory Syndrome virus (PRRSV), Human immunodeficiency virus type 1 as well as DNA viruses such as Equine herpesvirus type 1 (EHV-1) and Pseudorabies virus (PRV).	Heidary, F et al.	2020	[29]
Level 5: Action on viral replication and assembly			
In Vero/hSLAM cells infected with the SARS-CoV-2 virus when "exposed" to 5 μM IVM showed a 5000-fold reduction in viral RNA at 48 h when compared to the control group	Caly L et al.	2020	[30]
utilizing modeling approach, predicted lung accumulation of Ivermectin over 10 times higher than EC 50	Arshad et al	2020	[31]
best binding interaction between IVM and RNA-dependent RNA polymerase (RdRp)	Swargiary et al.*	2020	[33]
highly efficient binding of IVM to nsp14	Ma et al.	2015	[35]
highly efficient binding of IVM to the viral N phosphoprotein and M protein	Eweas et al.	2021	[23]
Level 6: Action on post-translational processing of viral polyproteins			
IVM binds to both proteins, Mpro, and to a lesser extent to PLpro of SARS-CoV-2	Eweas et al.	2021	[23]
Level 7: Action on Karyopherin (KPNA/KPNB) receptors			
IVM inhibits the KPNA/KPNB1- mediated nuclear import of viral proteins	Caly L et al.	2020	[30]
C. ACTION ON HOST TARGETS FOR INFLAMMATION			
Level 8: Action on Interferon (INF) levels			
IVM promotes the expression of several IFN-related genes, such as IFIT1, IFIT2, IF144, ISG20, IRF9, and OASL	Seth C	2016	[40]
Level 9: Action on Toll- like-Receptors (TLRs)			
IVM blocks activation of NF-kappa B pathway and inhibition of toll-like receptor 4 (TLR4) signaling	Zhang X et al.	2008	[42]
Level 10: Action on Nuclear Factor-κB (NF-κB) pathway			
IVM at its very low dose, which did not induce cytotoxicity, drastically reversed the resistance of tumor cells to the chemotherapeutic drugs both in vitro and in vivo by inhibition of the transcriptional factor NF-κB.	Jiang L et al.	2019	[44]

Table 2 (continued)

MAIN ROLE OF IVERMECTIN AGAINST SARS-COV-2	STUDY AUTHORS	STUDY YEAR	REFERENCES
IVM inhibits lipopolysaccharide (LPS)-induced production of inflammatory cytokines by blocking the NF-κB pathway and improving LPS-induced survival in mice.	Zhang X et al.	2008	[42]
Level 11: Action on the JAK-STAT pathway, PAI-1 and COVID-19 sequalae			
IVM inhibits STAT-3, SARS-CoV-2-mediated inhibition of IFN and STAT 1, with the subsequent shift to a STAT 3- dominant signaling network that could result in almost all of the clinical features of COVID-19; STAT-3 acts as a "central hub" that mediates the detrimental COVID-19 cascade	Matsuyama, T.,	2020	[39]
STAT-3 induces a C-reactive protein that upregulates PAI-1 levels. Ivermectin inhibits STAT-3.	Matsuyama, T.,	2020	[39]
The PD-L1 receptors present on the endothelial cells are activated by STAT-3 causing T cell lymphopenia. IVM inhibits STAT-3 through direct inhibition	Matsuyama, T.,	2020	[39]
Level 12: Action on P21 activated Kinase 1 (PAK-1)			
IVM suppresses the Akt/mTOR signaling and promotes ubiquitin-mediated degradation of PAK-1 hence compromising STAT-3 activity and decreasing IL-6 production.	Dou Q et al.	2016	[54]
Level 13: Action on Interleukin-6 (IL-6) levels			
IVM suppressed IL-6 and TNFα production	Zhang X et al.	2008	[42]
IVM "dramatically reduced" IL-6/IL-10 ratio modulating infection outcomes.	G D de Melo et al. *	2020	[55]
Level 14: Action on allosteric modulation of P2X4 receptor			
Positive allosteric modulation of $P2X_4$ by IVM enhances ATP-mediated secretion of CXCL5	Layhadi JA et al.	2018	[58]
Level 15: Action on high mobility group box 1 (HMGB1)			
Ivermectin inhibits HMGB1	Juarez M et al.	2018	[60]
Level 16: Action as an immunomodulator on Lung tissue and olfaction			
No olfactory deficit was observed in IVM-treated females; IVM dramatically reduced the IL-6/IL-10 ratio in lung	G D de Melo et al. *	2020	[55]
Level 17: Action as an anti-inflammatory			
anti-inflammatory action of IVM was explained as inhibition of cytokine production by lipopolysaccharide challenged macrophages, blockade of activation of NF-kB, and the stress-activated MAP kinases JNK and p38, and inhibition of TLR4 signaling.	Zhang X et al., Ci X et al., Yan S et al.	2008 2009 2011	[42, 62, 63]
Immune cell recruitment, cytokine production in bronchoalveolar lavage fluid, IgE, and IgG1 secretion in serum as well as hyper-secretion of mucus by goblet cells was reduced significantly by IVM	Yan S et al.	2011	[63]
D. ACTION ON OTHER HOST TARGETS			
Level 18: Action on Plasmin and Annexin A2			
Annexin acts as a co-receptor for the conversion of plasminogen to plasmin in the presence of t-PA. increased levels of plasmin leads to direct activation of STAT-3.	Kamber Zaidi et al.	2020	[64]
IVM directly inhibits STAT-3 and could play a role in the inhibition of COVID-19 complications.	Matsuyama et al.	2020	[39]
Level 19: Action on CD147 on the RBC			
The SARS-CoV-2 does not internalize into the red blood cells but such attachments can lead to clumping. IVM binds to the S protein of the SARS-CoV-2 virus making it unavailable to bind with CD147.	David E.Scheim et al.	2020	[65]
Level 20: Action on mitochondrial ATP under hypoxia on cardiac function			
IVM increased mitochondrial ATP production by inducing Cox6a2 expression and maintains mitochondrial ATP under hypoxic conditions. This prevents pathological hypertrophy and improves cardiac function.	Nagai H et al.	2017	[67]

*available as preprint; Clinical trials of IVM on COVID-19 available on https://clinicaltrials.gov[7]; Ivermectin for COVID-19: real-time meta-analysis available on https://ivmmeta.com [8]

FOI 26-3132 - Document 5

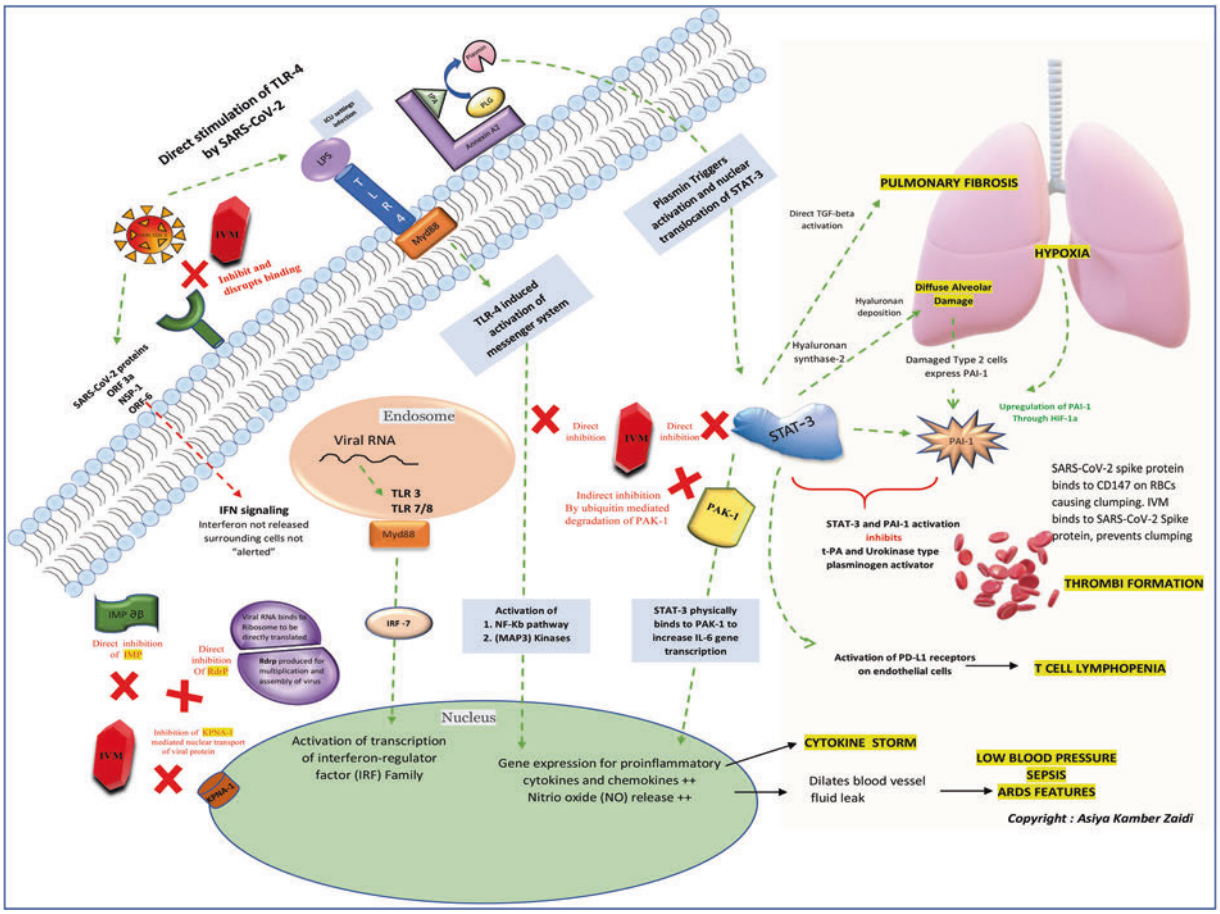

Fig. 1 A schematic of the key cellular and biomolecular interactions between Ivermectin, host cell, and SARS-CoV-2 in COVID-19 pathogenesis and prevention of complications. Ivermectin; IVM (red block) inhibits and disrupts binding of the SARS-CoV-2 S protein at the ACE-2 receptors (green). The green dotted lines depict activation pathways and the red dotted lines depict the inhibition pathways. The TLR-4 receptors are directly activated by SARS-CoV-2 and also by LPS mediated activation (seen during ICU settings) causing activation of NF-Kb pathway and MAP3 Kinases leading to increased intranuclear gene expression for proinflammatory cytokines and chemokines (responsible for cytokine storm) and NO release (responsible for blood vessel dilatation, fluid leak, low blood pressure, ARDS and sepsis). The NF-Kb and STAT-3 pathway activation is central to the pathogenesis and sequelae of COVID-19. STAT-3 physically binds to PAK-1 and increases IL-6 transcription. The annexin A2 at the cell surface converts plasminogen; PLG to plasmin under the presence of t-PA. Plasmin triggers activation and nuclear translocation of STAT-3. An upregulation of STAT-3 stimulates hyaluronan synthase-2 in the lung cells causing hyaluronan deposition leading to diffuse alveolar damage and hypoxia. STAT-3 also directly activates TGF-beta initiating pulmonary fibrosis; a typical characteristic of SARS-COV-2 lung pathology. The damaged type 2 cells express PAI-1 and an already hypoxic state also causes an upregulation of PAI (through Hypoxic inducible factor-1) along with direct stimulation by STAT-3. Simultaneous STAT-3 and PAI-1 activation inhibits t-PA and urokinase-type plasminogen activator leading to thrombi formation. Also, the SARS-CoV-2 spike protein binds to the CD147 on red blood cells and causes clumping. *IVM in turn, binds to SARS-CoV-2 Spike protein and hence prevents clumping*. T cell lymphopenia in COVID-19 can also be attributed to the direct activation of PD-L1 receptors on endothelial cells by STAT-3. *IVM directly inhibits the NF-kb pathway, STAT-3, and indirectly inhibits PAK-1 by increasing its ubiquitin-mediated degradation*. The natural antiviral response of a cell is through interferon regulatory genes and viral RNA mediated activation of TLR-3 and TLR7/8- Myd88 activation of transcription of interferon-regulator (IRF) family. For a virus to establish an infection, this antiviral response needs to be inhibited by blocking interferon production. The proteins such as importin and KPNA mediate nuclear transport of viral protein and subsequent IFN signaling. The SARS-CoV-2 proteins (ORF-3a, NSP-1, and ORF-6) directly block IFN signaling causing the surrounding cells to become unsuspecting victims of the infection. *IVM inhibits both importin a-b (green) as well as the KPNA-1 receptors (brown) causing natural antiviral IFN release. IVM also inhibits viral RdrP, responsible for viral replication*. *IVM* Ivermectin, *ACE-2* angiotensin-converting-enzyme 2, *LPS* Lipopolysaccharide, *TLR* Toll-like receptor, *t-PA* tissue-like plasminogen activator, *PLG* Plasminogen, *IMPab* Importin alpha-beta, *Rdrp* RNA dependant RNA polymerase, *KPNA-1* Karyopherin Subunit Alpha 1, *NF-kB* nuclear factor kappa-light-chain-enhancer of activated B cells, *Map3Kinases* Mitogen-activated Kinases, *PAK-1* P21 Activated Kinase 1, *STAT-3* Signal transducer and activator of transcription 3, *PAI-1* Plasminogen activator inhibitor-1, *HIF-1* Hypoxia-Inducible Factor

on the pharmacokinetics of Ivermectin in humans [11]. Ivermectin binds strongly to plasma proteins in healthy subjects (93.2%) [12]. Such an "avid binding" can be beneficial when administered in countries where malnutrition and hypoalbuminemia are common, leading to an increased availability of "free fraction" of ivermectin [4].

Hypoalbuminemia is a frequent finding in patients with COVID-19 and it also appears to be linked to the severity of lung injury [13]. Therefore, Ivermectin might be useful when used in such a setting.

There is evidence supporting the use of Ivermectin in decreasing mortality figures in patients with SARS-CoV-2 infection. However, the use of ivermectin orally in an outpatient setting also requires strict and well defined guidelines to avoid any form of overdosing that could lead to toxicity. A study by Baudou, E et. al described two human ABCB1 nonsense mutations associated with a loss of function in a patient who had an adverse reaction to ivermectin after the administration of a usual dose. This finding warrants caution regarding medical prescriptions of ivermectin and other ABCB1 substrates [14].

This article aims to discuss the mechanism of action by summarizing the in vitro and in vivo evidence demonstrating the role of Ivermectin in COVID-19 as per the available literature over the years. [Table 2] A schematic of the key cellular and biomolecular interactions between Ivermectin, host cell, and SARS-CoV-2 in COVID-19 pathogenesis and prevention of complications has been proposed. [Fig. 1]

Methods

A comprehensive search of the PubMed database was conducted from January 1, 2008 up to January 30, 2021 using syntax constructed using MeSH Database as follows: (stromectol OR Ivermectin OR "dihydroavermectin") OR (22 AND 23-dihydroavermectin B) AND (antiviral OR virus OR COVID-19 OR SARS-CoV-2). All the results obtained were manually reviewed for content, relevance and included when considered appropriate. The papers cited in the references were also reviewed and included when considered appropriate. The articles were retrieved manually to exclude any duplicates.

Results

Ivermectin as an anti-helminth

Ivermectin has been approved as an anti-helminthic [15]. It is a selective positive allosteric modulator at the glutamate-gated chloride channels found in nematodes and insects and acts by binding to these channels leading to chloride ion influx causing hyperpolarization of the cell and hence, dysfunction [16]. However, at higher concentrations, Ivermectin can also bind to host GABA receptors only when the blood-brain barrier (BBB) is "leaky". This is not the case in healthy human beings with an intact BBB as the drug is "excluded" by a *p*-glycoprotein drug pump (MDR-1). Chandler et al. considered Ivermectin to be free of potential neurological adverse drug reactions, except in situations of overdose [17].

SARS-CoV-2 virus structure

SARS-CoV-2 is a sarbecovirus with structural similarity to SARS-CoV-1. Out of the four structural proteins of the SARS-CoV-2 beta coronavirus, namely: Spike (S) protein, membrane (M) protein, envelope (E) protein, and nucleocapsid (N) protein, the S protein is responsible for eliciting potent neutralizing antibody responses. The entry of SARS-CoV-2 into the host cell is mediated by the binding of the S1 subunit of its S protein (receptor binding domain) to the Angiotensin-converting enzyme 2 (ACE-2) receptors present on the host cell surface [18]. The S2 subunit is associated with a fusion protein that binds with the cell membrane after priming with Transmembrane protease, serine 2 (TMPRSS-2) and is responsible for fusion with the host cell.

The SARS-CoV-2 genome consists of ~29.8 kb nucleotides; it possesses 14 open reading frames (ORFs) encoding 27 proteins [19]. The 5′ two-thirds of the viral genome encodes the replicase gene. It contains two ORFs: ORF1a and ORF1b. ORF1a/b encodes two polyproteins by polymerase frameshifting; these are then post-translationally cleaved into 15 non-structural proteins (nsps): nsp1–10 and nsp12–16. The rest of the genome encodes for the four structural proteins [(S protein, E protein, M protein, N protein], in addition to eight accessory proteins (3a/3b, p6, 7a/7b, 8b, 9b, and ORF14) [19]. The replicase also encodes the papain-like protease (PLpro) and the serine-type protease or main protease (Mpro) [20].

In principle, a molecule can act as an anti-viral drug if it "inhibits some stage of the virus replication cycle, without being too toxic to the body's cells [21]."

The possible modes of action of anti-viral agents would include the following:

1. Inactivate extracellular virus particles.
2. Prevent viral attachment and/or entry.
3. Prevent replication of the viral genome.
4. Prevent synthesis of specific viral protein(s).
5. Prevent assembly or release of new infectious virions

The role of Ivermectin against the SARS-CoV-2 virus

The targets of activity of Ivermectin can be divided into the following four groups:

A. *Direct action on SARS-CoV-2*
   Level 1: Action on SARS-CoV-2 cell entry
   Level 2: Action on Importin (IMP) superfamily
   Level 3: Action as an Ionophore
B. *Action on host targets important for viral replication*
   Level 4: Action as an antiviral
   Level 5: Action on viral replication and assembly
   Level 6: Action on post-translational processing of viral polyproteins
   Level 7: Action on Karyopherin (KPNA/KPNB) receptors
C. *Action on host targets important for inflammation*
   Level 8: Action on Interferon (INF) levels
   Level 9: Action on Toll- like-Receptors (TLRs)
   Level 10: Action on Nuclear Factor-κB (NF-κB) pathway
   Level 11: Action on the JAK-STAT pathway, PAI-1 and COVID-19 sequalae
   Level 12: Action on P21 activated Kinase 1 (PAK-1)
   Level 13: Action on Interleukin-6 (IL-6) levels
   Level 14: Action on allosteric modulation of P2X4 receptor
   Level 15: Action on high mobility group box 1 (HMGB1),
   Level 16: Action as an immunomodulator on Lung tissue and olfaction
   Level 17: Action as an anti-inflammatory
D. *Action on other host targets*
   Level 18: Action on Plasmin and Annexin A2
   Level 19: Action on CD147 on the RBC
   Level 20: Action on mitochondrial ATP under hypoxia on cardiac function

The direct "antiviral targets" may be useful in the early stages while the anti-inflammatory targets might be addressed in the later stages of the disease.

Direct action of Ivermectin on SARS-CoV-2

Level 1: Action on SARS-CoV-2 cell entry

A study by Lehrer S et al observed that Ivermectin docked in the region of leucine 91 of the SARS-CoV-2 spike protein and histidine 378 of the host cell ACE-2 receptor blocking its entry into the host cell [22]. In yet another study by Eweas et al., potential repurposed drugs such as Ivermectin, chloroquine, hydroxychloroquine, remdesivir, and favipiravir were screened and molecular docking with different SARS-CoV-2 target proteins including S and M proteins, RNA-dependent RNA polymerase (RdRp), nucleoproteins, viral proteases, and nsp14, was performed. Ivermectin showed the following 5 important docking properties [23]:

1. Highest binding affinity to the predicted active site of the S glycoprotein (Mol Dock score −140.584) and protein–ligand interactions (MolDock score−139.371).
2. Considerable binding affinity to the predicted active site of the SARS-CoV-2 RdRp protein (MolDock score −149.9900) and protein–ligand interactions (MolDock score −147.608), it formed H-bonds with only two amino acids: Cys622 and Asp760.
3. Highest binding affinity (MolDock score −212.265) to the predicted active site of nsp14.
4. The highest binding affinity to the active site of the TMPRSS2 protein (MolDock score −174.971) and protein–ligand interactions (MolDock score −180.548). Moreover, it formed five H-bonds with Cys297, Glu299, Gln438, Gly462, and Gly464 amino acid residues present at the predicted active site of the TMPRSS protein
5. The free binding energy of the spike protein (open) was higher in Ivermectin (−398.536 kJ/mol) than remdesivir (−232.973 kJ/mol).

An In-silico data analysis conducted by Choudhury et al. demonstrated that Ivermectin efficiently utilizes viral spike protein, main protease, replicase, and human TMPRSS2 receptors as the most possible targets for executing its "antiviral efficiency" by disrupting binding. Since Ivermectin exploits protein targets from both, the virus and human, this could be the behind its excellent in vitro efficacy against SARS-CoV-2 [24].

The development of vaccines for SARS-CoV-2 is centered around spike protein biology (virus targeted) and the recently documented "vaccine escape strains" have been a cause of worry. In such a situation, Ivermectin, is both, virus as well as host targeted and hence could act as a potential therapeutic against these new strains that could "escape" immunity offered by the vaccine.

Level 2: Action on Importin (IMP) superfamily

Inside the cell, the nuclear transport of proteins into and out of the nucleus is signal-dependent and mediated by the Importin (IMP) superfamily of proteins that exist in α and β forms. This IMPα/β1 exists as a heterodimer with a "IBB" (IMP β-binding) site present over IMP α that binds to IMP β1 on "cargo recognition" by IMPα. The SARS-CoV-2 virus upon host cell entry tends to "load" its proteins over the host protein IMP α/β1 heterodimer (importin) to enter the nucleus through the nuclear pore complex. Once inside, the importin molecule detaches while the viral protein from the SARS-CoV-2 virus hijacks the host cell machinery and inhibits the natural cell "anti-viral" response by blocking the release of

interferon (an antiviral substance released by an infected cell to alert the surrounding cells of an ongoing viral attack). As a result, the surrounding cells become "unsuspecting victims" of the virus and the infection continues with the virus escaping recognition by the immune cells [25]. Ivermectin, in presence of a viral infection, targets the IMPα component of the IMP α/β1 heterodimer and binds to it, preventing interaction with IMP β1, subsequently blocking the nuclear transport of viral proteins. This allows the cell to carry out its normal antiviral response [26]. In such a case, it should be noted that the activity of Ivermectin here is viro-static, that is, it neutralizes the virus by competing for the same receptor.

Level 3: Action as an Ionophore

Ionophores are molecules that typically have a hydrophilic pocket which constitutes a specific binding site for one or more ions (usually cations), while its external surface is hydrophobic, allowing the complex thus formed to cross the cell membranes, affecting the hydro-electrolyte balance [27]. It can be hypothesized that two ivermectin molecules, reacting with each other in a "head-tail" mode, can create a complex suitable to be considered such [28]. These ionophores allow neutralizing the virus at an early stage of the infection before it can adhere to the host cells and enter it to exploit their biochemical machinery for the production of other viral particles.

Action on host targets for viral replication

Level 4: Action as an antiviral

A systematic review article by Heidary, F. discussed the "anti-viral" properties of Ivermectin against other viruses including the RNA viruses such as Zika Virus (ZKV), Dengue virus, yellow fever virus (YFV), and West Nile virus (WNV), Hendra virus (HEV), Newcastle virus, Venezuelan equine encephalitis virus (VEEV), Chikungunya virus (CHIKV), Semliki Forest virus (SFV), and Sindbis virus (SINV), Avian influenza A virus, Porcine Reproductive and Respiratory Syndrome virus (PRRSV), Human immunodeficiency virus type 1 as well as DNA viruses such as Equine herpesvirus type 1 (EHV-1) and Pseudorabies virus (PRV) [29].

Level 5: Action on viral replication and assembly

An in-vitro study by Caly L et al. demonstrated that the Vero/hSLAM cells infected with the SARS-CoV-2 virus when "exposed" to 5 μM Ivermectin showed a 5000-fold reduction in viral RNA at 48 h when compared to the control group [30]. This study attracted opinions regarding the inability of Ivermectin to achieve the therapeutic effect of COVID-19 through routine dosage. Contrary to this, Arshad et al, by utilizing modeling approach, predicted lung accumulation of Ivermectin over 10 times higher than EC_{50}. This likelihood of attainment of higher lung tissue concentrations of Ivermectin leaves the door open for further research especially for respiratory infections [31].

An explanation for the study by Caly et al was provided in a review article: Global trends in clinical studies of ivermectin in COVID-19 by Yagisawa et al., co-authored by Prof. Satoshi Ōmura, regarding the "setting of the sensitivity for experimental systems in vitro". As per the authors, using Vero/hSLAM cells, the antiviral activity of the test drug was reliably measured and the sensitivity of the $IC_{50} = 2\,\mu M$ set by them was appropriate as neither false positives nor false negatives occurred. Therefore, the study by Caly et al. merely indicated that ivermectin was found to have anti-SARS-CoV-2 activity in vitro—no more, no less. Also, the fact that there are in vivo infection experiments that could be used to connect in vitro experiments to clinical studies [32].

Another in-silico study by Swargiary et al. demonstrated the best binding interaction of −9.7 kcal/mol between Ivermectin and RdRp suggesting inhibition of viral replication [33]. The RdRP residing in nsp12 is the centerpiece of the coronavirus replication and transcription complex and has been suggested as a promising drug target as it is a crucial enzyme in the virus life cycle both for replication of the viral genome but also for transcription of subgenomic mRNAs (sgRNAs) [34]. Ivermectin binds to the viral rdrp and disrupts it. The highly efficient binding of ivermectin to nsp14 confirms its role in inhibiting viral replication and assembly. It is well known that nsp14 is essential in transcription and replication. It acts as a proofreading exoribonuclease and plays a role in viral RNA capping by its methyltransferase activity [35]. Moreover, highly efficient binding of ivermectin to the viral N phosphoprotein and M protein is suggestive of its role in inhibiting viral replication and assembly [23].

Level 6: Action on post-translational processing of viral polyproteins

Once gaining entry into the host cell, the viral RNA is translated by the host ribosome into a large "polyprotein". Some enzymes break away through autoproteolysis from this polyprotein and further help other proteins to break off and carry out their function for replication. One such enzyme, 3 chymotrypsin-like proteases (3'cl pro/ Mpro) is responsible for working on this polyprotein causing other proteins to "librate" and carry out viral replication. Ivermectin binds to this enzyme and disrupts it. It also efficiently binds to both proteins, Mpro, and to a lesser extent to PLpro of SARS-CoV-2; therefore, it has a role in preventing the post-translational processing of viral polyproteins [23].

Level 7: Action on Karyopherin (KPNA/KPNB) receptors

Karyopherin-α1 (KPNA1) is essential for the nuclear transport of signal transducers and activators of transcription 1 (STAT1) [36], and the interaction between STAT1 and KPNA1 (STAT1/KPNA1) involves a nonclassical nuclear

localization signal (NLS). Ivermectin inhibits the KPNA/KPNB1- mediated nuclear import of viral proteins allowing the cell to carry out its normal antiviral response [30].

Action on host targets for inflammation

Level 8: Action on Interferon (INF) levels

These virus-infected cells release interferons that bind to the IFN receptors present on neighboring cells alerting them of a viral attack. The IFN-I and IFN-III receptors then further activate members of the JAK-STAT family. The virus after gaining entry into the host cell hijacks the host cell machinery and works towards antagonizing the normal interferon-mediated host cell antiviral response. SARS-CoV-2 proteins such as ORF3a, NSP1, and ORF6 inhibit IFN-I signaling [37, 38]. As a result, the cells surrounding the SARS-CoV-2 virus-infected cell "fail" to receive "critical and protective IFN signals" causing this SARS-CoV-2 virus to replicate and spread without any hindrance. This is one of the main reasons that, at this stage, COVID-19 infection is "hard to detect" clinically [39].

Ivermectin has been shown to promote the expression of several IFN-related genes, such as IFIT1, IFIT2, IF144, ISG20, IRF9, and OASL [40].

Level 9: Action on Toll- like-Receptors (TLRs)

Upon virus entry, the intracellular pattern recognition receptors (PRRs) present on the host cells are responsible for detecting the viral attack. The virus activates one such PRR named the Toll-like receptors (TLRs). These receptors are present on various immune system cells that help them locate and bind with the pathogen. The activation of TLRs, causes oligomerization, further activating downstream interferon regulatory factors (IRFs) and nuclear factor-kappa B (NF-kB) transcription factors inducing INF production [41]. Ivermectin plays a role in the blockade of activation of NF-kB pathway and inhibition of TLR4 signaling [42].

Level 10: Action on Nuclear Factor-κB (NF-κB) pathway

Activation of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathway induces the expression of various pro-inflammatory genes, including those encoding cytokines and chemokines [43]. Jiang et al. demonstrated that Ivermectin at its very low dose, which did not induce cytotoxicity, drastically reversed the resistance of tumor cells to the chemotherapeutic drugs both in vitro and in vivo by inhibition of the transcriptional factor NF-κB [44]. Also, Zhang et al., suggested that Ivermectin inhibits lipopolysaccharide (LPS)-induced production of inflammatory cytokines by blocking the NF-κB pathway and improving LPS-induced survival in mice [42]. Therefore, using Ivermectin would be helpful in ICU settings where there are increased chances of bacterial infections (LPS mediated).

Level 11: Action on the JAK-STAT pathway, PAI-1 and COVID-19 sequalae

A strong correlation exists between SARS-CoV-2 viral load, disease severity, and progression [45]. COVID-19 not only causes flu-like symptoms such as fever, dry cough but could also lead to widespread thrombosis with micro-angiopathy in pulmonary vessels [46], raise D-dimer levels [47], cause lymphopenia [48], raise proinflammatory cytokine and chemokine production [49] as well as lead to a significant elevation of CRP levels [50]. SARS-CoV-2 has structural similarity with SARS-CoV-1. Several SARS-CoV-1 proteins antagonize the antiviral activities of IFNs and the downstream JAK (Janus kinase)-STAT signaling pathways they activate. JAK family kinases display a wide range of functions in ontogeny, immunity, chronic inflammation, fibrosis, and cancer [51].

The host proteins, such as the members of the signal transducers and activators of transcription (STATs) and NF-κB, enter the nucleus through nuclear envelope-embedded nuclear pores mediated by the IMPα/β1 heterodimer and play a role in COVID-19 pathogenesis. Frieman et al. demonstrated that accessory SARS ORF6 antagonizes STAT1 function by sequestering nuclear import factors on the rough endoplasmic reticulum/Golgi membrane [52]. A review article by Matsuyama et al, hinted at SARS-CoV-2-mediated inhibition of IFN and STAT 1, with the subsequent shift to a STAT 3 dominant signaling network that could result in almost all of the clinical features of COVID-19 [39].

Before discussing further, it is important to understand the link between STAT-3 upregulation and COVID-19 sequelae and the role of Ivermectin in inhibiting STAT-3. STAT-3 acts as a "central hub" that mediates the detrimental COVID-19 cascade. In the lungs, STAT-3 activates Hyaluronan synthase-2 leading to deposition of hyaluronan causing diffuse alveolar damage. The damaged type 2 alveolar cells express PAI-1 (plasminogen activator inhibitor-1). Additionally, hypoxia due to diffuse alveolar damage causes an upregulation of PAI-1 through HIF-1a. STAT-3 also directly activates PAI-1. The simultaneous activation of PAI-1 and STAT-3 inhibits t-PA and urokinase-type plasminogen activator leading to thrombi formation in the capillaries. PAI-1 also binds to TLR-4 receptors on macrophages further activating the NF-kB pathway.

The "cytokine storm" typical of severe COVID-19 involves STAT-3 mediated upregulation of proinflammatory cytokines, TNFα, and IL-6 in macrophages. Additionally, STAT-3 induces a C-reactive protein that upregulates PAI-1 levels. STAT-3 is directly responsible for activating IL-6 gene transcription which further leads to an increase in TGF-β causing pulmonary fibrosis. The PD-L1 receptors present on the endothelial cells are activated by

STAT-3 causing T cell lymphopenia. Ivermectin inhibits STAT-3 through direct inhibition preventing COVID-19 sequalae [39].

Level 12: Action on P21 activated Kinase 1 (PAK-1)

The p21 activated kinase 1 (PAK1) physically binds to both JAK1 and STAT3, and the resultant PAK1/STAT3 complex activates IL-6 gene transcription responsible for cytokine storm in COVID-19 [53]. Ivermectin suppresses the Akt/mTOR signaling and promotes ubiquitin-mediated degradation of PAK-1 hence compromising STAT-3 activity and decreasing IL-6 production [54].

Level 13: Action on Interleukin-6 (IL-6) levels

A study by Zhang et al. demonstrated that Ivermectin suppressed IL-6 and TNFα production, two major components of the detrimental cytokine storm induced by SARS-CoV-2 and "dramatically reduced" IL-6/IL-10 ratio modulating infection outcomes [42, 55].

Level 14: Action on allosteric modulation of P2X4 receptor

P2X receptors are the channels selective to cation, are gated by extracellular ATP [56] and mediate several functions in health and disease [57]. From the seven subunits of P2X receptors, $P2X_4$ is most sensitive to Ivermectin. Positive allosteric modulation of $P2X_4$ by Ivermectin enhances ATP-mediated secretion of CXCL5 (pro-inflammatory chemokine). CXCL5 is a chemo-attractant molecule expressed in inflammatory cells in different tissues and modulates neutrophil chemotaxis and chemokine scavenging [58].

Level 15: Action on high mobility group box 1 (HMGB1)

The damage-associated molecular pattern high mobility group box 1 (HMGB1), is released by damaged cells acting as an agonist for the TLR4 receptor and hence mediating lung inflammation associated with COVID-19 [59]. Ivermectin inhibits HMGB1 [60].

Level 16: Action as an immunomodulator on Lung tissue and olfaction

In a study by DeMelo et al., the effects of Ivermectin were investigated on SARS-CoV-2 infection using the golden Syrian hamster as a model for COVID-19. Both, male and female adult golden Syrian hamsters were intranasally inoculated with 6×10^4 PFU of SARS-CoV-2. At the time of infection, animals received a single subcutaneous injection of Ivermectin (antiparasitic dose of 400 µg/kg) classically used in a clinical setting and were monitored over four days. Mock-infected animals received the physiological solution only. Interestingly, Ivermectin had a sex-dependent and compartmentalized immunomodulatory effect, preventing clinical deterioration and reducing the olfactory deficit in infected animals. This effect was sex-dependent: infected males presented a reduction in the clinical score whereas a complete absence of signs was noticed in the infected females. Regarding the olfactory performance, 83.3% (10/12) of the saline-treated males presented with hyposmia/anosmia, in contrast to only 33.3% (4/12) of IVM-treated males (Fisher's exact test $p = 0.036$). No olfactory deficit was observed in IVM-treated females (0/6), while 33.3% (2/6) of saline-treated females presented with hyposmia/anosmia (Fisher's exact test $p = 0.455$). Ivermectin dramatically reduced the IL-6/IL-10 ratio in lung tissue, which likely accounts for the more favorable clinical presentation in treated animals [55]. Loss of smell has been reported as one of the common symptoms in COVID-19 [61]. Interestingly, majority of patients in India regained their sense of smell after a brief anosmic period during their clinical course. Ivermectin is being used in India as one of the first-line drugs for COVID-19 treatment. It could be hypothesized that Ivermectin might have a role to play in reducing SARS-CoV-2 induced olfactory deficit.

Level 17: Action as an anti-inflammatory

The mechanism for anti-inflammatory action of Ivermectin was explained as inhibition of cytokine production by lipopolysaccharide challenged macrophages, blockade of activation of NF-kB, and the stress-activated MAP kinases JNK and p38, and inhibition of TLR4 signaling [42, 61, 62]. Moreover, Immune cell recruitment, cytokine production in bronchoalveolar lavage fluid, IgE, and IgG1 secretion in serum as well as hyper-secretion of mucus by goblet cells was reduced significantly by Ivermectin [63].

Action on other host targets

Level 18: Action on Plasmin and Annexin A2

As per study by Kamber Zaidi et al, annexin A2 may be linked to COVID-19 pathophysiology. Annexin A2 acts as a co-receptor for the conversion of plasminogen to plasmin in the presence of t-PA. Increased plasmin levels are found in co-morbid states and is also responsible for early stages of viral infection. Plasmin leads to direct activation of STAT-3 inducing detrimental COVID-19 sequelae. Ivermectin directly inhibits STAT-3 and could play a role in the inhibition of COVID-19 complications.

Level 19: Action on CD147 on the RBC

The transmembrane receptor CD147, present on the red blood cell (RBC) along with ACE-2 has been recognized as a key binding site for SARS-CoV-2 spike protein. The SARS-CoV-2 does not internalize into the RBC but such attachments can lead to clumping [65]. Ivermectin binds to the S protein of the virus making it unavailable to bind with CD147. This action might also be beneficial in advanced stages of COVID-19 presenting with clotting/thrombotic phenomena.

Level 20: Action on mitochondrial ATP under hypoxia on cardiac function

SARS-CoV-2 has been a well-known cause for acute myocardial injury and chronic damage to the cardiovascular

FOI 26-3132 - Document 5

system in active infection as well as in long haulers [66]. Nagai et al. demonstrated that Ivermectin increased mitochondrial ATP production by inducing Cox6a2 expression and maintains mitochondrial ATP under hypoxic conditions preventing pathological hypertrophy and improving cardiac function [67].

Conclusion

Considering the urgency of the ongoing COVID-19 pandemic, simultaneous detection of various new mutant strains and future potential re-emergence of novel coronaviruses, repurposing of approved drugs such as Ivermectin could be worthy of attention.

Acknowledgements We would like to thank all the academicians, physicians, and scientists dedicating their efforts and time to COVID-19 research. A special thank you to children who bring positivity and hope in these difficult times, especially Ginevra Dehgani.

Abstract. *Objective and Design*: To investigate whether ivermectin, a semi-synthetic derivative of a family of macrocyclic lactones could inhibit lipopolysaccharide (LPS)-induced inflammation in vivo and in vitro.
Materials and Methods: C57BL/6 mice were administered ivermectin (or saline) orally and challenged intraperitoneally with LPS at a lethal dose of 32 mg/kg. RAW 264.7 murine macrophages were stimulated with LPS at 1 μg/ml, with or without ivermectin for 6, 12 and 24 h. The production of tumor necrosis factor-α (TNF-α), interleukin-1ß (IL-1ß) and interleukin-6 (IL-6) in serum from mice and supernatants from cells were measured by ELISA. Nuclear factor-κB (NF-κB) translocation with subunit p65 was evaluated by immunocytochemical analysis.
Results: Ivermectin improved mouse survival rate induced by a lethal dose of LPS. In addition, ivermectin significantly decreased the production of TNF-α, IL-1ß and IL-6 in vivo and in vitro. Furthermore, ivermectin suppressed NF-κB translocation induced by LPS.
Conclusions: The results indicate that ivermectin may inhibit LPS-induced production of inflammatory cytokines by blocking NF-κB pathway and improve LPS-induced survival in mice. This finding might provide a new strategy for the treatment of endotoxemia and associated inflammation.

Key words: Ivermectin – Lipopolysaccharide (LPS) – Inflammatory cytokines – Nuclear factor-κB (NF-κB) – Survival

Introduction

Macrolide antibiotics have been widely used to treat a broad array of infectious diseases. As a class of agents, they have been shown to be safe and have highly effective antibacterial activity. Furthermore, some macrolide antibiotics have been reported to modify the host immune and inflammatory responses in addition to their antibacterial activity, they are effective in the treatment and management of some inflammatory diseases [1–6]. Ivermectin is a semi-synthetic derivative of a family of macrocyclic lactones. This drug has a broad-spectrum anti-parasitic effect against various nematodes and ectoparasites [7]. It causes paralysis in many nematodes and arthropods because of its effect on ion-channels in cell membranes. Ivermectin was first used in veterinary medicine; in human studies, it has been shown to be a microfilaricid against *Onchocerca volvulus*. Most of the adverse reactions following treatment have been mild [8], earning it the title of "wonder drug" [9, 10]. The immunomodulatory effect of ivermectin in a variety of bacterial, viral, parasitic and neoplastic diseases and the influence of ivermectin on cellular and humoral immune responses have been suggested [11, 12]. Ivermectin has been shown to block or suppress LPS-induced secretion of NO and prostaglandin E2 in liver macrophages and Kupffer cells [13, 14]. These observations thus suggest that ivermectin could influence host defenses. However, the effects of this drug on RAW 264.7 murine macrophage cells and inflammatory responses in animals and on diseases associated with these responses have not been demonstrated.

Septic shock, which results from gram-negative bacterial infections, is a major cause of death among patients and animals [15]. One of the major reasons is that endotoxin or lipopolysaccharide (LPS), a component of the gram-negative bacterial cell wall, induces the disturbance of immune and inflammatory responses and causes fever, hypotension and,

FOI 26-3132 - Document 5

in severe cases, resulting in tissue damage, septic shock or even death [16–19]. LPS is recognized by toll-like receptor 4 (TLR4) on cell membrane such as macrophages and triggers an acute and early release of proinflammatory mediators through TLR4-NF-κB signaling pathways that mediate host damage [20, 21]. The production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1) and interleukin-6 (IL-6) has been shown to be important in determining the early phases of inflammation, which can progress to systemic inflammatory response syndrome [22–25].

In the present study, using RAW 264.7 murine macrophage cells and a murine endotoxic shock model, we studied first the effects of ivermectin on LPS-induced production of early inflammatory cytokines and on survival of mice induced with a lethal dose of LPS, and then the mechanism by which ivermectin exerted its effects.

Materials and methods

Reagents

Ivermectin, LPS (*Escherichia coli* 055:B5), Cy3-conjugated sheep anti-rabbit IgG, 3-(4,5-dimethylthiazol-2-y1)-2,5-diphenyltetrazolium bromide (MTT) and Dimethyl sulfoxide (DMSO) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), penicillin, streptomycin and other reagents for cell culture were obtained from Life Technologies Inc. (Grand Island, NY, U.S.A.). Rabbit anti-NF-κB/p65 polyclonal antibody was obtained from Santa Cruz Biotechnology (Santa Cruz, CA).

Mice

All experiments were performed in accordance with the guide for the Care and Use of Laboratory Animals published by US National Institute of Health. Female C57BL/6 mice, weighing approximately 18 to 20 g, were purchased from the Shanghai Laisite Experimental Animals Co., LTD (Certificate SCXK2003-0003). The mice were housed in microisolator cages and received food and water *ad libitum*. Laboratory temperature was 24 ± 1 °C and relative humidity was 40–80 %. Before experimentation, the mice were left to adapt to the experimental environment for 2 to 3 days.

Cell culture

RAW 264.7 murine macrophage cell line was obtained from the China Cell Line Bank (Beijing, China). The cells were cultured in DMEM supplemented with 10 % heat-inactivated FBS, 100 U/ml penicillin and 100 µg/ml streptomycin sulfate at 37 °C under a humidified atmosphere of 5 % CO_2 and 95 % air atmosphere.

Cell viability assay

Cytotoxicity studies induced by ivermectin were performed by MTT assay. RAW 264.7 cells were mechanically scraped, plated at 4×10^5 cells/ml onto 96-well plates (Costar USA) containing 100 µl of DMEM medium, and incubated overnight. Ivermectin was dissolved in DMSO; the DMSO concentrations did not exceed 0.1 % in any assay. After overnight incubation, the cells were treated with diverse concentrations of ivermectin (0–12 µg/ml) according to the experimental design. After 24 h, 50 µl of 5 mg/ml MTT in FBS-free medium was added to each well and samples were further incubated for 4 h in a humidified atmosphere at 37 °C, 5 % CO_2. MTT was removed and cells were lysed with 100 µl/well DMSO. The optical density was measured at 570 nm on a microplate reader (TECAN, Austria).

Cytokine assays in vitro

To determine the effects of ivermectin on the production of cytokines from LPS-induced cells, RAW 264.7 cells were plated onto 24-well plates (10^5 cells/well), and pretreated in the presence or absence of 0.5, 2 and 4 µg/ml of ivermectin for 1 h and then stimulated with 1 µg/ml of LPS for 6, 12, or 24 h at 37 °C, 5 % CO_2. At each period, cell-free supernatants were collected and then stored at –20 °C until assayed for cytokines. The concentrations of cytokines TNF-α, IL-1ß and IL-6 in the supernatants of RAW 264.7 cells culture were measured by sandwich enzyme-lined immunosorbent assay (ELISA) using commercially available reagents according to the manufacturer's instructions (BioLegend, Inc. Camino Santa Fe, Suite E San Diego, CA, USA).

Survival study

C57BL/6 mice were divided into five groups: the control group, administered intragastrically with normal saline; the LPS group, injected intraperitoneally with LPS at a lethal dose of 32 mg/kg; and three ivermectin + LPS groups, administered intragastrically with a single dose of ivermectin at 1, 2 and 4 mg/kg, respectively, 2 h prior to intraperitoneal injection of LPS. Mice were monitored for survival twice a day for 7 days.

Analysis of serum cytokines

Cytokines were assessed by measuring serum concentrations. Mice were randomly assigned into two groups: the LPS group, injected intraperitoneally with 32 mg/kg LPS; and the LPS + ivermectin group, administered intragastrically with a single dose of ivermectin (2 mg/kg) 2 h prior to administration of LPS. Mice in both groups were killed and their serum separated from clotted blood at 1, 3, and 6 h following administration of LPS. Serum was stored at –70 °C and concentrations of cytokine TNF-α, IL-1ß and IL-6 were measured by sandwich ELISA using commercially available reagents according to the manufacturer's instructions (BioLegend, Inc. Camino Santa Fe, Suite E San Diego, CA, USA).

Immunocytochemical analysis

The effect of ivermectin on nuclear translocation of NF-κB induced by LPS was measured by immunocytochemical analysis. RAW 264.7 cells (10^5 cells/ml) were cultured on glass cover slips, plated onto 24-well plates, and then pretreated in the presence or absence of 0.5, 2 and 4 µg/ml of ivermectin for 1 h and then stimulated with 1 µg/ml of LPS for 1 h at 37 °C, 5 % CO_2. The cells were washed with PBS and fixed in 4 % formaldehyde for 30 min, then detergent extracted with 3 % TritonX-100 for 10 min at room temperature. Cover slips were saturated with PBS containing 5 % bovine serum albumin (BSA) for 30 min at room temperature and processed for immunofluorescence with rabbit anti-NF-κB/p65 polyclonal antibody (1:50) followed by Cy3-conjugated sheep antirabbit IgG (1:100) and DAPI staining. Cover slips were mounted on slides. Fluorescence signals were analyzed by fluorescent microscopy (Olympus, Japan).

Statistical analysis

All values were expressed as mean ± SEM. Differences in survival rate of groups were assessed using the log-rank test. Differences between

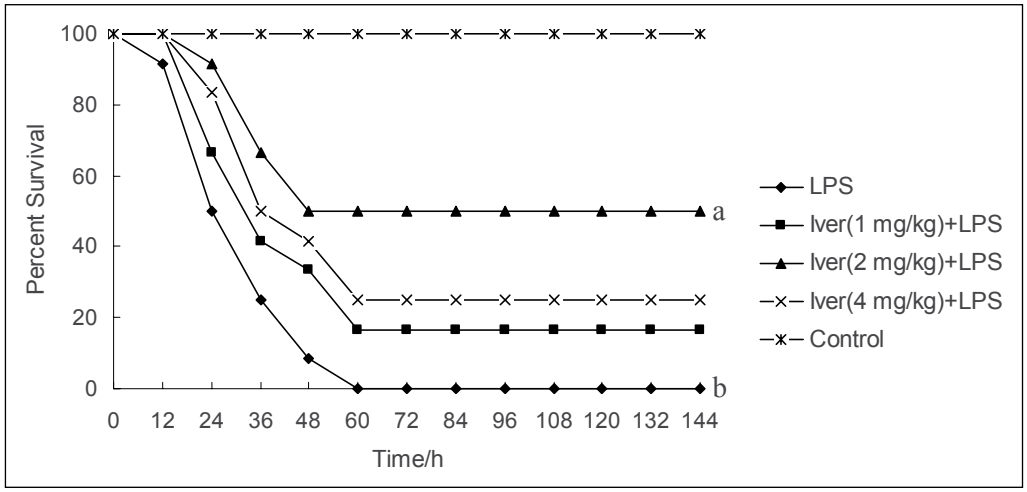

Fig. 1. Effect of ivermectin (Iver) on survival of mice induced with LPS. Mice (n = 12 for each group) were divided into control, LPS, and Iver + LPS groups. Mice in Iver + LPS groups were administered intragastrically with 1, 2 or 4 mg/kg Iver 2 h prior to intraperitoneal injection of LPS. Mice in control and LPS groups were only given normal saline or LPS. Survival was assessed every 12 h for 7 days throughout the experiment. [a]P <0.05 vs LPS group. [b]P <0.01 vs control.

mean values of normally distributed data were assessed by one-way ANOVA (Dunnett's *t*-test) and Student's *t*-test. Statistical difference was accepted at P <0.05.

Results

Ivermectin improves survival in mice challenged with lethal-dose LPS

The effect of ivermectin on LPS-induced death was assessed by measuring survival rate of mice induced with a lethal dose of LPS. The different doses of ivermectin on survival of mice induced with LPS are shown in Fig. 1. The administration of 32 mg/kg LPS resulted in 100 % mortality in mice. In contrast, when mice were given ivermectin at doses of 1, 2 and 4 mg/kg following LPS administration, survival rates were 16.7 %, 50.0 %, 25.0 %, respectively. The survival rate of mice in the ivermectin + LPS (2 mg/kg) group was significantly better than mice that only received LPS (P <0.05).

Ivermectin suppresses cytokine production in mice challenged with LPS

Early cytokine responses after LPS challenge have been well characterized and are known to occur within hours of LPS challenge. Specifically, TNF-α, IL-1ß and IL-6 have been shown to be produced early in this response and are suggested to play critical roles in driving physiological responses, however, if the cytokine production disregulated, it leads to pathological damage and septic shock. To define the effects of ivermectin on the production of cytokines in vivo that have been associated with fatal outcome, serum concentrations of these cytokines were determined at different time points following LPS administration. As shown in Fig. 2, mean concentrations of cytokines in the LPS + ivermectin (2 mg/kg) group were significantly different from that of the LPS group at 1 h for TNF-α (P <0.05) (Fig. 2A), at 3 h and 6 h for IL-1ß (P <0.01) (Fig. 2B) and at 3 h and 6 h for IL-6 (P <0.05 or <0.01) (Fig. 2C). Ivermectin significantly

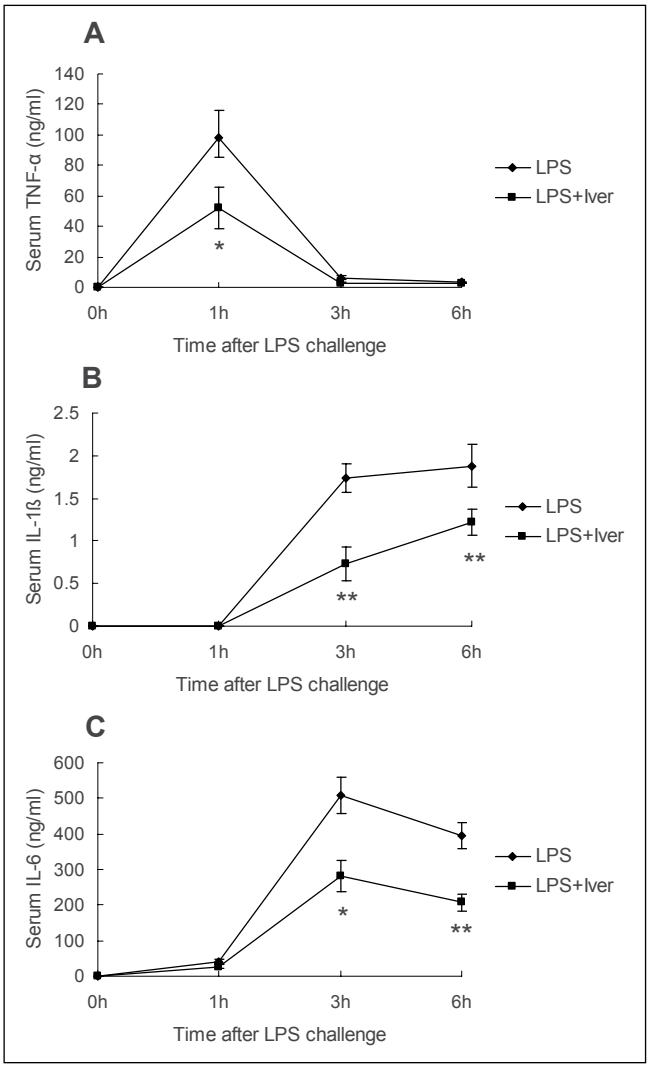

Fig. 2. Effect of ivermectin (Iver) on serum TNF-α, IL-1β and IL-6 induced by LPS. Mice were given Iver (2 mg/kg) or normal saline 2 h prior to intraperitoneal injection of LPS. Serum concentrations of TNF-α, IL-1β and IL-6 in LPS and LPS + Iver groups were measured at 1, 3 and 6 h following LPS challenge (n = 16 for each group). Mean ± SEM. *P <0.05, **P <0.01 vs LPS.

FOI 26-3132 - Document 5

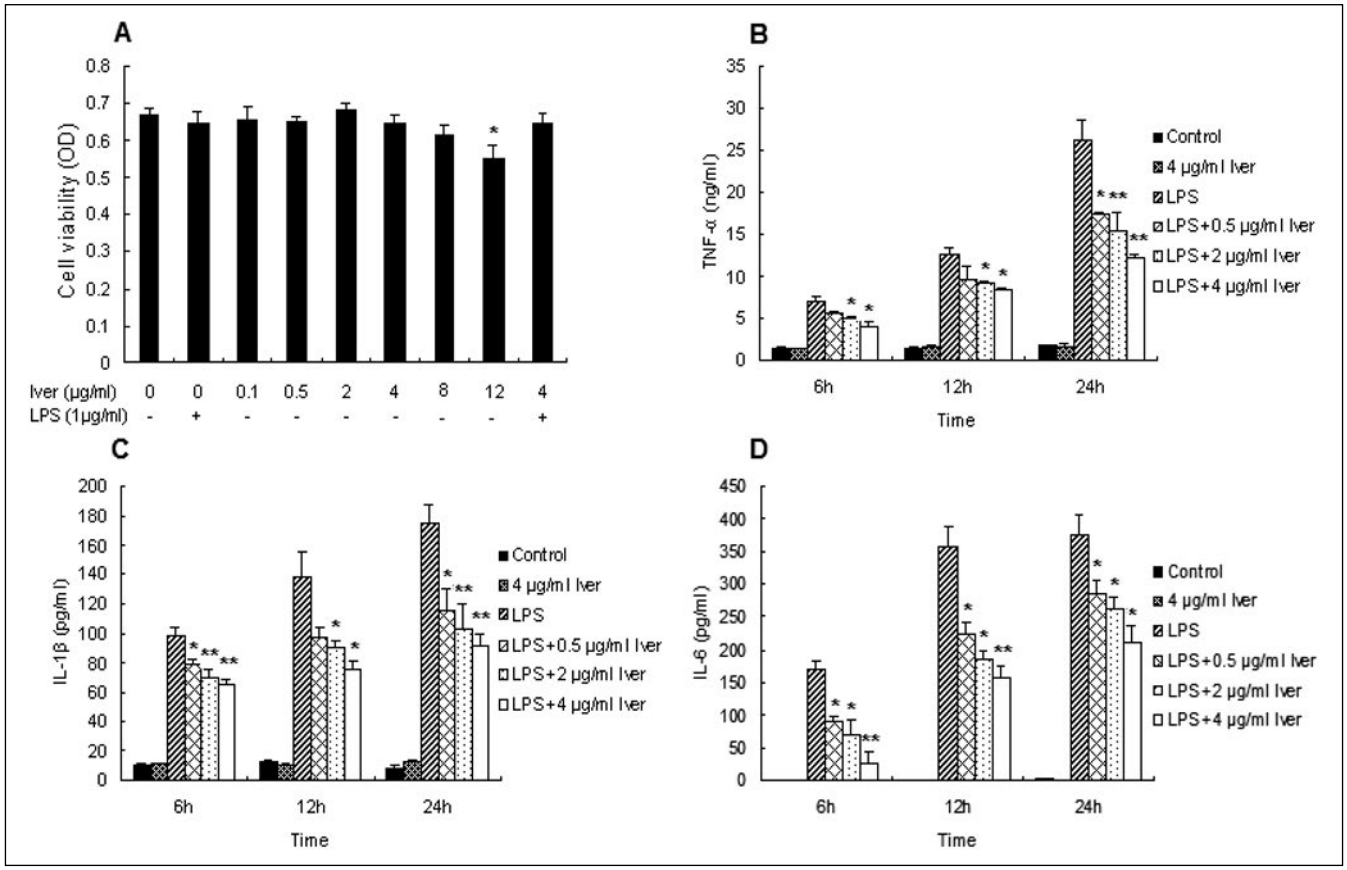

Fig. 3. Effects of Ivermectin on the viability of RAW 264.7 cells and production of TNF-α, IL-1ß and IL-6 in LPS-induced RAW 264.7 cells. (A) Effect of Ivermectin (Iver) on the viability of RAW 264.7 cells. RAW 264.7 cells were incubated in the presence or absence of 0.1-12 μg/ml Iver for 24 h. Cell viabilities were determined by MTT assay. Data are presented as the means ± SEM of three independent experiments. *P <0.05 vs control. (B, C, D) Effect of different concentrations of Ivermectin (Iver) on production of TNF-α, IL-1ß and IL-6 in LPS-induced RAW 264.7 cells. The cells were treated with 1 μg/ml LPS alone or LPS plus different concentrations (0.5, 2, 4 μg/ml) of Iver for 6, 12 and 24 h. Control values were obtained in the absence of LPS or Iver. The values are the means ± SEM of three independent experiments. *P <0.05, **P <0.01 vs LPS group.

reduced TNF-α response at 1 h, IL-1ß and IL-6 responses at 3 h and 6 h. In addition to the concentrations in serum, TNF-α, IL-1ß and IL-6 were nearly undetectable in the control group and ivermectin-only group (data not shown).

Effects of ivermectin on cell viability

The cytotoxic effect of ivermectin on RAW 264.7 cells was initially evaluated. The cells were treated with various concentrations of ivermectin ranging from 0.1 to 12 μg/ml for 24 h. Ivermectin at concentrations from 0.1 to 8 μg/ml had no effect on cell survival. However, the viability of the cells was reduced when 12 μg/ml of ivermectin was used (Fig. 3A). In all other cell experiments, the concentrations of ivermectin applied never exceeded 8 μg/ml. Ivermectin (4 μg/ml) alone and in the presence of LPS (1 μg/ml) did not further affect the viability of RAW 264.7 cells (Fig. 3A). These results confirmed that the effects of ivermectin on RAW 264.7 cells were not due to a reduction in cell viability in each condition.

Ivermectin suppresses LPS-induced cytokine production in RAW 264.7 cells

TNF-α, IL-1ß and IL-6 concentrations in the culture supernatant of RAW 264.7 cells were measured by sandwich ELISA (Figs. 3B, C and D). Treatment of RAW 264.7 cells with LPS alone resulted in a significant increase in accumulation of each of the cytokines as compared to that in controls (P <0.01) after incubation for 6 h, 12 h and 24 h. However, in a dose-dependent manner at each time period, TNF-α, IL-1ß and IL-6 levels in the supernatants of cells treated with LPS plus 0.5, 2 and 4 μg/ml of ivermectin significantly decreased compared to the LPS group (P <0.05 or 0.01).

Ivermectin blocks LPS-induced NF-κB translocation in RAW 264.7 cells

We next evaluated the effect of ivermectin on LPS induction of the NF-κB pathway. We first analyzed the subcellular distribution of p65 by immunofluorescence and found that p65 was distributed in the cytoplasmic compartment in

FOI 26-3132 - Document 5

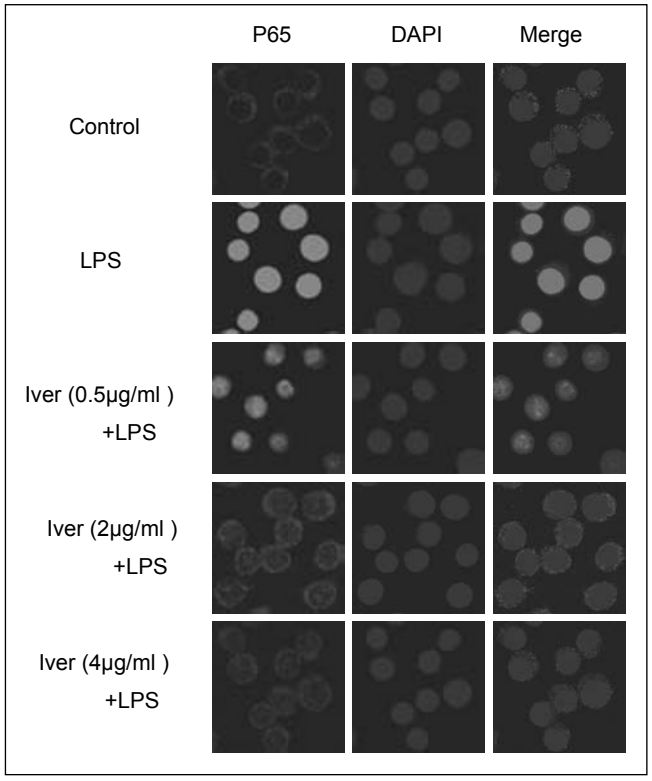

Fig. 4. Effect of ivermectin (Iver) on LPS-induced NF-κB translocation by immunocytochemistry. The cells were pretreated with Iver (0.5, 2, 4 μg/ml) for 1 h and stimulated for 1 h with LPS, then were fixed, permeabilized, and incubated with rabbit anti-NF-κB/p65 polyclonal antibody followed by Cy3-conjugated anti-rabbit IgG (red). The nuclei of the corresponding cells were demonstrated by DAPI staining (blue). Magnification for images was 600×.

all cells before LPS stimulation. One hour after stimulation with LPS (1 μg/ml), most intracellular p65 was translocated from the cytoplasm to the nucleus, demonstrated with strong p65 staining in the nucleus. However, in a dose-dependent manner, nuclear translocation of p65 induced by LPS was dramatically inhibited in cells cultured with ivermectin (Fig. 4).

Discussion

Macrophages are one of the primary innate immune cell types that recognize pathogen-associated molecular patterns such as LPS in the case of gram-negative bacterial infections and trigger innate immune response through TLR signaling. Binding of LPS to TRL4 receptor activates an intracellular tyrosine kinase system that eventually leads to activation of a redox-sensitive transcription factor NF-κB, which in turn induces expression of a number of inflammatory mediators including TNF-α, IL-1β and IL-6 [20]. Proinflammatory cytokines (TNF-α, IL-1β and IL-6) have been suggested to induce tissue damage and multiple organ failure, are considered to be an important initiator of the inflammatory response and to mediate the development of various inflammatory diseases [26–29]. In the present study, we demonstrate for the first time that ivermectin inhibits TNF-α, IL-1β and IL-6 production in a dose-dependent manner in LPS-induced RAW 264.7 macrophage cells (Figs. 3B, C and D).

LPS-induced murine septic shock model is widely used in the search for drugs and treatment tools for sepsis caused by gram-negative bacterial infections. We used a murine endotoxic shock model and studied the effect of ivermectin on survival of mice induced with a lethal dose of LPS. Ivermectin improved the survival rate of mice (Fig. 1), and the results indicate that ivermectin can consistently prevent LPS-induced death in mice. However, at a dose of 4 mg/ml, the survival rate tended to be lower, suggesting that ivermectin may be toxic at higher concentrations according to the toxic dose (LD_{50}) of 50–60 mg/kg for p.o. ivermectin in normal mice [30].

In the survival study, we demonstrated that treatment with ivermectin at a dose of 2 mg/kg produced the best inhibitory effects on the mortality rate of mice induced with LPS. Thus, we observed the effects of ivermectin at this dosage on serum TNF-α, IL-1β and IL-6 production in a LPS-induced mouse model. As we expected, ivermectin inhibited serum TNF-α, IL-1β and IL-6 production, and was consistent with our results in vitro (Fig. 2). Ivermectin-mediated reductions in serum TNF-α, IL-1β and IL-6 production were considered to contribute to improved mouse survival.

In order to further explore the mechanisms by which ivermectin exerted its effects, we investigated the effect of ivermectin on LPS-induced NF-κB translocation. NF-κB has been evidenced to play a major role in LPS-induced expression of inflammatory cytokines including TNF-α, IL-1β and IL-6 in macrophages [31, 32]. NF-κB participates in regulating the expression of cytokines and other mediators that are involved in the inflammatory response [33]. In the present study, we clearly found that the NF-κB factor p65, which was translocated from the cytoplasm to the nucleus by LPS exposure, was strongly inhibited by ivermectin in a dose-dependent manner (Fig. 4). Accordingly, we conclude that the inhibition of ivermectin on LPS-induced inflammatory cytokine production and the improvement of survival in mice with endotoxic shock are at least partially mediated by the suppression of the NF-κB pathway.

In summary, our study demonstrates that ivermectin markedly suppresses cytokine production in vitro and in vivo, may be mediated by suppressing NF-κB pathway, and consequently improves survival in endotoxic shock. Thus, ivermectin may prove to be a valuable protective agent against septic shock.

Acknowledgments. This work was supported by the National Science Foundation of China (No. 30671586).

Hi s22

With regard to the queries on Ziverdox, in your emails dated 30 June 2023 and 10 July 2023, please see the following comments from the TGA.

Nonclinical

In vivo PK data is required to determine whether the pharmacokinetic profiles in the laboratory animal species (particularly those used in the pivotal repeat-dose toxicity studies) were sufficiently similar to allow them to serve as appropriate models for the assessment of drug toxicity in humans.

Drug interactions between the 3 ingredients and between the drug combination and other drugs, which may be administered with Ziverdox will assist in determining potential interactions in humans as per CPMP/EWP/560/95/Rev. 1 Corr. 2 (https://www.ema.europa.eu/en/documents/scientific-guideline/guideline-investigation-drug-interactions-revision-1_en.pdf).

Clinical

(queries in email of 30 Jun)

Suggest there needs to be tightly defined inclusion criteria – eg mild to moderately severe COVID-19 (how exactly will this be defined) at risk of progression. There should also be detailed knowledge of why there is an increased risk of progression to severe disease. Suggest that preferential inclusion of older patients makes the most sense – we know that most younger people do not progress to serious disease. There needs to be record of vaccination status, and previous COVID-19 illness. It is also not clear as to how the length of follow up is determined, and how long before the start of medication the person can have had symptoms etc. A double blind RCT is an appropriate design – but there needs to be careful attention to ensure blinding is maintained. It is noted there is no discussion regarding the current antivirals (eg Paxlovid/ molnupiravir) and whether these are to be an exclusion criteria.

There needs to be careful consideration as to avoiding any perceived or real conflicts of interest. It is unclear who the approving ethics committee will be.

It remains unclear at this time as to the FDC justification as per the advice provided by TGA on 31 Oct 2022. s47

(queries in email of 10 Jul)

For Q.1 - s47 would likely be appropriate.

For Q.2 - As previously advised by the TGA (e.g. email dated 6 Apr 2023), the TGA does not typically provide advice on the clinical study design.

Regards,
s22

Dear Madam/Sir,

On behalf of our client Topelia Pty Ltd, Commercial Eyes Pty Ltd (CEPL) seek TGA advice on the nonclinical and clinical development program for "ZIVERDOX" s47 containing the active ingredients ivermectin, doxycycline hyclate (hydrochloride) and zinc citrate dihydrate.

The proposed indication for ZIVERDOX is:

- *The treatment of mild to moderate symptomatic adult patients diagnosed with COVID-19 caused by SARS-CoV-2 virus.*

Background

Topelia Pty Ltd initially proposed to support the registration of ZIVERDOX via a literature-based submission (LBS). Regulatory activities during the preparation of the LBS included request for a pre-submission meeting with the TGA (written advice received 7 April 2022), seeking TGA approval on the proposed literature search strategy (TGA advice received 25 August 2022) and submission of a justification for the s47 (TGA feedback received 6 April 2023).

Taking into consideration the feedback from the TGA, Topelia Pty Ltd now propose to support the registration of ZIVERDOX with nonclinical and clinical studies as applicable.

The proposed nonclinical and clinical program includes the following studies:

Nonclinical studies

Pharmacokinetics

s47 [redacted]

Toxicology:

s47 [redacted]

Clinical studies

s47 [redacted]

Specific questions

s47 [redacted]

Our client would appreciate any feedback TGA can offer on the above.
Thank you in advance.

Regards,

s22 [redacted]

Hi s22 ,

Thanks again for your enquiry,
To assist the Clinical team with providing accurate advice, could the sponsor please confirm the following:

Can the Sponsor please define which population they intend to treat:

- *To treat mid-moderate covid in generally healthy population who are at lower risk for disease progression?*
- *To treat mild moderate covid in the population who are at high risk for disease progression from mild moderate covid to severe covid?*

What is their proposed indication and what is the efficacy endpoint (outcome measure) to be studied

- *to reduce the duration of covid symptom*
- *to reduce the rate of hospitalisation and death (in high risk population)?*

Kind regards
s22

Dear Madam/Sir,

On behalf of our client Topelia Pty Ltd, Commercial Eyes Pty Ltd (CEPL) seek TGA advice on the nonclinical and clinical development program for "ZIVERDOX" s47 containing the active ingredients ivermectin, doxycycline hyclate (hydrochloride) and zinc citrate dihydrate.

The proposed indication for ZIVERDOX is:

- *The treatment of mild to moderate symptomatic adult patients diagnosed with COVID-19 caused by SARS-CoV-2 virus.*

Background

Topelia Pty Ltd initially proposed to support the registration of ZIVERDOX via a literature-based submission (LBS). Regulatory activities during the preparation of the LBS included request for a pre-submission meeting with the TGA (written advice received 7 April 2022), seeking TGA approval on the proposed literature search strategy (TGA advice received 25 August 2022) and submission of a justification for the s47 (TGA feedback received 6 April 2023).

Taking into consideration the feedback from the TGA, Topelia Pty Ltd now propose to support the registration of ZIVERDOX with nonclinical and clinical studies as applicable.

The proposed nonclinical and clinical program includes the following studies:

Nonclinical studies

Pharmacokinetics

s47

Toxicology:

s47

Clinical studies

s47

s47 [redacted]

Specific questions

s47 [redacted]

Our client would appreciate any feedback TGA can offer on the above.
Thank you in advance.

Regards,

s22 [redacted]

Nonclinical development studies Ziverdox.pdf

Hi s22 ,

On behalf of our client, Topelia Pty Ltd, thank you again for all the advice provided on the development of the triple therapy Ziverdox, for use in COVID patients.

In response to the valuable feedback from TGA regarding the nonclinical data requirements, our client has prepared a study protocol to generate data to satisfy the requirements.

We respectfully seek TGA's review and any feedback on the attached proposed studies that have been designed to align with TGA's feedback on the nonclinical data requirements for Ziverdox.

Please do not hesitate to advise if anything requires further clarification or if a phone call would assist.

Thank you.

Hi s22 ,

With regard to the queries on Ziverdox, in your emails dated 30 June 2023 and 10 July 2023, please see the following comments from the TGA.

Nonclinical

In vivo PK data is required to determine whether the pharmacokinetic profiles in the laboratory animal species (particularly those used in the pivotal repeat-dose toxicity studies) were sufficiently similar to allow them to serve as appropriate models for the assessment of drug toxicity in humans.

Drug interactions between the 3 ingredients and between the drug combination and other drugs, which may be administered with Ziverdox will assist in determining potential interactions in humans as per CPMP/EWP/560/95/Rev. 1 Corr. 2 (https://www.ema.europa.eu/en/documents/scientific-guideline/guideline-investigation-drug-interactions-revision-1_en.pdf).

Clinical

(queries in email of 30 Jun)

Suggest there needs to be tightly defined inclusion criteria – eg mild to moderately severe COVID-19 (how exactly will this be defined) at risk of progression. There should also be detailed knowledge of why there is an increased risk of progression to severe disease. Suggest that preferential inclusion of older patients makes the most sense – we know that most younger people do not progress to serious disease. There needs to be record of vaccination status, and previous COVID-19 illness. It is also not clear as to how the length of follow up is determined, and how long before the start of medication the person can have had symptoms etc. A double blind RCT is an appropriate design – but there needs to be careful attention to ensure blinding is maintained. It is noted there is no discussion regarding the current antivirals (eg Paxlovid/ molnupiravir) and whether these are to be an exclusion criteria.

There needs to be careful consideration as to avoiding any perceived or real conflicts of interest. It is unclear who the approving ethics committee will be.

It remains unclear at this time as to the s47 justification as per the advice provided by TGA on 31 Oct 2022. s47

(queries in email of 10 Jul)

For Q.1 - s47 would likely be appropriate.

For Q.2 - As previously advised by the TGA (e.g. email dated 6 Apr 2023), the TGA does not typically provide advice on the clinical study design.

Regards,
s22

Dear s22 ,

APPROVAL REF NO: EXP22/6051819
RE: REQUEST FOR APPROVAL TO EXPORT THERAPEUTIC GOODS
TO s47 FOR
CLINICAL TRIAL USE

I refer to your correspondence dated **03 November 2022** requesting approval to export clinical trial good(s) to a distribution centre in the following country(ies) for use in an ICH Good Clinical Practice (GCP) compliant study, **Protocol No:** s47 .

Country(ies)
s47

The good(s) to be exported:

- **Ivermectin/Doxycycline/Zinc Chelate, Ziverdox,** s47

I note you have provided me with written assurances from **Dr David Fox Chief Executive Officer** on behalf of Topelia Australia Limited, the sponsor of this study. These written assurances state, amongst other things, that the trial will be conducted in accordance with the ICH GCP and that the trial sponsor will comply with any requests from the TGA for information about the trial. As exporter you have also provided assurances that the goods have been manufactured under standards that comply with Good Manufacturing Practice.

Pursuant to Section 19(1) of the *Therapeutic Goods Act 1989*, approval is granted for the export from Australia of the above mentioned therapeutic good(s) for use in clinical trials in humans. This approval is subject to the following conditions:

1. This approval is for the export of the good(s), as detailed above, from **Australia** to s47 .

2. These goods are solely for experimental purposes in humans as per the Clinical Trial Protocol No: s47 .

3. This approval is valid for the export of multiple consignments of the good(s) to the abovementioned site(s), **within 12 (twelve) months from the date of this letter**.

4. If any manufacturing steps occur at an Australian manufacturing site, the site must hold acceptable evidence of a Licence to Manufacture Therapeutic Goods issued by the TGA.

5. The Exporter will comply with all relevant laws of any other state or national government and any relevant international requirements pertaining to the exportation, importation supply and use of this product.

6. A record relating to the source of the supply, distribution and disposal of this unregistered product is kept and if requested by the Secretary of this Department, these records must be supplied.

7. The Therapeutic Goods Administration can provide no assurance as to the quality, safety and efficacy in the proposed usage. It should be noted that the proposed clinical use of this product must be regarded both medico-legally and ethically as experimental.

8. The Australian Government accepts no responsibility for any defects in these goods related to manufacture, distribution or directions for use, including dosage or any other matter related to their use.

9. A report detailing the quantity of goods that have been exported to the distribution centre must be submitted to the TGA every six months. Please note that the first report required will be for the period ending **30 Demeber 2022.** The report should be submitted in the format set out in Attachment 1.

Request for reconsideration of an initial decision
This decision is a reviewable initial decision under section 60 of the Act. Under section 60, a person whose interests are affected by a 'reviewable' initial decision, can seek reconsideration of the initial decision.

As this document constitutes written notice of the making of an initial decision being given by the Secretary, a request for reconsideration of this initial decision must be given to the Minister in writing within 90 (calendar) days after the initial decision notice is given and be accompanied by any information that you wish to have considered by the Minister. A request for reconsideration given to the Minister outside the statutory 90 day reconsideration period cannot be accepted.

The Minister may either personally undertake a request for reconsideration of an initial decision or delegate this function to an officer of the Department with the appropriate delegation.
Under section 60(3A) of the Act, the Minister (or the Minister's delegate) is not able to consider any information provided after the making of a request for reconsideration of an initial decision unless the information is provided in response to a request from the Minister (or the Minister's delegate), or it is information that indicates that the quality, safety or efficacy of the relevant therapeutic goods is unacceptable.

Guidelines for requesting reconsideration of an initial decision
Prior to requesting reconsideration of an initial decision, persons affected by an initial decision are advised to refer to the TGA website <https://www.tga.gov.au/reconsideration-reviewable-initial-decisions> for specific information and detailed guidance for making a request for reconsideration. A request for reconsideration should then be made in writing, signed and dated by the person requesting reconsideration and should include the following:

- a copy of the initial decision notification letter, i.e. this letter (or other evidence of notification);
- identify, and describe with as much specificity as possible, which component(s) of the initial decision should be reconsidered and set out the reasons why reconsideration is requested;
- any information/documentation in support of the request, clearly labelled to correspond with (any or each of) the reasons why reconsideration is requested; and
- an email address nominated for the purposes of receiving correspondence in relation to the request for reconsideration.

All requests for reconsideration should be given to the Minister by email:

Email: '**decision.review@health.gov.au**'

Subject: "**<insert name of person/company making request>** - Request for Reconsideration Under Section 60 of the *Therapeutic Goods Act 1989*"

Requests for reconsideration that include material which cannot be attached to a single email, may be submitted under multiple, sequentially numbered emails (e.g. "… - Email 1 of 3", "… - Email 2 of 3" etc). All sequentially numbered emails must be given to the Minister on the same date.

Under section 60 of the Act, the decision upon reconsideration by the Minister (or the Minister's delegate) must be to either 'confirm', 'revoke' or 'revoke and substitute' the initial decision. The Minister (or the Minister's delegate) must give notice in writing of the outcome of the decision upon reconsideration to the person whose interests are affected, within 60 (calendar) days after making a request for reconsideration. If the Minister (or the Minister's delegate) fails to give such notice within 60 days, the Minister (or the Minister's delegate) is deemed to have confirmed the initial decision. Subject to the *Administrative Appeals Tribunal Act 1975* (AAT Act), if you are dissatisfied with the decision upon reconsideration by the Minister (or the Minister's delegate), you can apply to the Administrative Appeals Tribunal (AAT) for a review of that decision upon reconsideration.

NOTE: This initial decision remains in effect unless and until it is revoked or revoked and substituted by the Minister (or the Minister's delegate) as a result of a request for reconsideration under section 60 of the Act OR is set aside, varied or remitted by the AAT or is otherwise overturned or stayed.

If you require any further assistance concerning this matter please contact me by telephone on s22

Yours sincerely,

Signed and authorised by
s22
Delegate of the Secretary
